Method: Patients > 18 years old, with EULAR Criteria for SpA were enrolled in PULSAR from 4 VA Medical Centers. SpAs included were AS, Psoriatic arthritis (PsA), Reactive arthritis (ReA), SpA due to inflammatory bowel disease (IBD), and undifferentiated SpA (USpA). All participating sites received IRB approval and all subjects gave written informed consent. Data collected included demographic data, clinical and laboratory features of SpA, HLA-B27, DMARD/biologic agents, comorbid diseases, and extra-articular manifestations. AAU was defined as painful photophobia, with ophthalmologic confirmation of uveal tract inflammation, and visual acuity (va) and intra-occular pressure (IOP) data obtained.

Results: There were 265 SpA patients enrolled in PULSAR, the majority were male (95.5%), with a mean age of 57.13 years, and mean disease duration of 20.5 years and 57.9% were HLA-B27 positive. Seventy-six had AS, 137 had PsA, 27 ReA, and 22 had USpA or IBD arthritis. AAU was present in 28 (10.6%), with a mean disease duration of 10.9 years. One hundred and ninety-five (73.6%) were Caucasian, 34 (12.8%) were African American (AA). Patients with AS had the highest prevalence of AAU, [14/76 (18.4%)] and frequencies in other SpA were: PsA, [5/137 (3.7%)], ReA [5/27 (18.5.%)], and USpA/IBD [4 of 22 (18.2%)]. The ethnic distribution of AAU was similar to that of SpA: Caucasians 72.7% and AA 11.8%. Most were HLA-B27 positive [89/150 (59.3%)]. AAU was more common in HLA-B27 positive versus HLA-B27 negative patients, (19/105 patients; 18.1% vs 3/87; 3.5%, respectively). The majority (16/22), had chronic or recurrent episodes of AAU. Thirteen of 20 had arthritis concurrent with uveitis flares. Two patients were ineligible for drivers licenses (va 20/50 – 20/70), while only one was legally blind (va < 20/200). Glaucoma (IOP > 21) was present in only 4 of 19 subjects and approximately one third (7/20) developed cataracts. In addition to topical steroids, 30% received oral prednisone,46% were on traditional DMARDS, while 18 of 26 (67%) received an anti-Tumor Necrosis Factor alpha (anti-TNF) agent.

Conclusion: In a cohort of male US Veterans, AAU was more common in HLA-B27 positive individuals, occurred half as frequently as reported in the literature, but oral prednisone and/or steroid sparing agents were required in as many as a third. Therapy for concomitant active SpA with DMARDs and/or anti-TNF agents may have accounted for the infrequent occurrence of AAU in our cohort.

Prevalence of Metabolic Syndrome in Patients with Seronegative Spondyloarthritis. Marwin Gutierrez[1], Andrea Becciolini[1], Emilio Filippucci[1], Fausto Salaffi[1], Rossella De Angelis[1], Bernd Raffeiner[4], Marco Canzoni[2], Viviana Ravagnani[3], Chiara Bertolazzi[1], Maria L. Sorgi[2], Domenico Biasi[3], Leonardo Punzi[4] and Walter Grassi[1]. [1]Clinica Reumatologica, Università Politecnica delle Marche, Jesi, Ancona, Italy, [2]Dipartimento di Clinica e Terapia Medica, Sapienza Università di Roma, Italy, [3]Unità Semplice di Reumatologia, Università degli Studi di Verona, Italy, [4]UOC Reumatologia, Clinica Medica e Sperimentale, Politecnico Universitario, Padova, Italy

Background: Seronegative spondyloarthritis (SpA), may be associated with an increased risk of cardiovascular disease (1). Metabolic syndrome (MetS) clusters risk factors for atherosclerotic cardiovascular disease including: insuline resistance, central obesity, low levels of high density lipoprotein, high triglyceride levels and elevated blood pressure. To date, different studies demonstrating a high prevalence of MetS in patients with rheumatic diseases have been published (2). However, little is still known about its prevalence among patients with SpA.

Objective: To investigate the prevalence of MetS in patients with SpA.

Methods: 119 consecutive patients (72 men and 42 women; disease duration 116.42 months, 95% CI 85–137.7; median of age 51.37, range 22–79) affected by SpA (73 with psoriatic arthritis, 20 with ankylosing spondylitis, 15 with undifferentiated spondyloarthritis, 6 with enteropathic spondyloarthritis and 5 with reactive arthritis), attending the out-patient and in-patient clinic of the Rheumatology Departments involved in this multicenter cross-sectional study were enrolled. The diagnoses were made according to European Spondyloarthritis Study Group criteria (3). The following

items for each patient were taken: waist circumference, triglycerides, high density lipoprotein, fasting glucose and blood pressure. The presence of MetS was determined according to the modified National Cholesterol Education Program 2004 (NCEP 2004) criteria (4).

Results: The overall prevalence of the MetS among SpA patients was 36.9% (44/119). The patients who did not satisfy at least one item for MetS was 21.8% (26/119). The group with the highest prevalence of MetS was enteropathic spondyloarthritis (50%), followed by psoriatic arthritis (41%), ankylosing spondylitis (35%), undifferentiated spondyloarthritis (26.6%) and reactive arthritis (0%). MetS resulted more prevalent in patients with more than 60 years (58.3%) respect to 35.4%, 34.4% and 8.6%, in patients between 50–59 years, 40–49 years and less of 40 years respectively. We found more frequently MetS in male patients (43%) compared with female patients (27.6%).

Conclusion: The MetS is a common finding in patients with SpA to increases cardiovascular risk. NCEP 2004 criteria are a fast and easy screening tool that should be adopted in the management of patients with SpA.

Prospective Serum Levels Assessment of DKK-1 and SOST in Patients with Ankylosing Spondylitis and Treated with Anti-TNFa Treatments. Corinne Miceli-Richard[1], Stéphanie Malbos[1], Stephan Pavy[1], Sami Kolta[3], Karine Briot[3], Jérémie Sellam[5], Xavier Mariette[2], Christian Roux[3] and Maxime Dougados[4]. [1]Bicêtre Hospital, Université Paris XI Sud, [2]Bicetre Hospital/Paris Univ, Le Kremlin Bicetre, France, [3]Cochin Hospital, Université Paris-Descartes, [4]Hospital Cochin, Paris, France, [5]Saint-Antoine Hospital, Paris

Background: Sclerostin (SOST) and Dickkopf-1 (DKK-1) are two inhibitory proteins of Wnt signalling pathway which is involved in osteoblastogenesis. Studies assessing serum levels of DKK-1 and SOST in ankylosing spondylitis (AS) are scarce and have provided conflicting results. DKK-1 and SOST could rationally be involved either in AS osteoporosis or in osteoblastogenesis associated with syndesmophyte construction.

Objective: To investigate the role of DKK-1 and SOST among AS patients and to assess the effect of anti-TNF treatments on DKK-1 and SOST serum levels.

Methods: We assessed 28 AS patients (17 males/11 females, age 39 ± 11 years, disease duration 17 ± 13 years, mean± SD), and 25 controls (11 males/14 females, age 57 ±17 years, mean+/− SD) without any inflammatory condition. AS patients were prospectively studied for DKK-1 and SOST serum levels by sandwich enzyme-linked immunosorbent assay (ELISA) before, and 3 months (N=24) or 6 months (N=5) after the initiation of an anti-TNFa treatment. All AS patients were naive of any TNF blockers at inclusion in the study. All but 3 patients were treated with NSAIDs at inclusion in the study (89%).

Results: Serum DKK-1 levels were significantly increased in AS patients (mean; SEM 54.28 ± 4.82 pg/mL) compared with controls (11.13 ± 0.61pg/mL) ($p<0.0001$). Serum SOST levels were not different between AS patients and controls. Neither SOST nor DKK-1 serum levels were significantly modified by anti-TNFa treatment ($P=0.68$ and $P=0.77$, respectively). A trend for a negative correlation between DKK-1 serum levels and lumbar spine T-score was observed (P=0.056; r=−0.12) but such correlation was not observed with femoral T-score. SOST was not correlated with any of the studied BMD parameters. SOST (but not DKK-1) was significantly correlated with disease duration (P=0.0009; r=0.58). None of the other studied parameters were significantly associated with DKK-1 or SOST serum levels (BASFI, BASDAI, C-reactive protein, ESR, gender).

Conclusions: These results suggest an up-regulation of DKK-1 in AS, neither explained by patient's demographic characteristics nor by parameters related to disease activity (BASDAI, or biological markers of inflammation). DKK-1 serum level tends to be negatively correlated with lumbar spine T-score and SOST was highly correlated with disease duration, suggesting that both factors could contribute to osteopenia and/or osteoporosis described in AS patients. The respective role of DKK-1 and/or SOST in the structural progression of the disease has not been assessed in this study but high basal levels for DKK-1 and increased levels of SOST according to disease duration are unlikely to explain syndesmophyte formation in AS. The lack of significant variation of DKK-1 and SOST under anti-TNF treatment is in accordance with the absence of structural effect reported for these treatments, at least after a short time follow-up. Conversely, NSAIDs daily intake for most patients (89%) at inclusion in the study may partially account for such DKK-1 serum level increase, a hypothesis that could suggest a potential structural effect of NSAIDs in AS.

Radiographic Progression Is Influenced by *ERAP1* Polymorphisms with Gender and Age Being Cofactors. Nigil Haroon[2], Walter P. Maksymowych[4], Proton Rahman[1], Florence W. Tsui[3] and Robert D. Inman[2]. [1]St Claires Mercy Hospital, St Johns, NL, Canada, [2]Toronto Western Hospital, Toronto, ON, Canada, [3]Toronto Western Research Institute and University of Toornto, [4]University of Alberta, Edmonton, AB, Canada

Introduction: Endoplasmic reticulum aminopeptidase 1 (ERAP1) polymorphisms have recently been identified to be associated with ankylosing spondylitis (AS). It is not however known if ERAP1 variants influence radiographic severity in AS.

Methods: Caucasian patients with AS (by the modified New York Criteria) from two centers were included in the study. X-rays of the lumbar and cervical spine were scored by the modified Stoke AS spine score (mSASSS). Patients had to have at least two mSASSS scores for inclusion. Genotyping for 14 AS-associated ERAP1 single nucleotide polymorphisms (SNPs) were done using the MassARRAY system. SNPs were excluded from analysis if the minor allele frequency (MAF) was <0.05. Linear regression analysis was done to examine the influence of the SNPs on the baseline mSASSS. For logistic regression, the patients were classified as progressors (any progression in mSASSS) and moderate or faster progressors if they had ≥1 or ≥2 mSASSS unit change/year respectively. Chi-square test was used to further analyze individual SNPS with significance in the regression analysis.

Results: A total of 334 patients (19% female, 137 and 197 from the respective centers) with a mean age of 41.8 ± 13 yrs were included in the study. The mean (± SD) BASDAI, ESR and CRP were 4.8 ± 2.4, 18 ± 23 mm/hr and 13 ± 16 g/L respectively. The mean mSASSS score at baseline was 19.8 ± 22.6 with 40% showing some progression at a mean rate of 0.8 ± 1.5 units/year. The SNPs rs17587(LMP2), rs26618, rs26653, rs27044, rs30187 (ERAP1) and rs241447 (TAP2) were included in the analysis while the MAF of the SNPS rs1057141, rs1800454, rs2071543, rs2228396, rs3734016, rs4148876 and rs10050860 were too low and excluded.

In binary logistic regression by forward stepwise conditional method, a model with rs17587 (p=0.01) predicted patients with high baseline mSASSS (defined as >50% of maximum = 36). Gender significantly improved the model (p=0.004) with males being more likely to have higher scores (OR=3.6; p=0.01). The addition of ESR, CRP or BASDAI did not improve the model. Chi-square test across the different genotypic groups for high baseline mSASSS scores were significant for rs17587 ($\chi^2=8.4$, p=0.01) and there was a trend in rs30187 (p=0.054). The mean baseline mSASSS in patients with change in mSASSS of < 4 units was significantly lower than those with >4 mSASSS units change (15 vs 25; p=0.0005).

There were significant baseline differences between the two cohorts with patients in one center being younger (38±13 vs 43±13 years; p=0.0003), and tended to have lower baseline mSASSS (20±21 vs 16±21) and more progression (2±3.1 vs 1.6±3.2). As baseline mSASSS is a strong predictor of progression, and the radiographic progression can vary between early and late disease, the cohorts were analyzed separately. Logistic regression model predictive of progression included rs30187 in patients from centre 1 and these patients were more likely to progress with the rs30187CC genotype compared to rs30187TT (OR 13.5; p=0.006), with this effect being further enhanced in males.

Conclusions: Genetic variants of ERAP1 and LMP2 are associated with radiographic severity in AS. Gender, age and disease duration are important cofactors influencing this interaction.

Recently Diagnosed Ankylosing Spondylitis: Gender Differences and Factors Related to Delay in the Diagnosis. The North Israeli Study of ANkylosing Spondylitis (NISAN). Gleb Slobodin[1], Iris Reychan[7], Nina Avshovich[5], Alexandra Balbir-Gurman[6], Nina Boulman[2], Mona Elias[3], Joy Feld[3], Reuven Mader[4], Doron Markovitz[6], Doron Rimar[2], Itzhak Rosner[2], Michael Rozenbaum[2], Devy Zisman[3] and Majed Odeh[2]. [1]Bnai Zion Medical Center, Haifa, Israel, [2]Bnai Zion Medical Center, [3]Carmel Medical Center, [4]Haemek Medical Center, Afula, Israel, [5]Hillel Yaffe Mecial Center, [6]Rambam Medical Center, [7]Technion

Background: Gender differences have been demonstrated in patients with advanced ankylosing spondylitis (AS). There are no studies evaluating this in patients with recently diagnosed disease. The aim of the study was to characterize a cohort of patients with recently diagnosed AS, both preradiographic and established, with emphasis on gender differences and factors leading to delay in diagnosis.

Methods: All consecutive patients diagnosed with AS in 2004–2009 were recruited over a 6 month period by participating rheumatologists. Clinical, laboratory and imaging data was collected during the screening visit and/or retrospectively for all patients enrolled.

Results: Seventy-nine men and 72 women with AS were enrolled.

Table 1. Gender-dependent features of AS

Variable	Men (79)	Women (72)	p
Age at diagnosis (years)	35.6 ± 11.7	38.5 ± 12.3	0.13
Delay time to diagnosis (years)	5.9 ± 6.4	5.7 ± 6.0	0.87

CT/MRI studies of SIJ	43 (54%)	53 (74%)	0.018

*[N] - number of subjects with available measurements

Both groups (men versus women) had similar age of onset of disease-related symptoms, as well as similar delay time to diagnosis, follow-up duration and frequency of anti-TNF treatment. Typical inflammatory back pain as a first symptom related to AS was reported more often by men (p=0.02). Women reported significantly more frequent lower abdominal or pelvic pain (p=0.0032), heel pain (p=0.003) and widespread pain (WP) (p=0.0001) during the course of AS. There was no gender-related difference in the incidence of uveitis, dactylitis or peripheral joint involvement. At the time of diagnosis, men were more limited in chest expansion (p=0.012) and showed increased occiput-to-wall distance compared to women (p=0.0032). At diagnosis, elevated erythrocyte sedimentation rate (ESR) and/or C-reactive protein (CRP) were detected in a similar proportion of men and women. X-ray films were more often diagnostic for AS in males, with more females undergoing CT or MRI studies to confirm the presence of sacroiliitis (p=0.018). In the subgroup analysis, women with WP had longer delay to diagnosis (p=0.0073) and more frequently elevated ESR/CRP levels (p=0.0068) compared to women without WP. No other statistically significant differences in disease presentation or burden, laboratory findings, or imaging characteristics were demonstrated to correlate with delay to diagnosis.

Conclusions: Women constituted almost 50% of all recently diagnosed patients with AS, with CT or MRI studies more frequently utilized in their diagnosis. Gender-related differences were demonstrated in both disease presentations and burden. WP in women was frequently reported, being related to significant delay in the diagnosis. As no other disease-related features were found responsible for delay in AS diagnosis, the physician's high level of suspicion may be the dominant factor in the early diagnosis of AS.

Table 2. Disease features in AS women with and without widespread pain (WP) #

Variable	With WP (28)	Without WP (41)	p
Age at diagnosis (years)	43.3 ± 11.7	35.4 ± 12.1	0.0091
Delay time to diagnosis (years)	8.3 ± 7.2	4.3 ± 4.8	0.0073
Follow-up time (years)	1.8 ± 1.1	2.0 ± 1.3	0.35
Frequency of anti-TNFα usage (%)	15/28 (54%)	17/41 (41%)	0.34
Symptoms of the disease:			
Inflammatory low back pain	28 (100%)	39 (95%)	0.51

The ECHOSPA MRI Module for Diagnosis of Early Spondyloarthritis (SpA): Preliminary Validation and Assessment of Diagnostic Utility. Walter P. Maksymowych[4], Damien Loeuille[2], Alexandra Desvignes-Engelbert[2], Olivia Judet[3], Isabelle Chary-Valckenaere[2], Robert Lambert[4], Maxime A. Breban[1] and Maria-Antonietta D'Agostino[3]. [1]Courbevoie, France, [2]Faculté de Médecine de Nancy, Vandoeuvre les Nancy, France, [3]Université Versailles Saint Quentin en Yvelines, Boulogne-Billancourt, France, [4]University of Alberta, Edmonton, AB, Canada

Purpose: MRI is now accepted as an imaging criterion for the classification of axial SpA but its diagnostic utility using conventional sequences in early pre-radiographic SpA requires further study. In particular, it is unclear which features on MRI of the sacroiliac joints (SIJ) have greatest diagnostic utility.

Methods: We developed an atlas of reference MRI images depicting the entire range of abnormalities observed in the SIJ. This included various patterns of bone marrow edema (linear, subchondral, capsular, posterior ligamentous, extra-articular, transitional vertebra), entheseal (capsulitis, ligamentary) and joint space inflammation, and structural lesions. These were

incorporated into an online data entry module that displays schematics of the SIJ allowing the recording of lesions in each SIJ quadrant of each slice. Three readers blinded to patient and diagnosis, independently assessed MRI scans (T1-weighted (TIW), short tau inversion recovery (STIR), and post-gadolinium fat-saturated T1W sequences) from the following subjects: 24 patients with AS, 20 age and sex-matched patients with mechanical causes of low back pain (NSBP), and 20 patients followed in the French multi-center ECHOSPA pre-radiographic SpA prospective cohort, in which patients were included for symptoms suggestive of SpA (i.e. IBP, arthritis, enthesitis or dactylitis, B27+ uveitis and family history of SpA). Semi-coronal slices through the synovial portion of the SIJ were read systematically from anterior to posterior as described in a standardized online training module developed by the Spondyloarthritis Research Consortium of Canada (SPARCC). Readers answered the following question dichotomously (yes/no): This SIJ scan confirms the presence of SpA? Sensitivity, specificity were calculated according to clinical diagnosis and reliability of detection of individual lesions was assessed using intra-class correlation coefficient (ICC).

Results: Sensitivity/specificity of MRI for the diagnosis of SpA in confirmed AS patients was 87.5/100, 95.8/80, and 83.3/83.3 for the 3 readers, respectively. The specific inflammatory lesions seen by all 3 readers in >30% of AS patients were capsular edema, ligamentous edema, and capsulitis, and each was reliably detected (κ = 0.76, 0.70, and 0.85, respectively). Sensitivity of MRI for the diagnosis of SpA in the pre-radiographic cohort was 5%, 20%, and 55% for the 3 readers respectively. There was no significant difference between readers in the detection of either specific inflammatory lesions or in the mean number of SIJ quadrants with bone edema. However, reliability for detection of erosions (ICC = 0.65) was less than for edema (ICC = 0.75) and fat infiltration (ICC = 0.75). Moreover, the reader who had the highest sensitivity (55%) rated abnormalities on T1W MRI as contributory to the diagnosis of SpA in 72.7% of patients diagnosed with SpA as compared to only one patient by either of the two other readers.

Conclusion: Our data shows that although various inflammatory features on MRI can be reliably detected, further improvement in diagnostic utility of MRI for early SpA may depend on further training of readers to recognize structural lesions on T1W MRI.

The New ASAS Classification Criteria for Axial and Peripheral Spondylarthritis: Valid in the Latin American Patients, but. . . . John D. Londono[1], Marlon B. Porras[2], Enrique Calvo[4], Pedro Santos[3], Wilson Bautista[3], Consuelo Romero-Sánchez[3], Mabel Avila[3], Ana María Santos[3] and Rafael Valle-Oñate[3]. [1]Spondylarthropathies Group/Rheumatology Division, Hospital Militar Central/Universidad de La Sabana, Chía, Cundinamarca, Colombia, [2]Spondylarthropathies Group/Rheumatology Division, Hospital Militar Central/Universidad de La Sabana, Bogotá, Cundinamarca, Colombia, [3]Spondylarthropathies Group/Rheumatology Division, Hospital Militar Central/Universidad de La Sabana, Bogotá, Colombia, [4]Universidad Nacional de Colombia, Bogotá, Colombia

Background: Different Spondylarthritis (SpA) presentation pattern have been described in Latin American countries. The Undiferentiated Spondylarthritis (uSpA) and Reactive Arthritis (ReA) forms are frequent (about 75%), whereas Ankylosing Spondylitis (AS) is near to 25%. Mixtures of axial and peripheral manifestations are common at onset and during evolution of the disease. We assess the new ASAS classification criteria for axial and peripheral SpA in a cohort of Colombian patients with established diagnostic of the disease.

Methods: Two hundred and eighty-one consecutive patients were evaluated in the last 10 years following the ASAS recommendations. Seventy four, with established diagnostic (by experts) were selected. All of them had complete clinical and laboratory information (including HLA-B27 screening), X-ray and magnetic resonance imaging of sacroiliac joints and were under 45 years old at the beginning of the disease. We also collected a control group: patients referred to our clinic in the same period of time with chronic back pain in which the diagnostic of SpA was ruled out, after following the same protocol.

Summary of the Results: A total of 74 patients (58 males, 16 females) with definite SpA (15 AS, 39 uSpA and 20 ReA), and 48 controls (34 males, 14 females) were analyzed. Mean disease duration in SpA patients was 1,4±1,1 vs. 4,5±4,3 years; mean age at disease onset was: 25,2±7,3 vs. 30,5±7,6 years. The key clinical findings were: arthritis and enthesitis in 75,7% (vs. 4,2% in controls), and inflammatory back pain (IBP) in 56,8% of the patients (vs. 4,2%). The other differences between the groups were: twenty-seven (36,5%) HLA-B27 positive patients (vs. 4,2%); buttock pain present in 32,4% of the patients and only 8,3% of the controls. Dactylitis was present in 24,7% of the patients vs. 0% in the controls. Uveitis was documented in 10,8% of the patients but not in controls. The family history of SpA was present in 4,2% of the patients (0% in the controls). The new Axial SpA classification criteria had a sensitivity and specificity of 66,2 and 91,7%; and the peripheral SpA classification criteria had a sensitivity and specificity of 90,5 and 87,5% respectively. When we decided to test them combined, we obtained a sensitivity of 93,2% and specificity of 87,5%. The European Spondylarthritis Study Group (ESSG) criteria had a sensitivity and specificity of 91,9 and 100%.

Conclusions: Although, the new ASAS classification criteria for axial and peripheral SpA show a good performance in our cohort, the predominant mixed form of the disease in the Latin American patients and low prevalence of HLA-B27 positivity should make us keep in mind the ESSG criteria. These results should be validated in a large group of patients.

The New ASAS Criteria for Axial SpA Does Not Predict the Development of mNYC AS at 8 Years in a Cohort of Very Early IBP Patients. Sibel Z. Aydin[2], Alex Bennett[1], Paul Emery[2], Dennis McGonagle[2] and Helena Marzo-Ortega[2]. [1]Defence Medical Rehabilitation Centre, Headley Court, Epsom, Surrey, United Kingdom, [2]Section of Musculoskeletal Diseases, The Leeds Institute of Molecular Medicine. University of Leeds, Leeds, United Kingdom

Objective: Axial SpA can be identified by using the new ASAS criteria. We aimed to test the predictive value of the imaging (MRI) and HLA-B27 arms of these criteria for the future development of Ankylosing Spondylitis (AS).

Method: An inception cohort of 33 patients with early inflammatory back pain (IBP) (median symptom duration 24 weeks) were retrospectively evaluated against both arms (imaging and HLA-B27) of the criteria. Plain radiographs and MRIs of the SIJs at baseline and radiographs after a mean duration of 8-years were assessed. MRIs were scored according to the ASAS definition of a "positive MRI" and the predictive value of both arms was compared. Further scoring to identify patients with severe MRI sacroiliitis (grade 3 according to the Leeds MRI SIJ Scoring System) was also available.

Results: All patients could be classified as axial SpA with more patients fulfilling the imaging (85%, n=28/33) than the clinical arm (58%, n=19/33) of the criteria. Eight patients with baseline evidence of radiographic sacroiliitis fulfilling the mNYC were excluded from the predictive analysis. Of the rest (25/33), n=4 patients developed AS at follow-up (all had a positive baseline MRI and 2 were HLA-B27+ve) and 11/33 had an increase in the radiographic sacroiliitis scores at 8 years. For prediction of new AS the MRI arm showed 100% sensitivity and 19% specificity whereas the HLA-B27 arm had 50% sensitivity and 43% specificity. No differences were seen between both arms for developing new AS or for progression of sacroiliitis when applying the ASAS definition of a positive MRI.

Table 1. New AS or worsening of sacroiliitis by X-rays according to the MRI findings and HLA-B27 positivity

		Positive MRI (ASAS definition)			Severe MRI (Leeds Scoring System)			HLA-B27		
		+	−	p	+	−	p	+	−	p
New AS (mNYC) n = 25	+	4	0	1	2	2	0.057	2	2	1
	−	17	4		1	20		12	9	
Progression of sacroiliitis n = 33	+	10	1	0.6	5	6	0.03	7	4	0.7
	−	17	4		2	19		11	10	

However an association was seen between development of AS (PPV 67%, NPV 91%, LR: 10) and progression of sacroiliitis (PPV 71%, NPV 76%, LR: 4.8) when using the Leeds definition of severe MRI sacroiliitis.

Conclusion: Neither arm of the new ASAS classification criteria predicted the progression of radiographic sacroiliitis (including the development of mNYC AS) over an 8 year period in this cohort of very early IBP. This

may be due to the inclusion of "mild" MRI sacroilitis in the ASAS definition of a "positive MRI" since severe MRI sacroiliitis was a better predictor.

The Prevalence of Cardiovascular Risk Factors in Patients with Early Psoriatic Arthritis. Majed M. Khraishi[3], Rana Aslanov[1] and Don MacDonald[2]. [1]Memorial University of Newfoundland, [2]Newfoundland and Labrador Centre for Health Information, [3]Nexus Clinical Research, St Johns, NL, Canada

Background: Psoriatic Arthritis (PsA) is a chronic inflammatory disease affecting 5–35% of patients with psoriasis(PsO). Recently, both diseases were associated with an increased risk and a higher prevalence of cardiovascular (CVD) risk factors when compared to the general population.

Objective: To examine the prevalence of the risk factors of cardiovascular disease in patients with Early PsA (EPSA) and compare the prevalence of co-morbidities to those of established PsA patients.

Methods: The patients were recruited prospectively from a clinic specializing in treating patients with PsO and PsA. We set out to determine the prevalence of CVD risk factors including the Framingham Risk Score in the cohort of patients with early PsA of less than 2 years symptoms (EPSA cohort). Co-morbidities considered potential risk factors for cardiovascular disease (e.g. obesity, diabetes) were evaluated in the EPSA patients. Markers of inflammation and skin and joint disease severity and as risk factors for CVD were assessed by using CRP, ESR, DAS28, HAQ and PASI scores. The co-morbidities were compared to those of an established PsA cohort (more than 2 years of symptoms)

Results: A total of 72 patients with Early PsA and 108 patients with Established PsA were included in this analysis. Females prevailed over males in EPSA cohort (58.3% vs. 41.7%) and their age at the onset of PSO (49.80 vs. 45.13) and PsA (50.42 vs. 44.65). Females were at higher risk for CVD in association with the Framingham Risk Category above 10% (58.3% vs. 32.0%). The prevalence of hypertension in EPSA was higher in males (50% vs. 38.5%; p=0.0329), while the prevalence of diabetes in EPsA was higher in females (30.8% vs. 18.8%; p=0.0025). Generally, the distribution of conventional risk factors was similar in both cohorts, except for obesity. From total number of 35 (50%) obese people in EPSA, 19 (54.3%) were females and 16 (45.7%) were males. Odds of being obese were 2.34 times higher for patients in EPSA compared to Established PsA (OR = 0.427; p = 0.0076). The prevalence of severe psoriasis was higher in patients with Established PsA (p = 0.0507); however, the expected PASI values were 1.52 units lower in patients in Established Cohort (p= 0.0001). Also, the ESR values in EPSA were significantly lower than those in Established PsA (p = 0.0008).Tthe utilization of NSAIDs, DMARDs and Biologics was significantly higher in Established PsA compared to EPsA (p= 0.0001), while the differences in using other medications remained non-significant.

Conclusion: These results support the hypothesis that PsA even at early stages may be associated with increased co-morbidities and cardiovascular risks. Obesity was more prevalent in patients with early arthritis, raising the possibility that the metabolic syndrome that is reported to be associated with established psoriasis is also present at the onset of arthritis (PsA). Longitudinal follow-up of these patients and analysis of their genetic background may help better understand the pathogenesis of these diseases. The PsA-specific risk factors reflected the disease activity, duration and severity, which suggest a need for a multidisciplinary approach so that patients can be identified and treated effectively.

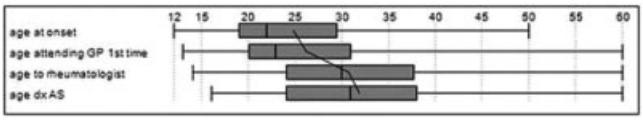
Time to Diagnosis of Ankylosing Spondylitis in an Irish Cohort and the Effect on Work Disability. Catherine Sullivan[2] and Oliver M. FitzGerald[1]. [1]Department of Rheumatology, St Vincents University Hospital, Ranelagh Dublin, Ireland, [2]Department of Rheumatology, St Vincents University Hospital, Elm Park, Dublin 4, Ireland

Introduction: Ankylosing Spondylitis (AS) is characterised by inflammatory back pain which may be associated with peripheral arthritis, enthesitis or uveitis. It has an insidious onset and results in radiographic progression with resultant pain, stiffness and loss of function. Studies have shown a delay in diagnosis of up to 7 years from onset of symtpoms.[1] Because there is no unique laboratory test to help in the diagnosis in primary care it is difficult to identify the 5% of patients with lower back pain who may have a spondyloparthropathy (SpA), including AS.[2] Research has demonstrated that patients with AS may have substantial periods of sick leave leading to a significant socioeconomic cost.[3]

Aim: We sought to identify the average time to diagnosis of AS from sypmtom onset in an Irish cohort and further to identify patterns of work disability in this group.

Methods: Patients with AS (n=100) were identified from the physiotherapy database of a Dublin tertiary referral rheumatology department. Patients were sent a postal questionnaire about disease onset, diagnosis, treatment and employment status. All replies were anonymous and 59% responded.

Results: Of the respondants 59% were male, the average age of onset of symptoms was 25 years (yrs), with diagnosis at 32 yrs and the average age when completing the survey was 44 yrs. 96.6% had some spinal involvement with 23.7% having only spinal involvement. The average time from symptom onset to diagnosis was 7.25 yrs (min 0, max 23).



74.6% of patients were on an anti-TNF agent alone, with 8.5% on an anti-TNF agent plus a synthetic disease modifying agent (DMARD), 3.4% on DMARD alone and 13.5% on neither. The time to diagnosis of AS did not impact on treatment protocol.

In total 30.5% of respondants reported not being in employment as a result of AS. 20% of those diagnosed in under 4 yrs from symptom onset were unemployed. This rose to 29.4% in those diagnosed between 5 and 9 yrs after onset and a staggering 41% of patients were unemployed in patients whose disease diagnosis was delayed by more than 10 yrs. 62.5% of participants who were off work said they did not anticipate returning to emplyment in the next 12 months.

Conclusion: In this cohort of Irish patients we see a delay in diagnosis of AS of 7 years, similar to that seen in studies in 1998 and 2003. This suggests a persistent problem with under recognition of SpA in primary care. Additionally, while not designed to look at all aspects of work disability, these data suggest a correlation between the time to diagnosis of AS and work disability. In light of these results a new diagnostic pathway for SpA has been developed and distributed to Irish General Practitioners.

Urolithiasis in Ankylosing Spondylitis—Are Stone Formers Also Bone Formers? Nai Lee Lui[1], Adele Carty[5], Nigil Haroon[3], Hua Shen[2], Richard Cook[2] and Robert D. Inman[4]. [1]Department of Rheumatology and Immunology, Singapore General Hospital, Singapore, [2]Department of Statistics and Actuarial Science, University of Waterloo, Canada, [3]Division of Rheumatology, Toronto Western Hospital, Toronto, ON, Canada, [4]Toronto Western Hospital, Toronto, ON, Canada, [5]Toronto Western Hospital

Objective: The frequency with which urolithiasis occurs in patients with ankylosing spondylitis (AS) has not been systematically analyzed in a large cohort. Urolithiasis represents an inherent propensity for calcium precipitation and calcification which might influence the osteoproliferation process in AS. We performed a cross-sectional analysis to determine risk factors for stone formation in AS and to address differences association with clinical features and osteoproliferation profiles.

Methods: In a longitudinal study of 504 AS patients, we conducted an analysis of all AS patients who developed urolithiasis. All patients met the modified New York criteria for AS. Demographics, clinical features, extra-articular features and co-morbidities are recorded in the database. We compared disease activity, functional indices, medical therapy and radiographic damage using the modified Stoke Ankylosing Spondylitis

Spinal Score (mSASSS) between AS patients with and without urolithiasis.

Results: Thirty eight AS patients had a history of urolithiasis, a frequency of 7.5% in this AS cohort. Seventy six AS patients with no history of urolithiasis, matched for age, gender and ethnicity, were selected as controls. There was no difference in the incidence of urolithiasis in terms of gender, ethnic groups, HLA-B27 status, smoking history or alcohol consumption. AS patients with urolithiasis were more likely to have more functional disability, as measured by Bath AS Functional Index (BASFI) (mean 5.3 versus 3.6 in control group, p=0.003). There was trends toward higher Bath AS Disease Activity Index (BASDAI) (mean 4.9 versus 4.0, p=0.09), more peripheral joint involvement (p=0.075) and higher frequency of biologic therapy (p=0.09). However, no significant difference was detected in the mSASSS scores (p=0.65) or Bath AS Metrology Index (BASMI) (p=0.98). There was a significant association of urolithiasis with diabetes (p=0.016) and with Crohn's disease (p=0.006).

Conclusion: There is no acceleration of syndesmophyte formation or spinal fusion associated with urolithiasis in AS. But AS patients with urolithiasis have unexpectedly more functional disability than AS patients overall. The higher risk with concomitant DM or Crohn's disease should alert clinicians to these co-morbidities in AS patients developing urolithiasis.

Validation of the Patient Acceptable Work State (PAWS): Establishing Thresholds for Major Work Transition in Ankylosing Spondylitis. Walter P. Maksymowych[3], Sumati Rao[1], Annelies Boonen[2], Naijun Chen[1] and Mary Cifaldi[1]. [1]Abbott Laboratories, Abbott Park, IL, [2]University Hospital Maastricht, Maastricht, Netherlands, [3]University of Alberta, Edmonton, AB

Background: Restrictions in paid and unpaid work are a feature of AS and is measured using several instruments that score impairment on a continuous scale, although the significance of these scores in relation to major work transition such as sick leave and disability leave is unclear. Therefore, it is helpful to define work performance on a dichotomous basis as either satisfactory or not satisfactory using the patient acceptable work state (PAWS). It is further important to validate patient designation of unacceptable work state in relation to major work transition. In this study, we developed and validated 3 questions that assess PAWS.

Methods: Data were obtained from the Patient-Reported Outcomes in Employment Study (PROSE), a longitudinal, observational study of AS and work productivity. Patients with AS answered the 3 PAWS questions (yes/no) at baseline: "Considering all the different ways your disease is affecting you, if you would stay in this state for the next few months, do you consider that: 1) your ability to perform your current job is satisfactory?; 2) you will continue to work in your present job?; and 3) you may need to stop working and go on sick leave or disability leave?" Patients were considered to be PAWS responders if they answered "yes" to Questions 1 and 2 and "no" to Question 3 and nonresponders if they answered "no" to Questions 1 and 2 and "yes" to Question 3. We examined PAWS responses in relation to the BASDAI, BASFI, and the following work productivity instruments: WPAI, WLQ, QQ1 (Quality) and QQ2 (Quantity). We also compared PAWS thresholds for the WPAI, WLQ, and BASFI according to the 75th percentile of patient responders for the 3 PAWS questions.

Results: Of 204 surveys obtained, 157 were AS employed patients. Out of which, 130 indicated they would be satisfied with their current job in the next few month, given their current disease state, 145 indicated they would continue working in their present job, and 136 patients indicated they would stop working given their disease state. There were more PAWS responders than nonresponders at baseline. A significant difference was observed in BASDAI, BASFI, WPAI, WLQ, and QQ1, and QQ2 scores between PAWS1 and PAWS3 responders and nonresponders (p<0.0001). PAWS responders attained a threshold ranging from 20%–30% for WPAI presenteeism, a threshold ranging from 27.7%–30% for overall work impairment, a threshold ranging from 30%–40% for work activity impairment, a threshold of 10 for both QQ1 and QQ2, and a threshold ranging from 6.5–7 for WLQ. Similarly, PAWS responders attained a threshold ranging from 4.8–5 for BASDAI and 4.2–4.7 for BASFI.

75th percentile (with 95% confidence interval) of WPAI domain scores, BASDAI, BASFI, QQ1, QQ2, and WLQ for PAWS responders at baseline (only for employed patients)

	PAWS Question 1 Responders (N = 130)	PAWS Question 2 Responders (N = 145)	PAWS Question 3 Responders (N = 136)
WPAI presenteeism	20 (20, 30)	30 (20, 30)	30 (20, 30)
WPAI overall work impairment	29.4 (20, 30)	30 (20, 30)	30 (20, 30)
WPAI work activity impairment	30 (30, 40)	40 (30, 50)	40 (30, 40)
QQ1 (0–10)	10 (10, 10)	10 (10, 10)	10 (10, 10)
QQ2 (0–10)	10 (10, 10)	10 (10, 10)	10 (10, 10)
WLQ	6.5 (5.3,7.1)	7.0 (6.2,8.3)	6.5 (5.6,7.7)
BASDAI (0–10)	4.8 (4.0,5.4)	5.0 (4.6,5.6)	5.0 (4.4,5.6)
BASFI (0–10)	4.2 (3.5,5.4)	4.7 (3.9,5.8)	4.4 (3.5,5.4)

Conclusions: PAWS may be a valid concept defining satisfactory versus unsatisfactory work status and should be further validated for it relationship to major work transition. Further research is required to assess the change in PAWS thresholds for work productivity and health-related quality of life over time.

Variation during Different Decades of Diagnostic and Therapeutic Delay in Patients of Ankylosing Spondylitis (AS). Giuliana Salvadorini[2], Francesca Bandinelli[2], Andrea Delle Sedie[1], Lucrezia Riente[1], Antonio Candelieri[3], Sergio Generini[2], Nicola Possemato[1], Stefano Bombardieri[1] and Marco Matucci Cerinic[2]. [1]Department Rheumatology of University of Pisa, Pisa, Italy, [2]Division of Rheumatology AOUC, University of Florence, Department of Biomedicine, DENOThe Centre, Florence, Italy, [3]Laboratory of Decision Engineering for Health Care Delivery, Department of Electronics, Informatics and Systems, University of Cosenza, Italy

Background: Ankylosing Spondylitis (AS) is a chronic, progressive, and disabling disease, but the diagnosis is often missed and markedly delayed (1). The early diagnosis is important to establish a treatment to reduce disability and modify the natural course of disease (2).

Objective: To investigate the diagnostic (DD) and therapeutic (TD) delay according to the decade of diagnosis and the correlation between DL and radiological severity score. The influence of different imaging techniques on TD has been also investigated.

Methods: 125 AS patients (45 female and 90 male, 36,5±10,2 years old at diagnosis) with disease onset between 1950 and 2008, were investigated: the time between onset and first rheumatologic visit, diagnosis (DD) and treatment (TD); the New York and ASAS criteria (3), the New York sacroiliac radiological score, the bamboo spine presence at first visit; the new imaging technique employed (magnetic resonance -MRI-, computerized tomography -CT- and scintigraphy for sacroiliac and ultrasonography -US- for periperipheral joints) at diagnosis. The difference of DD, TD and imaging technique between different onset decades ('50, '60, '70, '80, '90, '00), the correlation between DD and radiological severity, between TD and new imaging were analyzed.

Results: At first visit, 87% and 96% patients respectively met New York and mASAS criteria, with onset of symptoms 8,1±8,2 years before (28,3±10,2 years old). The delay since onset of symptoms to diagnosis and treatment was 9±8 and 12±11 years, respectively, but decreased significantly between different decades (p<0,001, Kruskal Wallis).

The severity of sacroileitis (mean 2±1, 13% IV grade at diagnosis) and bamboo spine (7,4% at diagnosis) correlated with DD (p<0,001, Pearson correlation) and decreased during decades (p<0,001, Kruskal Wallis).

The employment of new imaging technique increased significantly during decades (p<0,001) but only sacroiliac MRI significantly decreased TD (p<0,05, Mann Whitney test).

Conclusions: DD, TD, radiological severity significantly and progressively decreased during decades. In particular, the employment of sacroiliac MRI decreased time to first treatment.

Week 12 Response Is a Better Predictor Than Baseline Disease Characteristics of Long-Term Remission in Ankylosing Spondylitis. Joachim Sieper[3], Desiree van der Heijde[4], Steve Brown[2], Frederic Lavie[1] and Aileen Pangan[2]. [1]Abbott Laboratories, Rungis, France, [2]Abbott Laboratories, Abbott Park, IL, [3]Charité Universitätsmedizin Berlin, Berlin, Germany, [4]Leiden University Medical Center, Leiden, The Netherlands

Introduction: The ASAS consensus statement for the use of anti-TNF agents for ankylosing spondylitis (AS) includes an evaluation of response after 6–12 weeks to determine if continued therapy is warranted.

Objective: To determine predictors of long-term response in AS.

Methods: In ATLAS (Adalimumab Trial Evaluating Long-Term Efficacy and Safety for AS), patients were randomized to receive adalimumab (ADA) 40 mg every other week (wk) or placebo (PBO) during a 24-wk double-blind period, followed by an open-label extension of up to 236 wks (5 yrs). Possible predictors for ASAS partial remission (PR) and low AS disease activity score (ASDAS <1.3) after 1 and 5 yrs of ADA exposure were selected *a priori*. Categorical variables included age >50 yrs, disease duration >10 yrs, abnormal baseline CRP, HLA-B27+, female gender, presence of ≥1 syndesmophyte at baseline, and responder at Wk 12 for ASAS20, ASAS40, ASAS PR, low ASDAS, MI, and BASDAI50. Continuous variables included baseline values for BASFI, BASDAI, total back pain, Patient/Physician Global Assessments of disease activity, and morning stiffness (mean of BASDAI questions 5 and 6). Logistic regression was used to assess the univariate significance of each proposed predictor for the dependent variables. A multivariate survival curve analysis was done to determine predictors of sustained (≥6 consecutive months) response.

Results: ATLAS enrolled 315 patients (208 ADA, 107 PBO). Correlation of continuous variables was tested and all are significantly different. Univariate analysis showed that Wk 12 responses were more consistent predictors of remission at 1 and 5 years than baseline disease characteristics (Table). The presence of syndesmophytes as baseline was noted to be a negative predictor for long-term remission. The multivariate survival curve analysis confirmed this observation as Wk 12 response by a specific remission criteria was a significant ($P<0.01$) predictor of achieving sustained remission using the same criteria (Hazard ratio): ASAS PR (2.59) and low ASDAS (2.92). Of those who had available data for the analysis, 57% and 46% achieved sustained low ASDAS and ASAS PR during the 5-yr study.

Table 1.

	Odds Ratio			
	ASAS PR		Low ASDAS	
Predictors	1 yr	5 yrs	1 yr	5 yrs
Age > 50 yrs	0.47†	0.39†	0.58†	0.61
Disease Duration > 10 yrs	0.74	0.77	0.78	0.77
CRP Abnormal	1.22	2.18	0.71	0.71
HLA-B27+	1.08	0.94	1.10	0.80
Female	0.94	0.51	0.73	0.72
Syndesmophyte ≥1 (BL)	0.29*	0.28	0.32*	0.15*
BASFI (BL)	0.97*	0.96*	0.97*	0.97*
BASDAI (BL)	0.89	0.85	0.88	0.79*
Total Back Pain (BL)	0.98*	0.99	0.98*	0.97*
Patient Global Assessment (BL)	0.98*	0.98†	0.98*	0.97*
Physician Global Assessment (BL)	0.99	0.98†	0.99	0.99
Morning stiffness (BL)	0.95	0.84†	0.94	0.86†
Wk 12 ASAS20	5.37*	2.95*	4.76*	2.47*
Wk 12 ASAS40	5.35*	5.97*	5.68*	3.23*
Wk 12 ASAS PR	27.86*	28.56*	10.27*	9.19*
Wk 12 ASDAS MI	4.84*	5.53*	4.32*	4.23*
Wk 12 low ASDAS	6.49*	7.22*	10.19*	10.45*
Wk 12 BASDAI50	8.40*	6.02*	5.55*	3.98*

*$P < 0.01$; †$P < 0.05$; BL - at baseline

Conclusion: Early response (Wk 12) to ADA in AS patients is a better predictor than baseline disease characteristics of who would achieve sustained remission and continue to benefit from long-term therapy of up to 5 years. Presence of syndesmophytes at baseline was a negative predictor for remission, suggesting that earlier treatment of AS patients prior to syndesmophyte formation may be beneficial.

ACR Poster Session A
Systemic Sclerosis, Fibrosing Syndromes, and Raynaud's - Clinical Aspects and Therapeutics I
Monday, November 8, 2010, 9:00 AM–6:00 PM

560

A Multi-Center, Open-Label, Proof of Concept Study of Imatinib Mesylate Demonstrates No Benefit for the Treatment of Fibrosis in Patients with Early, Diffuse Systemic Sclerosis. Oliver Distler[8], Jorg H. W. Distler[9], John Varga[4], Christopher P. Denton[7], Robert A. Lafyatis[1], Fredrick M. Wigley[3], Georg Schett[2], Marco Matucci-Cerinic[10], Timothy M. Wright[5], Arthur P. Bertolino[6] and Peter Gergely, Jr[6]. [1]Boston University School of Medicine, Arlington, MA, [2]Friedrich Alexander Univ, Erlangen, Germany, [3]Johns Hopkins University, Baltimore, MD, [4]Northwestern Univ Feinberg School, Chicago, IL, [5]Novartis Institutes for Biomedical Research, Cambridge, MA, [6]Novartis Institutes for Biomedical Research, [7]Royal Free Hospital, London, United Kingdom, [8]University Hospital Zurich, Zurich, Switzerland, [9]University of Erlangen, Erlangen, Germany, [10]University of Florence, Firenze, Italy

Background and Purpose: Preclinical evidence and preliminary clinical data have suggested that imatinib mesylate may beneficially influence disease course in systemic sclerosis (SSc) mainly by suppressing TGFbeta and PDGF mediated fibrosis through the selective inhibition of the PDGFR and c-abl kinases. A multi-center, open-label, Proof of Concept (PoC) phase IIa study was conducted to evaluate the efficacy and tolerability of imatinib for the treatment of fibrosis in patients with early diffuse SSc.

Methods: Twenty-seven diffuse cutaneous SSc patients, older than 18 years, with disease duration less than 18 months and with modified Rodnan Skin Score (mRSS) of 16 – 36 were enrolled. Imatinib was initiated at an oral dose of 200 mg/day for 4 weeks then up-titrated to 400 mg/day for 2 weeks followed by 600 mg/day until Week 24, if safety and tolerability permitted. After discontinuation of imatinib, patients were followed for additional 24 weeks. Concomitant treatment with high-dose corticosteroids or immunosuppressants was not allowed. Primary outcomes were efficacy as assessed by the change in the mRSS and safety and tolerability. A 25% or greater decrease in mean mRSS with at least 50% level of proof after 24 weeks of treatment was pre-defined as a positive PoC. Further important efficacy assessments included lung functions and patient and physician global assessments. For biomarker assessments, immunohistochemistry and gene expression profiling of skin biopsy samples and assays for soluble markers were performed.

Results: Of the 27 patients enrolled, 16 completed 24 weeks of treatment with imatinib and 13 patients were followed up until week 48. Discontinuations were due to adverse events (6 patients, 22%), informed consent withdrawn (3 patients, 11 %) and other causes (5 patients, 19%). There were 5 patients with serious adverse events which included generalized edema, erosive gastritis, anemia, peripheral and facial edema, upper respiratory tract infection, viral infection, neutropenia and neutropenic infection, nausea and vomiting. No meaningful clinical improvement was observed during the treatment period for any endpoint. Positive PoC was not achieved as the mean change in mRSS at Week 24 was +9.9 %. No significant changes were observed in pulmonary function tests. Trends towards improvement in mRSS, patients and physicians global assessments were observed in the follow up period by Week 48. Biomarker analyses demonstrated a reduction of the mRNA levels of col1a1 and fibronectin.

Conclusions: The adverse events and tolerability in this study were as expected for imatinib and for the diffuse SSc population. Despite

preclinical and some preliminary clinical evidence, inhibition of PDGFR/c-abl/c-kit tyrosine kinases by imatinib had no major effect on the disease course of early diffuse systemic sclerosis in our study.

Baseline Differences in the "Borderline" Pulmonary Hypertension vs. "Normal" Hemodynamics: PHAROS Registry. Dinesh Khanna[4], Rajeev Saggar[4], Daniel Furst[4], Lorinda Chung[3], James Seibold[5], Tracy Frech[7], ELENA Schiopu[6], Rajan Saggar[4], Marcy Bolster[2], Virginia Steen[1] and PHAROS Investigators. [1]Georgetown University, [2]MUSC, [3]Stanford, [4]UCLA, [5]Univ of Connecticut, [6]Univ of Michigan, [7]Univ of Utah

Background: The Pulmonary Hypertension Assessment and Recognition of Outcomes in Scleroderma (PHAROS) is a prospective longitudinal study of patients at risk of developing PAH and those who have definite PH. The 4th World Symposium on Pulmonary Hypertension(PH) reclassified WHO group I patients with mean pulmonary artery pressure (mPAP) on right heart catheterization(RHC) of ≤ 20 mmHg as "Normal" and 21–24 mmHg as "Borderline (boPH)" PH. Data regarding natural history and outcome of boPH PH are lacking.

Objective: To examine 1) the baseline demographics and clinical features and 2) explore long –term outcomes in SSc patients with normal resting hemodynamics vs. boPH from the PHAROS study.

Methods: Entry criteria for patients at high risk for PAH included a DLCO<55% predicted, a FVC%/DLCO% ratio >1.6 or an estimated PASP on echo > 35mmHg. Patients complete questionnaires every 6 months and are seen yearly for physician evaluation, PFTs, echocardiogram, 6 minute walk, and clinical outcomes. Right heart catheterizations (RHC) are performed based on the clinical judgment of the physician.

Results: Of 379 enrollees, 127 patients had PH at baseline. Of remaining 262 patients with SSc, 50 had mPAP <25 at baseline and 15 follow-up first RHC (N=65) and form the analysis group. Of these 65 patients, 37 (57%) had normal hemodynamics (Normal, mPAP≤20 mmHg) and 28 (43%) had boPH (boPH; mPAP21–24 mmHg). The average age of the whole group was 55.4 years, mean disease duration was 8.7 years, 83% were women, and 63% had limited cutaneous SSc. There were no differences in baseline demographics between normal and boPH groups.

Pulmonary function tests showed lower FVC% in the boPH group (69 vs. 81, $p< 0.05$); A higher proportion of patients with boPH had FVC < 70% (63% vs. 31%, $p< 0.05$). There were no significant differences in scores of patient reported outcomes (UCSD dyspnea instrument, Scleroderma-HAQ, and SF-36 scores) between 2 groups. Patients with boPH had a significantly higher RVSP, mPAP, pulmonary capillary wedge pressure (PCWP), pulmonary vascular resistance (PVR), and transpulmonary gradient (TPG) compared to Normal, $p<0.05$ (Table). Only 1 patient in each group had PCWP≥15 at rest.

On exercise, boPH patients were more likely to have a mPAP>30 than the Normal group, 14/16 (88%) vs 11/20 (55%, p=0.04). 4 of the boPH patients had follow up caths. Of these, 1 was normal and 3 had WHO Group II PH (PVH). For Normal, 6 had repeat cath. Of these, 4 were normal, and 1 each had PAH and PVH. 2 patients died in the boPH group (PH-ILD and lung fibrosis) and 1 in the Normal group (non-SSc related).

Baseline Characteristics of Normal vs. Borderline PH

	NORMAL (N = 37)	BORDERLINE (n = 28)	p-value
Age in years, mean (SD)	56 (12)	55 (10)	0.7
Female, N%	34 (81)	27 (86)	0.5
Type of SSc, N (%)			
Limited	28 (67)	18 (62)	0.9
Disease Duration, yrs	9 (8)	8 (6)	0.5
PFT			
FVC %, mean (SD)	81 (19)	69 (16)	0.02
DLco %, mean (SD)	45 (11)	41 (18)	0.3
FVC/Dlco	1.9	2.1	0.3
Echo RVSP mmHg, mean (SD)	36 (8)	45 (13)	0.001
RHC			
mPA, mmHg, mean (SD)	17 (3)	23 (1)	<0.001
PCWP, mmHg, mean (SD)	7.7 (3.4)	10.3 (3.4)	0.02
CO, L/min, mean (SD)	5.7 (1.2)	5.4 (1.3)	0.2
PVR, dyns/cm5, mean (SD)	141 (74)	193 (66)	<0.001
TPG, mean (SD)	9 (3)	13 (4)	<0.001
6MW, meters, mean (SD)	448 (83)	396 (123)	0.08

Conclusion: Preliminary analysis of this group shows that SSc patients with borderline PH are likely to have lower FVC, higher PVR and TPG and have an abnormal response to exercise. Larger investigations on the prognostic and therapeutic implications of such borderline findings are warranted.

Cigarette Smoking Is Not a Risk Factor for Systemic Sclerosis. Prateek Chaudhary[3], Xing Chen[6], Shervin Assassi[3], Olga Gorlova[7], Hilda Draeger[5], Emilio Gonzalez[8], Terry McNearney[1], Marilyn Perry[3], Jason Anderson[4] and Maureen D. Mayes[2]. [1]Indianapolis, IN, [2]University of Texas Health Science Center at Houston, Houston, TX, [3]University of Texas Health Science Center Houston, Houston, TX, [4]University of Texas Health Science Center Houston, [5]University of Texas Health Science Center San Antonio, San Antonio, TX, [6]University of Texas MD Anderson Cancer Center, Houston, TX, [7]University of Texas MD Anderson Health Science Center, Houston, TX, [8]University of Texas Medical Branch at Galveston, Galveston, TX

Background: Cigarette smoking has been well established as a risk factor for seropositive rheumatoid arthritis. Although smoking has been reported to worsen the vascular complications of systemic sclerosis (SSc), the role of cigarette exposure in susceptibility to SSc has not been previously reported. Our objective was to investigate the association of smoking with susceptibility to SSc in a large well-defined patient population.

Methods: We conducted a review of 1,417 SSc patients enrolled in the *Scleroderma Family Registry and DNA Repository* and/or the *GENISOS (Genes versus Environment in Scleroderma Outcomes Study)* cohort. Smoking history was obtained from questionnaire data, chart review and, in some cases, via telephone interview with patients if sufficient information was not provided in medical records. Information extracted or asked included questions related to smoking status, duration and quantity.

SSc patients were subsequently categorized as never smokers, past smokers or current smokers. SSc patients with available smoking data were matched 2:1 by age, gender and ethnicity with a control group from the National Health and Nutrition Examination Survey (NHANES, 1999–2006). Furthermore, past smokers and current smokers were grouped as ever smokers in the comparative analysis.

Results: The average age of 1417 enrolled patients was 53.6 years and most were female (88.1%). The majority of cases were White (78.3%) with an almost identical percentage of Latinos and Blacks (8.9% and 8.4%, respectively). Most patients had limited disease type (58.8%).

Smoking data were available in 759 (53.6%) patients. There was no significant difference in age, gender, ethnicity and SSc disease type between patients with or without available smoking data. The majority of patients had never smoked (57.4%). Patients with a smoking history classified themselves as past smokers or current smokers in 32.1% and 10.4% of cases, respectively. The average duration of smoking prior to the diagnosis of SSc in ever smokers was 18.3 years.

Overall, 42.6% (323/759) of SSc patients were ever smokers whereas 46.6% (709/1489) of matched controls in the NHANES survey had ever smoked. A Chi-Square analysis comparing cases and controls revealed that patients with SSc were less likely to be ever smokers than controls (p=0.04, OR: 0.83, 95% CI: 0.7–0.99).

Conclusion: Unlike in rheumatoid arthritis, smoking does not confer a risk for development of SSc. In fact, these data would suggest a small protective effect of smoking. Further studies are needed to investigate whether

cigarette smoking modulates auto-antibody expression or disease manifestations of SSc.

563

Clinical Characteristics of Systemic Sclerosis Sine Scleroderma Associated Interstitial Lung Disease. Rohit Aggarwal[3], Mary Lucas[2], Noreen Fertig[2] and Thomas A. Medsger[1]. [1]Univ of Pittsburgh, Pittsburgh, PA, [2]University of Pittsburgh, [3]University of Pittsburgh Medical Center, Pittsburgh, PA

Aim: To describe the clinical characteristics features of systemic sclerosis sine scleroderma associated interstitial lung disease from a single tertiary care center over a 36- year period.

Methods: All 3322 patients from the tertiary care database with a clinical diagnosis of systemic sclerosis (SSc) with first visit between 1972–2008 were evaluated. Patients were classified as SSc-sine scleroderma (ssSS) if they had a clinical diagnosis of SSc with no skin thickening (Modified Rodnan skin score = 0) on physical examination and one or more of the following visceral involvement typical of SSc: distal esophageal hypomotility, pulmonary interstitial fibrosis, pulmonary arterial hypertension, SSc cardiac or renal disease. Pulmonary interstitial fibrosis was defined as the presence of pulmonary fibrosis seen on chest radiography (CXR) or high-resolution computed tomography (HRCT) scan, with or without pulmonary function criteria for restrictive lung disease: forced vital capacity in 1 second [FVC1] < 70% of predicted plus forced expiratory volume [FEV1] in 1 second/ FVC > 80% of predicted). All SSss patients with pulmonary fibrosis at first visit formed our final cohort of SSss-ILD patients, who were further studied for clinical and serological features. Serological evaluation for all SSc specific/associated autoantibodies was done on all patients with available serum.

Results: Our final cohort had 45 SSss patients with ILD at baseline. Demographics were: female (36/45, 80%), Caucasians (37/45, 82.2%), African American (7/45, 15.6 %). The mean (±SD) age (yrs) at first CTD symptom, first CTD diagnosis and first visit were 42.5 (17.2), 49.6 (16.9), and 53.5 (15.5), respectively. Mean diagnosis delay from first CTD symptom was 8.1 (9.6) yrs. Mean age at first pulmonary symptom was 51.5 (15.0) yrs. Mean duration from first non-pulmonary CTD symptom to pulmonary symptom was 8.6 (10.5) yrs, and most common first symptom was raynauds 29/45 (64.4%), followed by dyspnea (5/45, 11.1%), GI involvement (3/45, 6.7%). Most patients had multiple clinical features for SSc before the development of pulmonary disease: raynauds 36/41, 87.8 (median delay of 14.5 years from raynauds to pulmonary symptoms), arthritis 76.4%, esophageal symptoms 60.0%. 50% patients (18/36) had pulmonary symptoms before SSss diagnosis. Among various SSc-specific autoantibodies most common was ThTo 14/38 (36.8%), followed by U1 (or U2) 9/38 (23.7%), centromere 5/38. Positive ANA was seen in 93.3% (42/45) patients. Approximately 50% of patients (19/41, 46.3%) had nucleolar pattern, followed by speckled 10/41, centeromere 5/41. Most common clinical features at baseline evaluation were raynaud 39/45 (86.6%), telangiectasia 20/44, digital swelling 16/43, pyrositis 17/44, distal dysphagia 10/44. The Median, 5 and 10 year survival from the diagnosis was 16.9 years, 83.7% and 68.5% respectively.

Conclusion: Clinical features like Raynaud, arthritis and esophageal symptom generally precedes the development of pulmonary fibrosis and thus along with positive ANA can help diagnose SSss associated ILD. Nucleolar ANA pattern and anti-ThTo and anti-U1/U2 were the most common autoantibodies seen in SSss-ILD patients.

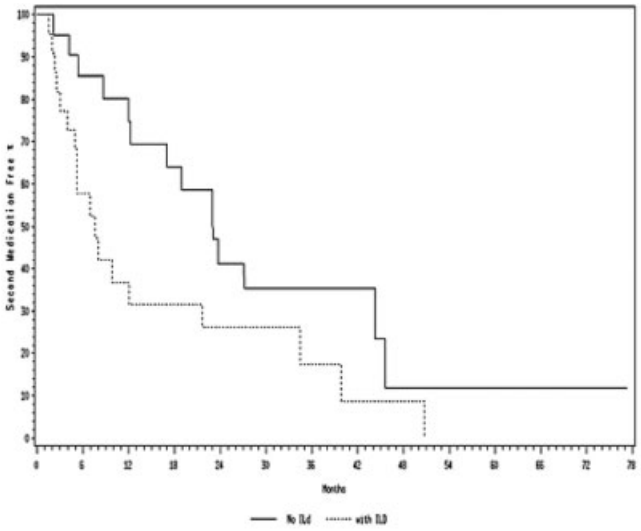
Clinical Predictive Factors on Response to Oral Monotherapy in Patients with Systemic Sclerosis-Associated Pulmonary Arterial Hypertension. Yih Chang Lin, Soumya Chatterjee, Meng Xu, Raed Dweik and Joseph Parambil. Cleveland Clinic

Rationale: Despite significant advances on vasodilator therapies for pulmonary arterial hypertension (PAH), the overall survival in systemic sclerosis-associated pulmonary arterial hypertension (SSc-PAH) remains poor and most patients eventually require more than one agent to help palliate their symptoms. This retrospective study was undertaken to better understand the relationship between clinical predictive factors and failure of oral monotherapy in SSc-PAH patients presenting in WHO functional class II/III.

Objective: To determine the time to initiation of a second therapeutic agent in SSc-PAH patients. Various parameters including demographic data, type of scleroderma and duration of disease, presence of interstitial lung disease (ILD), pulmonary function findings, hemodynamic parameters, and echocardiographic features were extracted in patients with SSc-PAH and analyzed in context with response to medical therapy with regards to time to addition of a second therapeutic agent.

Methods: We performed a retrospective review of electronic medical records between 2001–2008 involving patients with SSc-PAH. All patients had received upfront monotherapy with either an endothelin receptor antagonist or a phosphodiesterase type-5 inhibitor. Relationships of clinical predictive factors with monotherapy failure and time to utilization of a second therapeutic agent were analyzed using the Cox proportional hazard function with backward variable selection procedures.

Results: There were 66 WHO functional class II/III patients with SSc-PAH who received upfront monotherapy with either Bosentan or Sildenafil. 30 patients (45%) failed oral monotherapy after a mean duration of 13.1 ± 7.8 months. By univariate assessments African-American race ($p = 0.011$), limited type of scleroderma ($p = 0.028$), the presence of ILD ($p = 0.005$), pulmonary vascular resistance ≥6 Wood units ($p = 0.012$), and cardiac index < 2.25 L/min/m^2 ($p = 0.029$) appeared to have a significant association with the need to add a second medication. Multivariate analysis indicated that patients with ILD had a higher chance of needing a second agent with a hazard ratio of 4.12 (95% CI: 1.71– 9.94; $p = 0.001$). Patients who have SSc-PAH with ILD also had a shorter time period on monotherapy (8.9 months) compared to SSc-PAH without ILD (22.1 months) [log-rank p-value = 0.021] (**Figure 1**).



Conclusion: SSc-PAH patients who have underlying interstitial lung disease appear to be more likely to fail vasodilator monotherapy and also appear to require earlier utilization of a second therapeutic agent.

Combined Analysis of Outcomes of Sitaxentan Treatment of Pulmonary Arterial Hypertension (PAH) Associated with Systemic Sclerosis (Scleroderma). James R. Seibold[5], Marco Matucci-Cerinic[6], Michael Louie[3], Stephen Watt[3], Simon A. Teal[4], Xuexuan Liu[1], Lie-Ju Hwang[3] and David Langleben[2]. [1]Aerotek, Houston, TX, [2]Cardiology, Montreal Jewish Hospital, Montreal, Canada, [3]Pfizer Inc, New York, NY, [4]Pfizer Ltd, Tadworth, Surrey, UK, [5]Rheumatology, University of Connecticut, Farmington, Farmington, CT, [6]University of Florence, Firenze, Italy

Background: PAH is a leading cause of mortality and late disease morbidity in scleroderma. In PAH, endothelin (ET)-1 is a key vasoconstrictor, predominantly via ET_A receptors, and ET receptor antagonists are established therapies. Sitaxentan sodium is a once daily, orally bioavailable, highly selective (6500:1

ET_A vs ET_B) ET-receptor antagonist. This report is a post-hoc analysis of pooled data from the STRIDE (Sitaxentan To Relieve ImpaireD Exercise) 1, 2, and 4 trials. The aim is to describe the efficacy and safety of oral sitaxentan 100 mg once daily (QD; the currently approved dose in the European Union, Canada, and Australia) vs bosentan 125 mg twice daily (BID) and placebo in patients with PAH-scleroderma.

Methods: The STRIDE trials were double-blind, randomized, placebo-controlled trials of sitaxentan use in patients aged 12–75 years with WHO FC II–IV (predominantly II and III) idiopathic PAH or PAH associated with connective tissue disease or congenital heart disease. The trials ranged from 12 to 18 weeks in duration. The bosentan comparator arm in STRIDE- 2 was open-label.

Summary of the Results: Fifty four patients with scleroderma were included in the pooled, post-hoc analyses. Except for a higher mean (± SD) age in the sitaxentan group vs the bosentan group (62± 8 vs 55±15 y; P=0.0493), demographics and baseline disease severity were not statistically different across the 3 treatment groups. All patients were WHO FC II or III at baseline except for 1 FC IV placebo-recipient. Change in 6 minute walk distance (6MWD) and WHO FC, and time to clinical worsening were as follows:

	Placebo (N = 15)	Bosentan 125 mg bid (N = 15)	Sitaxentan 100 mg QD (N = 24)
Mean (SD) change in 6 MWD, m	−22 (79.0)	−14 (110.4)	18 (48.9)
Placebo-subtracted difference		7	39
Bosentan-subtracted difference			32
P-value vs placebo		NS	NS
P-value vs bosentan			
Change in WHO FC, n (%)			
Improved	1 (7%)	3 (20%)	6 (25%)
No Change	13 (87%)	8 (53%)	18 (75%)
Deteriorated	1 (7%)	4 (27%)	0 (0%)
P-value vs placebo		NS	NS
P-value vs bosentan			
Response*	14 (93%)	11 (73%)	24 (100%)
P-value vs placebo		NS	NS
P-value vs bosentan			0.011
Clinical Worsening, n (%)	3 (20%)	7 (47%)	0 (0%)
P-value vs placebo†		NS	0.033
P-value vs bosentan†			0.002

NS = nonsignificant.
*Improved or no change.
†P-values from log rank test for time to clinical worsening.

All therapies were well tolerated. For the safety analysis population (16 placebo, 24 sitaxentan 100 mg QD, and 16 bosentan 125 mg BID), the incidence of ALT/AST >3×ULN was 6% (placebo), 0% (sitaxentan), and 19% (bosentan). The incidence of discontinuations due to adverse events was 0% (placebo), 0% (sitaxentan) and 13% (bosentan).

Conclusions: Sitaxentan 100 mg QD appears to be an effective and well tolerated therapy for patients with PAH-scleroderma. Sitaxentan 100 mg QD significantly reduced the incidence of clinical worsening events, with fewer discontinuations due to adverse events and fewer cases of elevated ALT/AST compared with bosentan. These findings warrant further investigation in a large, prospective study.

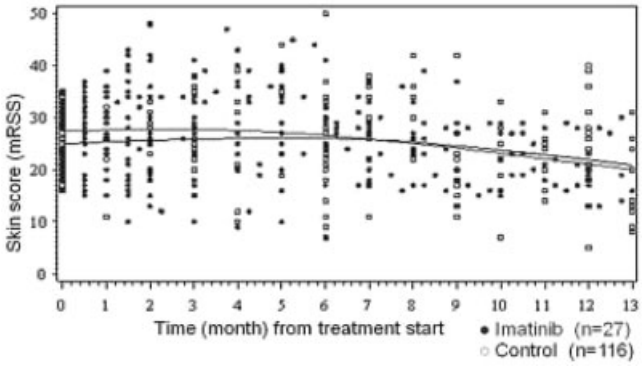
Comparative Analysis of Change in Modified Rodnan Skin Score in Patients with Diffuse Systemic Sclerosis Receiving Imatinib Mesylate Suggests Similar Disease Course to Matched Patients Receiving Standard Therapy. Christopher P. Denton[9], Svetlana I. Nihtyanova[2], John Varga[5], Oliver Distler[10], Fredrick M. Wigley[4], Robert A. Lafyatis[1], Jorg H. W. Distler[11], Georg Schett[3], Marco Matucci-Cerinic[12], Timothy M. Wright[6], Monica Costa Antunes[8], Amy Racine[8], Arthur P. Bertolino[7] and Peter Gergely, Jr[7]. [1]Boston University School of Medicine, Arlington, MA, [2]Center for Rheumatology and Connective Tissue Diseases, UCL Medical School, London, United Kingdom, [3]Friedrich Alexander Univ, Erlangen, Germany, [4]Johns Hopkins University, Baltimore, MD, [5]Northwestern Univ Feinberg School, Chicago, IL, [6]Novartis Institutes for Biomedical Research, Cambridge, MA, [7]Novartis Institutes for Biomedical Research, [8]Novartis Pharma, [9]Royal Free Hospital, London, United Kingdom, [10]University Hospital Zurich, Zurich, Switzerland, [11]University of Erlangen, Erlangen, Germany, [12]University of Florence, Firenze, Italy

Background and Purpose: Despite preclinical evidence and anecdotal case reports supporting potential benefit, clinical trials of the selective tyrosine kinase inhibitor imatinib mesylate in systemic sclerosis (SSc) have provided conflicting results with regard to efficacy as assessed by the modified Rodnan Skin score (mRSS). Our aim was to compare the course of mRSS in patients treated with imatinib in a multi-center, open-label, Proof of Concept (PoC) study in diffuse SSc [*submitted in parallel to ACR 2010*] and in patients receiving standard therapy in a well characterized large single centre cohort.

Methods: 27 cases of diffuse cutaneous SSc were treated with imatinib mesylate in an open-label prospective clinical trial. To develop a comparator cohort to help interpret clinical outcome in this trial, data from a SSc patient database (n>2000) from a large tertiary referral centre for SSc, were analyzed to select dcSSc patients whose main characteristics (disease duration and mRSS at baseline, age, sex, and concomitant diseases) matched those of the patient population in our PoC study. Patients (n=116 selected) in the control group received standard immunomodulatory treatment except for 19 (16 %) patients who received no immunosuppressive treatment. Imatinib was initiated at an oral dose of 200 mg/day for 4 weeks then up-titrated to 400 mg/day for 2 weeks followed by 600 mg/day until Week 24. A data driven descriptive analysis as well as a longitudinal mixed effects model were utilized to compare the changes in mRSS in the imatinib treated group (n=27) and in the control group (n=116).

Results: In the imatinib group in our PoC study, mean mRSS increased by 9.9 % at Week 24, however, there was a trend towards an improvement in mRSS (−21%) at Week 48, 24 weeks after the end of treatment. As compared to the control group, after an initial increase in mRSS in the imatinib group, the time course of mRSS was similar to that of the control group.



For two patients treated with imatinib who demonstrated a mRSS decrease greater than 25% at week 24, there were matching individuals from the control group with a similar profile.

Conclusions: Our data suggest that the changes in mRSS after 24 week treatment with imatinib in our PoC study are similar to those observed in cases receiving standard therapy. Such comparative analyses using large databases of well characterized cases may help better interpret results in further Proof of Concept studies of systemic sclerosis where the enrollment of a large number of patients is usually not feasible. Thus we provide a model for future early stage clinical studies in SSc.

Comparison of Estimated Pulmonary Artery Systolic Pressure by Echocardiography ($PASP_{ECHO}$) and Right Heart Catheterization ($PASP_{RHC}$) in Patients with Systemic Sclerosis (Scleroderma, SSc). Elena Schiopu[3], Ann J. Impens[3], Melvyn Rubenfire[2], Fazleomar Mahmood[3] and Kristine Phillips[1]. [1]University of Michigan, Ann Arbor, MI, [2]University of Michigan, Division of Cardiology, Ann Arbor, MI, [3]University of Michigan, Scleroderma Program, Ann Arbor, MI

Background: Pulmonary hypertension (PH) has emerged as the leading cause of death among patients with SSc. Early diagnosis in the pre-symptomatic phase of SSc-PH may lead to early intervention and improved outcome. Right heart catheterization (RHC), the diagnostic gold standard, is invasive and a need for accurate, noninvasive predictors of SSc-PH remains. Echo-Doppler is widely used in clinical practice to calculate the pulmonary artery systolic pressure (PASP) from the tricuspid valve velocity and an estimate of the right atrial pressure. We correlated the echo-Doppler estimated PASP ($PASP_{ECHO}$) with that measured by RHC ($PASP_{RHC}$).

Methods: 133 patients with SSc who underwent a RHC at University of Michigan between 1997 and 2010 had a technically adequate echo-Doppler within ≤ 180 days of the procedure. Abstracted data included: demographics, type of SSc, duration of SSc WHO functional class, serum brain natriuretic peptide (BNP) and hemodynamics. Pearson's correlations were used to compare the measurements.

Results: 108 (81.2%) patients were female, 92 (69.2%) had limited SSc and the mean (SD) disease duration was 10.1 yrs (8.4). The mean (SD) time between the RHC and the echocardiogram was 37 days (40). The WHO functional class distribution was: 3 (2.3%) class I, 21 (15.8%) class II, 97 (72.9%) class III and 12 (9%) class IV. The mean (SD) BNP was 476.7pg/mL (782.5). 105 (78.9%) of the patients met criteria for PAH (mPA > 25mmHg with PCW < 15mmHg). The mean (SD) mPA for the whole group was 40.4 (16.3). The body mass index (BMI) did not differ between the PH and the non-PH groups (mean 27.6 kg/m^2 for each).

Mean $PASP_{ECHO}$ was 69.1 (28.7) and $PASP_{RHC}$ 63.7 (24.9). The correlation between $PASP_{ECHO}$ and $PASP_{RHC}$ was r=0.70, P<0.01. The sensitivity, specificity, positive predictive value (PPV) and negative predictive value (NPV) for PAH for different cut-off values of $PASP_{ECHO}$ and $PASP_{RHC}$ were:

Cut-off value	Sensitivity (%)	Specificity (%)	PPV (%)	NPV (%)
$PASP_{ECHO}$ > 35	94.2	35.7	87.9	12
$PASP_{ECHO}$ > 40	91.4	50	82.7	17.2
$PASP_{ECHO}$ > 45	87.6	67.8	75.9	24
$PASP_{ECHO}$ > 50	84.7	75	72.1	27.8
$PASP_{ECHO}$ > 55	80	78.5	68.4	31.5
$PASP_{RHC}$ > 35	100	67.8	85.7	14.2
$PASP_{RHC}$ > 40	93.3	82.1	77.4	22.5

Conclusion: Among patients with SSc the estimated PASP by echo-Doppler correlated moderately well with the measured PASP by RHC. The sensitivity of $PASP_{ECHO}$ is high but the specificity is low when compared to the $PASP_{RHC}$. $PASP_{ECHO}$ can be part of a screening algorithm for predicting SSc-PH that would include other non-echocardiographic parameteres. The RHC remains the gold standard for establishing a diagnosis of SSc-PH.

Determination of the Accurate Incidence of Pulmonary Arterial Hypertension in Patients with Systemic Sclerosis, Mixed Connective Tissue Disease and Systemic Lupus Erythematosus by Prospective Study for 3-Years. Sumiaki Tanaka[1], Kenta Hoshi[4], Junichi Tanaka[4], Tatsuhiko Wada[4], Toshimichi Matsui[4], Tatsuo Nagai[4], Jun Okada[2] and Shunsei Hirohata[3]. [1]Drexel University College of MedicineDepartment of Rheumatology and Infectious Diseases, Kitasato University School of Medicine, Sagamihara, Kanagawa, Japan, [2]Drexel University College of MedicineDepartment of Rheumatology and Infectious Diseases, Kitasato University School of Medicine, Sagamihara, Japan, [3]Drexel University College of Medicine Department of Rheumatology and Infectious Diseases, Kitasato University School of Medicine, Kanagawa, Japan, [4]Drexel University College of MedicineDepartment of Rheumatology and Infectious Diseases, Kitasato University School of Medicine

Background: Connective tissue diseases (CTDs) are susceptible to pulmonary arterial hypertension (PAH), which has not been well evaluated.

Objective: To clarify the accurate incidence of PAH in patients with diffuse cutaneous SSc (dcSSc), limited cutaneous SSc (lcSSc), systemic lupus erythematosus (SLE), and mixed connective tissue disease (MCTD).

Patients and Methods: Prospective study of the 451 consecutive Japanese patients with dcSSc, lcSSc, SLE and MCTD enrolled from Nov 2006 until Mar 2010. All these patients had not been diagnosed of PAH before this study. The diagnosis of PAH was performed based on estimated systolic pulmonary arterial pressure (PAP) >40 mmHg with findings of right ventricular pressure and/or volume overload using ultrasound cardiography (UCG), followed by confirmation using right heart catheterization. Incidence of PAH (per 1000 person-years) was estimated using a generalized linear model (Poisson distribution, link function: log).

Results: 451 patients consisted of 75 dcSSc, 74 lcSSc, 230 SLE, and 82 MCTD patients. 8 patients were excluded due to the presence of PAH at the enrollment (Figure 1).

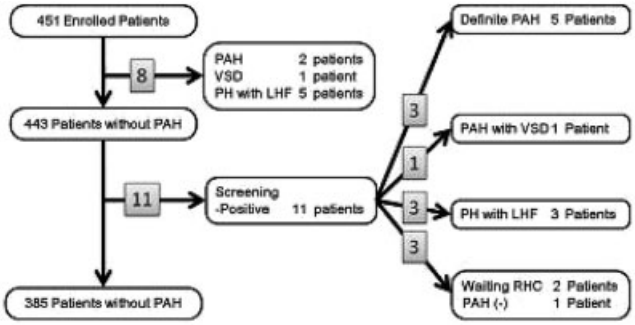

Figure 1. Follow-up Chart of Study
PAH: pulmonary arterial hypertension, VSD: ventricular septum defect, LHF: left heart failure, RHC: right heart catheterization

Thus 443 patients were enrolled and followed during 373 patient-years. Among the 443 patients, 11 patients were suspected to have PAH by UCG, and 5 of the 11 patients (2 dcSSc, 1 lcSSc, 1 SLE, 1 MCTD) were diagnosed as definite PAH. The incidence of PAH was significantly high in dcSSc and low in SLE (Table 1 and Figure 2).

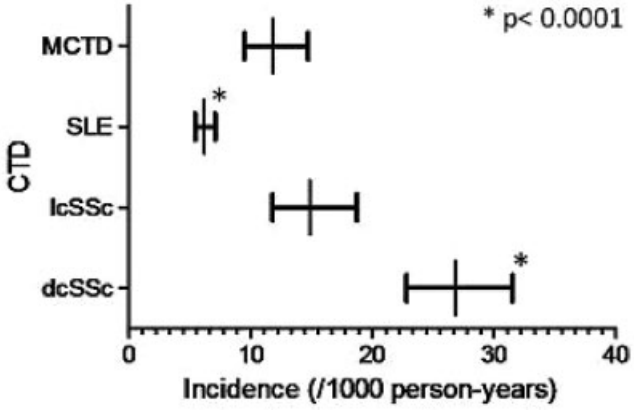

Figure 2. Incidences of PAH in various CTDs.

Table 1. Incidences of PAH in patients with various CTDs

CTDs	estimated averages	95% confidence interval
*dcSSc	26.83	22.83–31.51
lcSSc	14.87	11.81–18.74
*SLE	6.22	5.46–7.08
MCTD	11.82	9.50–14.72

Incidence:/person-years, *p < 0.0001

Conclusions: These results have disclosed the exact incidence of PAH in patients with CTDs, which was strikingly higher than that of idiopathic PAH (~2–3 per million person-years). The data also indicate that the incidence of PAH in dcSSc is much higher than that in MCTD and lcSSc.

Difficulty Using World Health Organization Criteria To Categorize Pulmonary Hypertension in Patients with Systemic Sclerosis. Jessica K. Gordon[3], Mardi Gomberg-Maitland[5], Barbara M. Segal[2], Robyn T. Domsic[6], Ami A. Shah[4], Laura K. Hummers[4], Virginia D. Steen[1], Evelyn Horn[7] and PHAROS Investigators. [1]Georgetown University Medical Center, Washington, DC, [2]Hennepin County Medical Center, Minneapolis, MN, [3]Hospital for Special Surgery, New York, NY, [4]Johns Hopkins University, Baltimore, MD, [5]University of Chicago, [6]University of Pittsburgh, Pittsburgh, PA, [7]Weill-Cornell Medical College

Background: Pulmonary hypertension (PH) is a leading cause of death in patients (pts) with Systemic Sclerosis (SSc). The World Health Organization (WHO) classifies PH into distinct groups to provide guidance on prognosis and therapy. In SSc, pulmonary arterial hypertension (PAH, WHO group 1) is most common. However, pulmonary venous hypertension (PVH, WHO Group 2) related to heart failure with a normal ejection fraction (HFNEF, formerly known as diastolic dysfunction) and interstitial lung disease (PH-ILD, WHO group 3) occur in isolation or in combination. We examined the frequency of coincident PVH in pts with PAH and PH-ILD followed in the Pulmonary Hypertension Assessment and Recognition of Outcomes in Scleroderma (PHAROS) Registry.

Methods: Pts with PH were categorized by WHO criteria. A pulmonary capillary wedge pressure (PCWP) $\leq$ 15 mmHg on the initial right heart catheterization (RHC) differentiated PAH from PVH pts, with some room for clinical impression. Those with moderate or severe ILD on imaging and forced vital capacity $<$60% predicted were included in ILD-PH, regardless of PCWP. Descriptive statistics were used to show the prevalence of PVH. ANOVA, Kruskal –Wallis, and Chi Square tests were used to compare baseline features.

Results: There are 150 pts with PH in the PHAROS database: PAH – 97 (64.7%), PVH – 23 (15.3%), and PH-ILD –30 (20%) with a median duration of follow-up of 1.1 years (IQR 0.5, 2.5). There were no significant differences between groups for gender, race, or duration of disease. Pts with PAH were more likely to have limited SSc subtype (73%, 48%, and 47% for PAH, PVH, and PH-ILD groups, respectively, p=0.02) and were older (61, 55, 52 years, p $<$0.01.) There were no differences in right ventricular systolic pressure, ejection fraction, or left atrial diameter (LAD) on echo. PAH pts had higher mean PAP and pulmonary vascular resistance (PVR.) Pulmonary function test (PFT) parameters were lower in the PH-ILD group, as expected.

Of those pts classified with PAH, 14.4% had some evidence of PVH either on baseline RHC, by development of PCWP $>$15 on repeat RHC, or by exercise PCWP$>$15. Of PAH pts, 33.0% had some degree of PVH as assessed by an increased LAD of $>$ 4.0 cm on echo. (Other echo parameters of diastolic dysfunction were not available.) Of those pts classified with PH-ILD, 36.6% had evidence for PVH based on RHC, and 30% based on LAD measurement. Interestingly, there was no correlation between the LAD and the PCWP (Spearman r = 0.1437, p = 0.06.).

	WHO 1-PAH (n = 97)	WHO 2-PVH (n = 23)	WHO 3-PH-ILD (n = 30)	P-value
EVIDENCE OF PVH				
Number of pts with RHC with resting PCWP $\geq$ 16 - n (%)	8 (8.2%)	22 (95.7%)	9 (30%)	not done
Number of pts with exercise RHC with PCWP $\geq$ 16 with normal resting RHC - n (%)	6 (6.2%)	1 (4.3%)	2 (6.6%)	not done
Number of pts with LAD $>$ 4.0 cm (%)	32 (33.0%)	12 (52.2%)	9 (30%)	not done
ECHO, RHC, AND PFT DATA AT ENROLLMENT				
Ejection Fraction (echo)-%, median (IQR)	60 (55, 65)	57 (55, 60)	60 (58.5, 65)	0.27
Pulmonary Artery Systolic Pressure (echo)- mmHg, median (IQR)	56 (44, 72)	46 (37, 55)	41 (37, 57)	$<$0.001
Left Atrial Diameter - cm, median (IQR)	3.7 (3.3, 4.1)	4.0 (3.2, 4.6)	3.6 (3.4, 4.0)	0.64
Mean PAP (RHC)-mmHg, median (IQR)	35 (29, 45)	29 (26, 33.3)	29 (25.5, 31.5)	$<$0.01
Pulmonary Vascular Resistance (RHC) -dynes-sec-cm^{-5}, median (IQR)	389 (256, 643)	160 (126, 316)	285 (166, 459)	0.0001
Forced Vital Capacity-% predicted, median (IQR)	80.8 (70.8, 92.7)	78.3 (54.3, 81.7)	51.2 (44.6, 64.6)	$<$0.0001
Diffusion Capacity - % predicted, median (IQR)	39.5 (31.7, 51.5)	37.5 (33.2, 44.1)	30.6 (24.0, 36.9)	0.002

Conclusions: Despite specific classification of PH subgroups using objective information, there is evidence for some degree of PVH in a large percentage of pts categorized with PAH or PH-ILD. In SSc, strict classification using WHO criteria is difficult to accomplish. PVR and PFTs may help clarify the type of PH. The significance of these findings with respect to prognosis and treatment response will be studied in the long-term follow-up of pts in PHAROS.

Dyspnea in Scleroderma Patients from the PHAROS Registry: A Major Contributor to Disability. Lorinda Chung[2], Hubert Chen[3], Dinesh Khanna[5], Ann J. Impens[4], Virginia D. Steen[1] and PHAROS Investigators. [1]Georgetown University Medical Center, Washington, DC, [2]Stanford Univ Medical Center, Palo Alto, CA, [3]UCSF, [4]Univ of Michigan Lobby M 2500, Ann Arbor, MI, [5]University of California Los Angeles, Los Angeles, CA

Purpose: Patients with systemic sclerosis (SSc) experience substantial disability related to systemic manifestations of their disease. We sought to determine the impact of dyspnea, as measured by the University of California San Diego (UCSD) Shortness-of-Breath Questionnaire (SOBQ), on disability in SSc patients with incident pulmonary hypertension (PH) and those at high risk for developing PH.

Methods: We used data from patients enrolled in the Pulmonary Hypertension Assessment and Recognition of Outcomes in Scleroderma (PHAROS) study. Criteria for enrollment include age $>$18, clinical diagnosis of SSc, and either PH diagnosed by right heart catheterization (mean pulmonary artery pressure $\geq$25mmHg) within 6 months of enrollment (definite PH) OR evidence of "pre" PH defined as: either right ventricular systolic pressure (RVSP) of $\geq$40mmHg on echocardiogram OR either forced vital capacity (FVC) $>$70% and diffusing capacity of carbon monoxide (DLCO) $<$55% of predicted OR an FVC/DLCO ratio $>$1.6. For this analysis, we included subjects with complete data for self-reported measures at baseline. The SOBQ was scored on a scale of 0 (no dyspnea) to 5 (severe dyspnea). Pre- and definite PH groups were compared using Student's t-test and chi-squared tests. Univariate and multivariate linear regression were used to determine the extent to which individual factors predict disability as measured by the Health Assessment Questionnaire (HAQ). Correlations r$\leq$0.29 were considered to be weak, between 0.30 and 0.49 were moderate, and $\geq$0.50 were strong.

Results: 353 patients (223 pre-PH, 130 definite PH) with complete baseline data had a mean age of 56.9$\pm$11.6 years, and the majority of patients was female (86%), Caucasian (73%), and had limited cutaneous disease (69%). Patients with definite PH had a shorter disease duration from first non-Raynaud's symptom than those with pre-PH (8.3$\pm$7 vs. 12$\pm$17 years, p=0.02). Patients with definite PH had higher mean dyspnea scores on the SOBQ (1.7$\pm$1.1 vs. 1.2$\pm$1.0, p$<$0.0001) and a non-significant trend toward greater disability as measured by the HAQ (0.99$\pm$0.75 vs. 0.85$\pm$0.77, scale 0–3, p=0.09) than patients with pre-PH. Univariate analyses identified the SOBQ (r=0.69, p$<$0.0001), 6 minute walk distance (6MWD) (r=0.32, p$<$0.0001), DLCO (r=0.12, p=0.03), RVSP (r=0.16, p=0.004), and New York Heart Association functional class (FC) (r=0.33, p$<$0.0001) as significant predictors of the HAQ. After accounting for age, gender, race, SSc disease duration, 6MWD, FVC, DLCO, RVSP, FC, and pre- vs. definite PH group, the SOBQ explained an additional 36% of the observed variance in disability (increase in adjusted R^2 from 0.13 to 0.49, p$<$0.0001).

Conclusions: Dyspnea in SSc patients with incident PH and at high risk for developing PH is a major contributor to disability. The UCSD SOBQ may be a useful tool in assessing dyspnea in this patient population.

Epidemiology of Systemic Sclerosis in the Afro-Caribbean Population of Martinique, FWI: A Population-Based Study. Christophe Deligny, Vincent Goeb, Marie Elise Truchetet, Valentine Kahn, Veronique Dehlinger, Patrick Numéric, Christian Derancourt, Georges Jean Baptiste and Serge Arfi. CHU de Fort de France, Fort de France, Martinique

Background: Population-based studies of systemic sclerosis in African descent population are exceptional.

Objective: To retrospectively assess incidence, prevalence and characteristics of systemic sclerosis (SSc) in the Afro-Caribbean population of Martinique, FWI.

Methods: Martinique is a West Indian French part of European community, with high economical status and 400000 inhabitants. Health care is easily accessible and the same as in metropolitan France. We conducted in 2009 and 2010 a multiple-source study to retrieve all cases fulfilling ACR criteria before 1st January 2009. Three different sources were used: hospitalisation files from the Academic Hospital, specialist physicians in private and public practice (rheumatologist, dermatologist, internist and pneumologist)

Results: 89 patients (88 meeting the ACR criteria) were found (female 73, male 16, female/male ratio: 4.6) in a screening of more than 400000 medical reports. Onset of the disease was, for 38 cases between 1999 and 2008 (female 30, male 8). Prevalence on December 31, 2008 and mean annual incidence from 1999 to 2008 of SSc were respectively $19.1/10^5$ inhabitants (confidence interval 95%: 14.5 – 25) and $1.33/10^5$ inhabitants (CI 95%: 0.5–3.3) aged 20 years old and over (female $1.84/10^5$, CI 0.5–5.1). In the 89 patients, the characteristics were: mean age at diagnosis 42.1 years old (range 12–86); mean follow up: 9.4 years (range 1–33); diffuse cutaneous scleroderma: 59 (66.3 %) and limited form: 26 (29.2 %); deaths during the follow up: 16 patients. Relative proportion of antitopoisomerase I antibody (31.5 %) and anticentromere antibody (12.4%) were typical of black patients and different than for Caucasians. Another connective tissue disease was present for 29 patients (32.6%) and muscular involvement was found in 31 (34.8 %). Interstitial lung disease concerned 67.4 % of our patients. Pulmonary hypertension, found in 28 %, was implicated in 6 deaths (37.5% of all deaths). Small and large intestine involvement, present in 14 patients, was responsible for 4 deaths (25% of all deaths)). Scleroderma renal crisis was diagnosed in 2 patients. The frequency of diffuse cutaneous form, interstitial lung disease, pulmonary hypertension and hypopigmentation (50.6%) seen in our Afro-Caribbean patients, has already been described in South African and Afro-American populations.

Conclusion: This is the first population-based study devoted to SSc in an African-descent population outside of the USA. It suggests that SSc is more frequent in our population than in most Caucasians populations already studied, but less frequently encountered than in African American population. Mean clinical and biological manifestations are close to African descent populations and also seem characteristic of the disease in Black populations.

European Scleroderma Study Group (ESCSG) Activity Index Is Correlated to Quality of Life Measures Both at Admission and Overtime. Gabriele Valentini[2], Michele Iudici[3], Giuseppina Abignano[3], Serena Vettori[1] and Giovanna Cuomo[3]. [1]Italy, [2]Rheumatology Unit - Second University of Naples, Napoli, Italy, [3]Rheumatology Unit- Second University of Naples, Italy

Objectives: EScSG activity index has been validated for construct validity (1). Its discriminant validity awaits to be investigated. In order to address this aspect, we investigated the relationships between the activity index and Health Assessment Questionnaire-Disability Index, and physical and mental component scores (PCS and MCS) of Short Form-36 (SF36).

Methods: 149 SSc patients consecutively admitted to a tertiary center were investigated for EScSG activity index, HAQ-DI and PCS and MCS of SF36 at enrolment and after 1 year. The change (Δ) for each measure was calculated.

Results: EScSG activity index was found to be correlated to HAQ-DI, PCS and MCS both at admission (Rho=0.41, p<0.0001; Rho=−0.41, p<0.0001; Rho= −0.29, p=0.0004, respectively) and after 1 year (Rho= 0.33, p <0.0001; Rho −0.35, p<0.0001; Rho=−0.21, p=0.0094 respectively). Moreover, the change between the value of the activity index at 1 year and that at admission (Δ activity index) was significantly correlated to ΔHAQ-DI, Δ PCS, ΔMCS (Rho=0.16, p=0.04; Rho= −0.24, p=0.003; Rho=- 0.48, p=0.0036, respectively).

Conclusion: HAQ-DI and SF36 (PCS and MCS) are considered to be validated outcome measures in SSc. Our results support the construct and the discriminant validity of EScSG activity index.

Evaluation of an Imatinib Response Gene Signature in Patients with Systemic Sclerosis. Lorinda Chung[3], Pedro Ruiz[5], Tammara Wood[1], Stanford Shoor[2], William Robinson[4], Michael Whitfield[1], Howard Chang[5] and David Fiorentino[5]. [1]Dartmouth Medical School, [2]Kaiser Permanente of Northern California, [3]Stanford Univ Medical Center, Palo Alto, CA, [4]Stanford Univ School of Med, Stanford, CA, [5]Stanford University School of Medicine

Purpose: We previously defined a set of imatinib-regulated genes from lesional skin of 2 patients with systemic sclerosis (SSc), termed the "imatinib response signature." We sought to further evaluate the clinical effects and gene expression changes induced by imatinib in patients with SSc.

Methods: Patients were treated with imatinib for 24 weeks at 100–400 mg daily as tolerated. The primary endpoints of the study were safety and change in modified Rodnan Skin Score (mRSS, scale 0–51) at 24 weeks compared with baseline. Lesional skin biopsies of the upper extremities were obtained at baseline, 4 and 24 weeks after therapy. Total RNA was extracted from skin biopsies using Qiagen RNeasy fibrous tissue kit. RNA was amplified using Agilent's Quick Amp Labeling Kit, no dye. Amplified skin RNA (labeled with NEN brand Cyanine 3-CTP, 100 nmol) and amplified Stratagene Human Universal Reference RNA (labeled with NEN brand Cyanine 5-CTP, 100 nmol) were competitively hybridized to Agilent Whole Human Genome 4×44K oligo microarrays.

Results: 7 patients with diffuse cutaneous SSc (dcSSc) and progressive skin disease (median disease duration 1 year, range 0.5–13) and 2 patients with limited cutaneous SSc (lcSSc) and interstitial lung disease (ILD) were enrolled in the study. Baseline mRSS in the dcSSc patients ranged from 19–49 (median 36). 7 patients (6 dcSSc, 1 lcSSc) completed 24 weeks of imatinib at a median dose of 300 mg daily. 1 patient withdrew at 4 weeks due to a keratopathy related to SSc, and 1 patient with lcSSc and severe ILD died after 8 weeks of therapy due to pneumonia and sepsis. Adverse events affecting 2/3 of patients included gastrointestinal complaints, edema, and infections. The mean mRSS improved by 32% at week 24 (p=.005).

Skin biopsies pre- and post-treatment were available from 4 additional patients, all of whom showed gene expression changes that were significantly enriched for the originally defined "imatinib response" gene set (p=.025 to 2.27×10^{-11}, hypergeometric distribution). 1 patient with lcSSc showed imatinib-induced changes in gene expression that were very similar to our original 2 patients ($p=4.6 \times 10^{-6}$). This patient had clinical improvement at week 24 with mRSS decreasing from 6 to 2, decreased ground glass opacities on high resolution chest CT, and decreased right ventricular systolic pressure from 69 to 54 mmHg on echo. The remaining 3 patients demonstrated significant repression of the genes induced by imatinib in our initial patients ($p=.029$ to 4.9×10^{-9}). These 3 patients had variable clinical responses to imatinib: 1 patient with dcSSc had mild improvement in skin but worsening ILD; the second was the lcSSc patient who died; and the third was a dcSSc patient who experienced minimal improvement in skin score. In the 3 responding patients only, imatinib upregulated genes involved in collagen metabolism and morphogenesis, while downregulating genes involved in mitosis and the cell cycle.

Conclusions: Imatinib therapy at low to moderate doses is tolerated by patients with SSc and may result in clinical improvement in a subset of patients. The cutaneous molecular response to imatinib is heterogeneous and may be partially reflected in the clinical response to the drug.

Evaluation of the Effect of Ambrisentan on Digital Microvascular Flow in Patients with Systemic Sclerosis Using Laser Doppler Perfusion Imaging. Nilanjana Bose[2], James F. Bena[2], Charles M. Trunick[3], Debora J. Bork[2], Geetha Krishnan[2], John Petrich[2] and Soumya Chatterjee[1]. [1]Cleveland Clinic, Richmond Heights, OH, [2]Cleveland Clinic, Cleveland, OH, [3]Cleveland Clinic

Background: Raynaud's phenomenon (RP) occurs in about 95% of patients with systemic sclerosis (SSc). Vasodilators such as calcium channel blockers may not be as helpful as in primary RP, as they have little effect on the vascular fibro-proliferative changes that lead to chronic digital ischemia in SSc. Ambrisentan (Am) is a selective endothelin receptor type A (ETA)

antagonist FDA approved for the treatment of pulmonary hypertension. Am differs from bosentan in its ability to permit the vasodilatory effect of endothelin through its interaction with the endothelin-B receptor, while inhibiting its vasoconstrictive effect through its interaction with the ETA receptor. Laser Doppler perfusion imaging (LDPI) is a non-invasive technique that involves perfusion mapping of areas of skin, rather than examination of blood flow at a single point. We hypothesized that Am would increase digital microvascular flow (as measured by LDPI) in patients with SSc-induced digital ischemia.

Methods: In this randomized, double-blinded, placebo controlled trial, we enrolled 20 patients with limited SSc for < 7 years. Smokers, patients desiring pregnancy, and those with pulmonary hypertension or active digital ulcers were excluded. After initial screening, there were 2 visits: day 0 (baseline) and day 7. Raynaud's Condition Score (RCS), Scleroderma Health Assessment Questionnaire (S-HAQ) and Pain-Visual Analog Scale (P-VAS) were completed at each visit. Fifteen patients received Am 5 mg orally daily and 5 received placebo. Patients were monitored for adverse events. At each visit, 3 baseline blood flow readings of fingers of the non-dominant hand were obtained at room temperature (RT) (25°C) and after cold challenge (CC) (10°C). The primary outcome measure was mean change of blood flow in selected regions of interest (ROI) of the fingers after 1 week of therapy. Secondary outcome measures included changes in RCS, S-HAQ, and P-VAS.

Results: There were 16 females (80%); mean age was 50 years (range: 20 to 70). Patients in the Am group showed similar median changes in RCS ($p = 0.51$), S-HAQ ($p = 0.93$), and P-VAS ($p = 0.62$) scores. Overall, a median increase of 0.12 units (8%) was observed at RT, with a lower overall median change of 0.06 units (8%) after CC. Across all ROIs, the Am group tended to show larger median actual and percentage changes in perfusion [RT: 0.14 (14%); CC: 0.07 (12%)] than the placebo group [RT: −0.10 (−6%); CC: −0.28 (−18%)]. Changes were similar within ROI as well. However, none of these differences overall or within ROI reached statistical significance. No adverse events occurred. A 3-month follow up study while on drug/placebo is ongoing.

Conclusion: While on average, small improvements in perfusion were seen in the Am group, these changes were too small to reach statistical significance. Though the trend observed may imply efficacy of Am, it is also possible that vasodilation may not be its predominant mechanism of action in improving digital ischemia, and reversing the microvascular remodeling process over a longer period may be more important. We are currently evaluating this hypothesis by continuing our present study for 3 months, when data will be collected and analyzed again.

Identification of New Autoantibody Specificities in Different Subsets of Systemic Sclerosis Patients. Guillaume Bussone[3], Hanadi Dib[4], Mathieu C. Tamby[1], Cédric Broussard[5], Loïc Guillevin[2] and Luc Mouthon[2]. [1]Université Paris Descartes, Institut Cochin, INSERM U1016, CNRS (UMR 8104), Paris, France, [2]Universite Paris Descartes, Faculte de Medecine, Pole de Medecine Interne et Centre de Reference Pour les Vascularites Necrosantes et la Sclerodermie Systemique, Hopital Cochin, Assistance Publique-Hopitaux de Paris, Paris, [3]Universite Paris Descartes, Institut Cochin, INSERM U1016, CNRS (UMR 8104), Paris, France, [4]Universite Paris Descartes, Institut Cochin, INSERM U1016, CNRS (UMR 8104), Paris, France, [5]Universite Paris Descartes, Institut Cochin, INSERM U1016, CNRS (UMR 8104), Plate-forme Proteomique Paris 5, Paris

Objectives: To identify new target auto-antigens in patients with systemic sclerosis (SSc) and antinuclear antibodies (ANA) without identified specificity, i.e. without anti-centromere, anti-topoisomerase 1 and anti-RNA-polymerase III antibodies.

Methods: We have used two-dimensional electrophoresis and immunoblotting with Hep-2 cell total and nuclear protein extracts as sources of auto-antigens. Sera from 45 SSc patients were tested in 15 pools of 3 phenotypically identical patients. Sera pool of 12 healthy blood donors was used as control.

Results: Serum IgG in 15 pools of SSc patients recognized 142±44 and 175±77 protein spots in total and nuclear protein extracts, respectively. Nineteen spots were specifically recognized by IgG from at least 4/10 pools of patients with ANA without identified specificity. Fourteen and 12 proteins were recognized by IgG from at least 75% of the 15 pools of patients in total and nuclear protein extracts, respectively. A number of these antigens were recognized with a higher intensity by IgG from patients with ANA without identified specificity than by IgG from other patients and healthy controls, including triosephosphate isomerase and superoxide dismutase [Mn], mitochondrial precursor in total protein extract, heterogeneous nuclear ribonucleoprotein L in nuclear protein extract and lamin A/C in both extracts. In addition, we identified antigens specifically recognized by IgG from subsets of phenotypically identical patients with ANA without identified specificity, including cofilin-1, peroxiredoxin-2 and calreticulin.

Conclusions: In SSc patients with ANA without identified specificity, we have identified a number of new target antigens either shared among these patients or specific for a given phenotype.

Intravenous Immunoglobulin (IVIg) in the Treatment of Systemic Sclerosis (SSc) Associated Myopathy. Arnaud Dzeing-Ella[7], Alice Bérezné[7], Brigitte Ranque[4], François-Jérôme Authier[1], Yannick Allanore[5], Jean Cabane[3], Eric Hachulla[2], Loïc Guillevin[7] and Luc Mouthon[6]. [1]Service d'Histologie, Hôpital Henri-Mondor, Creteil, France, [2]Service de Medecine Interne, Hôpital Claude-Huriez, Lille, [3]Service de Medecine Interne, Hôpital Saint-Antoine, Paris, France, [4]Service de Medecine Interne, HEGP, Paris, France, [5]Service de Rhumatologie A, Hôpital Cochin, Paris, France, [6]Universite Paris Descartes, Faculte de Medecine, Pole de Medecine Interne et Centre de Reference Pour les Vascularites Necrosantes et la Sclerodermie Systemique, Hopital Cochin, Assistance Publique-Hopitaux de Paris, Paris, France, [7]Universite Paris Descartes, Faculte de Medecine, Pole de Medecine Interne et Centre de Reference Pour les Vascularites Necrosantes et la Sclerodermie Systemique, Hopital Cochin, Assistance Publique-Hopitaux de Paris, Paris

Background: Skeletal muscle involvement is a common feature in systemic sclerosis (SSc). Conflicting results have been reported regarding the correlation between clinicobiological presentation and pathological muscle features, nevertheless there is a general agreement that histologically proven inflammatory myopathies usually regress under high-dose corticosteroid therapy. However, use of high dose of corticosteroids could participate to the induction of scleroderma renal crisis. IVIg are used for years in the treatment of dermatomyositis and polymyositis. In association with corticosteroids and methotrexate, IVIg could help control the SSc-associated inflammatory myopathy, allowing to avoid high dose corticosteroids.

Objective: To evaluate the efficacy and the tolerance of IgIV in the treatment of SSc-associated inflammatory myopathy.

Patients and Methods: Sixteen patients (14 females, 87.5%) with SSc-associated myopathy and available muscle biopsy were restrospectively investigated from the charts of four hospital centres for the efficacy of IVIg. All of them fulfilled the American College of Rheumatology and/or Leroy and Medsger criteria for the diagnosis of SSc. Inflammatory myopathy was either biopsy proven or based on We retrospectively include 16 patients. All patients fulfilled the American College of Rheumatology and/or Leroy and Medsger criteria for the diagnosis of SSc and had a history of myopathy explored by muscle biopsy. Myopathy was defined as the presence of muscle weakness, myalgia, or creatine kinase (CK) greater than 5 N (upper normal range), together with evidence of muscle involvement on electromyography (low voltage and/or short duration potential during maximal contraction, fibrillation or sharp wave) or on muscle biopsy.

Results: The 16 patients had a mean age of 40.4 years, a diffuse SSc in 87.5% of the cases with a mean Rodnan score of 16 at the time of inclusion into the study. Patients were followed for a mean of 2 years. Ninety three percent of patients had interstitial lung disease. Fifty percent of the patients had pulmonary fibrosis and/or left ventricular failure. Anti-PM-Scl and anti-RNP autoantibodies were detected in 18.75% and 12.5% of the patients, respectively. All patients received IVIg in the setting of failure of corticosteroids and immunosuppressants. IVIg were prescribed at a dose of 2 mg/kg every 4 weeks. Fourteen (87.5%) patients had a favorable outcome, with complete response in 5 patients and partial response in others. Half of patients relapsed after a mean follow up of 6.4 months after interruption of IVIg treatment. The treatment was well tolerated and no case of renal failure was notified.

Conclusion: IVIg may be helpful in the treatment of SSc-associated myopathy in case of failure of corticosteroids and/or methotrexate. However, the therapeutic effect is only suspensive. Prospective randomized studies are needed in order to evaluate the true efficacy of IVIg in SSc-associated myopathy.

Modeling Smoking in Systemic Sclerosis: A Comparison of Different Statistical Approaches. Marie Hudson[3], Ernest Lo[2], Russell Steele[3] and Murray Baron[1]. [1]Jewish General Hospital, Montreal, QC, Canada, [2]Lady Davis Institute, Jewish General Hospital, [3]McGill University

Background: Vascular disease is ubiquitous in SSc and cigarette smoking is well known to contribute to vascular disease. There is no standard way of modelling smoking in epidemiologic studies. The purpose of this study was to demonstrate the impact of different methods of modelling smoking when determining vascular outcomes in SSc.

Methods: We undertook a study using data from the Canadian Scleroderma Research Group Registry. Patients self-reported their smoking history, including intensity, duration and time since cessation. Vascular outcomes were severity of Raynaud's phenomenon, presence of finger ulcers and severity of finger ulcers. Five regression models using various definitions of smoking were developed: Model 1 compared ever to never smoking; Model 2 compared current and past smoking to never smoking; Model 3 modeled smoking using polynomial contrasts, treating never, past and current smoking as ordered values of a single variable; Model 4 modeled smoking status as current versus non-current; and, Model 5 represented smoking using the Comprehensive Smoking Index, which integrates smoking intensity, duration and time since cessation into a single covariate (Leffondre K et al. 2006 Stat Med 25:4132–46). All regression models were adjusted for age, sex, ethnicity, disease duration and limited or diffuse skin involvement.

Results: This study included 606 SSc patients, of which 87% were women, 90% were white, mean age was 55 (± 12) years, mean disease duration was 11 (± 9) years, and 36% had diffuse disease. Of these, 16% were current, 42% past and 42% never smokers. Current and past smokers smoked a mean of 25 (±17) and 17 (±18) pack-years, respectively. Smoking duration varied from 1 to 60 years, with past smokers having a shorter duration than current smokers (18.3 vs. 31.7 years, respectively). Past smokers stopped smoking approximately 16 (±12) years prior to their baseline registry visit, although this varied from 1 to 50 years. The results of the regression analyses for the five models of smoking are summarized in Table 1.

Table 1. Summary of the regression results of the 5 different models of smoking

Model 1: Ever vs. Never Smoking						
Outcome Variable	**b-EVER[a]**	**p-value**				
Severity of Raynaud's (0–10)	0.007	0.92				
Presence of finger ulcers	−0.03	0.88				
Severity of finger ulcers (0–10)	−0.01	0.69				
Model 2: Current vs. Never and Past vs. Never						
Outcome Variable	**b-CURRENT[b]**	**p-value**		**b-PAST[c]**	**p-value**	
Severity of Raynaud's (0–10)	0.20	0.05	.	−0.06	0.41	
Presence of finger ulcers	0.40	0.15		−0.18	0.36	
Severity of finger ulcers (0–10)	0.04	0.35		−0.03	0.33	
Model 3: Polynomial Contrasts						
Outcome Variable	**b-LINEAR[d]**	**p-value**		**b-QUAD[e]**	**p-value**	
Severity of Raynaud's (0–10)	1.14	0.18		1.85	0.03	*
Presence of finger ulcers	2.19	0.35		4.41	0.05	*
Severity of finger ulcers (0–10)	0.19	0.65		0.66	0.10	*
Model 4: Current vs. Non-current Smoking						
Outcome Variable	**b-CURRENT[f]**	**p-value**				
Severity of Raynaud's (0–10)	0.23	0.01	*			
Presence of finger ulcers	0.50	0.06	.			
Severity of finger ulcers (0–10)	0.06	0.16				
Model 5: Comprehensive Smoking Index (CSI)						
Outcome Variable	**b-CSI[g]**	**p-value**				
Severity of Raynaud's (0–10)	0.52	0.002	**			
Presence of finger ulcers	1.21	0.002	**			
Severity of finger ulcers (0–10)	0.12	0.07	*			

. p < 0.1, *p < 0.05, **p < 0.01
[a]Estimated regression coefficient for Ever vs. Never smokers;
[b]Estimated regression coefficient for Current vs. Never smokers;
[c]Estimated regression coefficient for Past vs. Never smokers;
[d]Estimated regression coefficient for the linear contrast covariate;
[e]Estimated regression coefficient for the quadratic contrast covariate;
[f]Estimated regression coefficient for Current vs. Non-current smokers;
[g]Estimated regression coefficient for the CSI

Model 1 *did not detect any significant effect of smoking on the vascular outcomes*. Models 2 and 3 showed a 'U-shaped' trend in the effect of smoking, with *past smokers appearing healthier than both never and current smokers,* with this effect reaching statistical significance in Model 3 only. Model 4 detected a negative effect of smoking on the severity of vascular outcomes, reaching statistical significance for the severity of Raynaud's and showing a strong trend for the presence of finger ulcers. The results of Model 5 were similar to those of Model 4, but with much stronger statistical significance.

Conclusions: These findings highlight the importance of proper modeling of smoking. Simple models may mask important effects of smoking on vascular outcomes in SSc. The CSI was the most sensitive model because it accounts for the wide range of smoking exposure.

Nailfold Microangiopathy and Pheripheral Blood Perfusion Correlate with Internal Organ Involvement in Sistemic Sclerosis. Alberto Sulli[1], Carmela Ferrone[2], Carmen Pizzorni[2], Elisa Alessandri[2], Francesca Ravera[2], Giuseppe Zampogna[2], Bruno Seriolo[2] and Maurizio Cutolo[1]. [1]Research Laboratory and Academic Unit of Clinical Rheumatology, Department of Internal Medicine, University of Genova, Genova, Italy, [2]Research Laboratory and Academic Unit of Clinical Rheumatology, Department of Internal Medicine, University of Genova, Genova, Italy

Background: Nailfold microangiopathy and peripheral blood hypoperfusion are key features of early systemic sclerosis (SSc) and internal organ involvement/skin lesions are frequently discovered during the follow-up.

Aim: The aim of the study was to investigate possible correlations between nailfold capillary abnormalities, pheripheral blood perfusion (PBP), and internal organ involvement in patients affected by SSc.

Methods: Seventy-one consecutive SSc patients (mean age 61±13 years, disease duration 7±5 years) were evaluated. Nailfold microangiopathy was detected by nailfold videocapillaroscopy (NVC), which was performed on 2nd to 5th finger of both hands, and the average semiquantitative scores for the capillaroscopic parameters were calculated1,2. PBP was analyzed by laser Doppler flowmetry at the central area of the fingertips of the same fingers, and the average value of PBP was recorded as perfusion units (PU)3. Oesophageal involvement was detected by manometry, pulmonary function by lung volume tests, DLCO and CT; cardiac performance was investigated by Doppler echocardiography, renal function by laboratory tests and arterial Doppler echography; active or recent history of ulcers were assessed by both clinical interview and examination. Statistical analysis was performed by non-parametric tests.

Results: PBP was found significantly lower in SSc patients with active or recent history of ulcers (median 28 PU), when compared with those without ulcers (median 55 PU) ($p=0.02$). PBP was also lower in patients with esophageal, lung, renal, and pulmonary arterial involvement (median 29, 28, 29, 25 PU, respectively), than in those without (median 51, 46, 41, 57 PU, respectively), but this was not statistically significant ($p=0.11$), possibly due to the small study population. SSc patients showing higher microvascular abnormalities scores for NVC parameters like microhaemorrhages, capillary number, and capillary disorganization had significantly lower PBP ($p<0.03$). Oesophageal involvement correlated with higher NVC scores for capillary number and disorganization ($p=0.03$); lung disease with higher score for capillary disorganization ($p=0.04$); renal function impairment with higher scores for capillary number and disorganization ($p=0.04$); pulmonary arterial hypertension with higher scores for enlarged capillaries, capillary number, ramification and disorganization ($p=0.05$); digital ulcers with higher scores for capillary number, ramification and disorganization ($p=0.01$), as well as with lower score for giant capillaries ($p=0.003$).

Conclusions: Nailfold capillary abnormalities extent negatively correlates with PBP and positively with internal organ involvement. Internal organ involvement seems to be associated with reduced PBP, but this should be confirmed on a larger SSc population. Finally, the occurrence of skin digital ulcers is associated with blunted peripheral blood perfusion in SSc patients, as well as with higher scores for several NVC parameters.

Oral N-acetylcysteine in the Treatment of Raynaud's Phenomenon Secondary to Systemic Sclerosis: A Randomized, Double-Blind, Placebo-Controlled Clinical Trial. Marcelo José Uchoa Correa[2], Henrique A. Mariz[3], Luis Eduardo Coelho Andrade[3] and Cristiane Kayser[1]. [1]Universidade Federal de São Palo, Brazil, [2]Universidade Federal de São Paulo, São Paulo, Brazil, [3]Universidade Federal de São Paulo, Brazil

Purpose: Intravenous N-acetylcysteine has been suggested to be useful in the treatment of Raynaud's phenomenon (RP) in patients with systemic sclerosis (SSc). This study aimed to evaluate the safety and the efficacy of oral N-acetylcysteine on the digital skin microvascular blood flow in patients with RP secondary to SSc.

Methods: This was a randomized, double-blind, placebo-controlled clinical trial with 42 patients with RP secondary to SSc. Patients were randomly assigned to receive oral N-acetylcysteine 600 mg three times daily or placebo three times daily for 4 weeks. Primary outcome was changes in digital skin microvascular blood flow before and after cold stimulus (CS) using laser Doppler imaging (LDI) at baseline and at week 4. Frequency of Raynaud's attacks, RP severity visual analog scale (VAS), RP pain VAS, and the number of digital ulcers were also evaluated at baseline and at week 4.

Results: 21 SSc patients (mean age 45.6±9.5 years) were randomly assigned to receive oral N-acetylcysteine and 21 patients (mean age 45.0±12.7 years), to receive placebo. Oral N-acetylcysteine was generally well tolerated, and at the end of 4 weeks nobody discontinue the treatment. There were no significant changes in digital skin blood flow measured by LDI before or after CS following 4 weeks of N-acetylcysteine or placebo. Both groups showed significant improvement of the frequency of Raynaud's attacks, RP severity VAS, and RP pain VAS after 4 weeks of treatment, with no difference between groups. There was no significant change in the number of digital ulcers in both groups after placebo or N-acetylcysteine treatment.

Conclusions: Oral N-acetylcysteine did not demonstrate increase on the digital skin blood flow measured by laser Doppler imaging in this short-time study in patients with SSc. Oral N-acetylcysteine was not significantly better than placebo in improving severity of RP in patients with RP secondary to SSc.

Outcomes of Barrett's Esophagus Related to Systemic Sclerosis: A 3-Year EULAR/EUSTAR Prospective Follow-Up Study. Julien Wipff[11], Romain Coriat[9], Michela Masciocchi[5], Paola Caramaschi[2], Chris T. Derk[7], Eric Hachulla[8], Valeria Riccieri[12], Luc Mouthon[10], Dorota Krasowska[1], L. P. Ananyeva[6], Andre Kahan[3], Marco Matucci-Cerinic[13], Stanislas Chaussade[9] and Yannick Allanore[4]. [1]Department of Dermatology, Medical University of Lublin, Lublin, [2]Department of Medicine, Verona University, Verona, [3]Hopital Cochin, Paris, France, [4]Hopitaux de Paris Cochin, Paris, France, [5]Immunological Clinic, Mangiagalli Regina Elena Fundation, Milan, [6]Institute of Rheumatology, Russian Academy of Medical Science, Moscow, [7]Jefferson Medical College, Philadelphia, PA, [8]National Scleroderma Centre, Lille Cedex, France, [9]Paris Descartes University, Gastroenterology Dpt, Cochin Hospital, [10]Paris Descartes University, Internal Medicine Dpt, Cochin Hospital, [11]Paris Descartes University, Rheumatology A Dpt, Cochin Hospital, [12]Sapienza University of Rome, Medical Clinic and Therapy Department, Rome, [13]University of Florence, Firenze, Italy

Background: Barrett's esophagus (BE) is the major risk factor for esophageal adenocarcinoma (EAC). Systemic sclerosis (SSc) is associated with an increased risk of BE related to chronic reflux.

Objectives: To determine the outcomes of BE and estimate the EAC risk in SSc patients over a 3-year prospective study.

Methods: SSc patients were recruited through EUSTAR network centers. Inclusion criterion was a recent histological finding of BE. The patients were then prospectively followed and, as recommended, a second esophageal endoscopy was performed according to the presence at baseline of BE-related dysplasia.

Results: 50 SSc patients with BE (40 without and 10 with dysplasia) were included and 46 completed the follow-up (138 patients-year). During the 3-year follow-up, 4/46 BE patients (3%/year) were diagnosed with high-grade dysplasia/EAC, of which one developed cardial EAC. EAC incidence in the BE sub-group with dysplasia increased to 4%/year compared to the absence of EAC case in the BE sub-group without dysplasia at baseline.

Conclusion: Our results, in accordance with previous published data suggesting an increased risk of esophageal or cardial adenocarcinoma in SSc, highlight the need for accurate follow-up of BE SSc patients at risk of developing adenocarcinoma.

Preclinical Evaluation of Cardiac Involvement in Systemic Sclerosis Patients by Speckle Tracking Strain Analysis. Anne A. Schouffoer[3], Kai H. Yiu[1], Maarten K. Ninaber[2], Jan Stolk[2], Thea P. M. Vliet-Vlieland[3], Eduard R. Holman[1], Tom W. J. Huizinga[3], Jeroen J. Bax[1], Nina Ajmone Marsan[1] and Annemie J. M. Schuerwegh[4]. [1]Department of Cardiology, Leiden, The Netherlands, [2]Department of Pulmonology, Leiden, The Netherlands, [3]Department of Rheumatology, Leiden, The Netherlands, [4]Department of Rheumatology, Leiden University Medical Center, Leiden, The Netherlands

Background: Cardiac involvement is common in patients with systemic sclerosis (SSc) and a well-known prognostic factor. Preclinical identification is therefore of crucial importance, although conventional echocardiography assessment showed limited sensitivity for the assessment of subtle changes in cardiac function. The aim of the study was to assess the value of the novel echocardiographic speckle tracking 3 directional (longitudinal, circumferential and radial) strain analysis to detect cardiac involvement in SSc patients and to investigate the association with rhythm disturbances, lung function parameters and cardiopulmonary exercise (CPET) parameters.

Methods: A total of 104 patients were included during a SSc screening program, which included pulmonary function tests, CPET, 24-hr ECG Holter recording and echocardiography with speckle tracking analysis. Echocardiographic data were compared with those obtained from 37 age and sex matched healthy controls.

Results: The mean age of the study population was 54 ± 11 years. Fifhty-seven patients presented a diffuse (d) SSc and 47 a limited (l) SSc. Disease duration was 8.1 ± 6.2 yr; Vital Capacity was 94.4 ± 14.4 % predicted, and % predicted maximum oxygen uptake (VO2max) was 90.6 ± 20.4%. Twenty-eight patients (27.7 %) had abnormal ECG holter findings defined by ventricular tachycardia or frequent ventricular ectopics >100 per day. Echocardiographic findings in SSc patients are shown in table 1. At the multivariable analysis, decreased left ventricular (LV) systolic function as assessed by global circumferential strain (B −0.52, 95% CI −5.63, −2.23, $p<0.01$) was independently associated with of lower % predicted VO2 max. Patients with 24-hr ECG Holter abnormalities showed significantly more decreased longitudinal (−18.5 ± 1.5 vs −17.1 ± 2.1, $p<0.01$) and circumferential (−18.7 ± 2.0 vs −17.3 ± 2.5, $p=0.01$) strain then patients without

abnormalities and circumferential strain was independently associated (HR 1.55, 95% CI 1.18 – 2.03, p<0.01) with abnormal Holter findings. For both % predicted VO2max and ECG holter the conventional LV echocardiografic parameter ejection fraction showed no significant difference.

	Controls (n = 37)	SSc (n = 104)	p value	SSc (n = 47)	dSSc (n = 57)	p value
Conventional echocardiographic parameters						
LV end diastolic volume (ml)	70.6 ± 20.6	76.0 ± 25.4	0.21	73.6 ± 23.1	77.9 ± 27.3	0.38
LV end systolic volume (ml)	26.6 ± 5.7	29.1 ± 13.1	0.13	29.6 ± 14.3	28.7 ± 12.2	0.75
LV ejection fraction (%)	64.6 ± 4.4	63.5 ± 7.2	0.20	64.8 ± 6.3	62.0 ± 6.3	0.18
PASP (mmHg)	21.7 ± 6.3	28.9 ± 8.7	**<0.01**	29.5 ± 7.9	28.3 ± 9.3	0.51
Diastolic function						
E diastolic velocity (cm/s)	75.8 ± 13.8	78.0 ± 18.1	0.45	76.5 ± 19.1	79.3 ± 17.3	0.45
A diastolic velocity (cm/s)	63.0 ± 14.5	74.8 ± 21.0	**<0.01**	17.3 ± 21.7	75.2 ± 20.5	0.84
E/A ratio	1.3 ± 0.3	1.1 ± 0.4	**0.04**	1.09 ± 0.37	1.1 ± 0.41	0.61
E′velocity (cm/s)	9.0 ± 2.3	7.0 ± 2.2	**<0.01**	6.6 ± 2.2	7.3 ± 2.2	0.08
E/E′ ratio	8.7 ± 2.3	11.9 ± 3.8	**<0.01**	12.3 ± 3.8	11.6 ± 3.8	0.38
Speckle tracking						
Global longitudinal strain (%)	−21.3 ± 1.7	−18.2 ± 1.8	**<0.01**	−18.7 ± 1.5	−17.9 ± 1.9	**0.01**
Global circumferential strain (%)	−21.3 ± 2.1	−18.3 ± 2.3	**<0.01**	−19.1 ± 2.0	−17.6 ± 2.2	**<0.01**
Global radial strain (%)	40.3 ± 12.4	37.0 ± 13.9	0.18	37.5 ± 13.5	36.5 ± 14.3	0.73

LV = Left ventricular; PASP = pulmonary arterial systolic pressure; E = early; A = late; E′ = early diastolic velocity at basal mitral annulus

Conclusion: Speckle tracking strain analysis is able to detect subtle myocardial systolic dysfunction in patients with SSc. Decreased global circumferential strain was associated with lower exercise tolerability and rhythm disturbances, whereas LV ejection fraction was not. Therefore, the use of speckle tracking analysis may facilitate preclinical identification of cardiac involvement in SSc.

Preliminary Composite Response Index for Raynaud's Phenomenon. Dinesh Khanna[2], Paul Maranian[2], Daniel Furst[2], James Seibold[3], Marco Matucci Cerinic[4], Jeff Gregory[1] and Harold Paulus[2]. [1]MediQuest, [2]UCLA, [3]Univ of Conneticut, [4]Univ of Florence

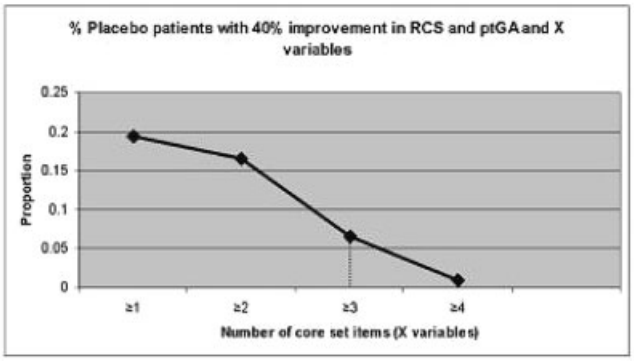
Background: In interventional studies of RP, variable responses are seen in different outcome measures and high placebo response is common. Our goal was to develop a Composite Response Index in RP that would improve the ability to measure efficacy of an investigational drug and facilitate the ability to compare responses across trials.

Methods: We analyzed 249 patients with primary or secondary RP in the placebo group who participated in 3 RCT (MediQuest Therapeutics). 8 core set measures were assessed in these studies: Raynaud's Condition Score (RCS- assesses the level of difficulty experienced due to RP), pt. assessment of RP, physician assessment of RP, pain, numbness, tingling, average number of attacks per day and duration of attacks. We conducted an online survey of scleroderma experts and asked them to rank all items on their importance for RCT and to identify core set items that must be included in RCTs.

Daily patient logs of Raynaud attacks were used to compute average number of attacks per day, average duration of attacks, daily averages of pt-reported pain, numbness, and tingling associated with each reported attack and a daily RCS. pt (ptGA) and physician assessments of RP were recorded weekly. Daily averages were used to compute weekly averages for the period between physician visits, and the weekly averages were averaged for the run-in period and for the treatment period. Percent improvement between run-in and treatment periods was calculated for 8 outcome measures. Since pain, numbness, and tingling showed a high degree of correlation (pairwise Pearson correlations of 0.76, 0.69, and 0.78), they were combined into a single measure (Attack symptoms) by selecting the %improvement of the outcome that showed the highest level of improvement, resulting in 6 core measures.

Preliminary definitions required ≥ x% improvement in y of the 6 variables where x was set at 10%, 20%, 30%, 40%, 50%, and 60% and y was set as 2, 3, 4, 5, or 6, variables. We hypothesized that placebo response should be <10% to show a difference from an effective drug.

Results: 50% and 40% of experts (N=71) ranked RCS and ptGA as top two measures for RCT and 93% and 92% stated that RCS and ptGA must be included in a composite index. Therefore, we assessed a definition requiring RCS and ptGA improvement by xx% along with y of the 4 other core set items to define a composite improvement. 92.8% of placebo-treated patients showed ≥10% improvement in at least one core set item with 38.5% showing ≥60% improvement in at least one variable. An improvement of 40% in both RCS and in ptGA, and 40% in 3 of the remaining 4 variables was associated with placebo response of 6% and provided greatest discrimination between 10–30% vs. 50–60% improvement in core set measures.



Conclusion: We have developed a preliminary composite response index for RCTs in RP. This index needs to be compared with an effective agent in a RCT to see if it can improve the ability to measure efficacy.

Prevalence of Coronary Heart Disease in a Cohort of Australian Scleroderma Patients. Gene-Siew Ngian[2], Joanne Sahhar[7], Jill Byron[14], Susanna Proudman[9], Catherine Hill[8], Janet Roddy[11], Peter Youssef[12], Kathleen Tymms[1], Leslie Schrieber[10], Wendy Stevens[14], Jane Zochling[6], Peter Nash[15], Allan Sturgess[13], Gabor Major[5], Ian Wicks[3] and Sharon Van Doornum[4]. [1]Canberra Rheumatology, Australia, [2]Department of Medicine (RMH/WH), University of Melbourne, Melbourne, Victoria, Australia, [3]Department of Medicine (RMH/WH), University of Melbourne, Melbourne, Australia, [4]Department of Medicine (RMH/WH), University of Melbourne, [5]John Hunter Hospital, Newcastle, Australia, [6]Menzies Research Institute, University of Tasmania, Hobart, Australia, [7]Monash Medical Centre, Melbourne, Australia, [8]Queen Elizabeth Hospital, Adelaide, Australia, [9]Royal Adelaide Hospital, Adelaide, Australia, [10]Royal North Shore Hospital, Sydney, Australia, [11]Royal Perth Hospital, Perth, Australia, [12]Royal Prince Alfred Hospital, Sydney, Australia, [13]St George Hospital, Sydney, Australia, [14]St Vincent's Hospital, Melbourne, Australia, [15]Sunshine Coast Rheumatology, Australia

Background: It is not established whether accelerated atherosclerosis occurs in scleroderma (SSc). Increased rates of peripheral vascular disease have been reported[1], however the prevalence of coronary heart disease (CHD) remains unknown.

Methods: We reviewed the prevalence of CHD and traditional and non-traditional cardiovascular risk factors in a well-characterized cohort of Australian SSc patients. Data were collected prospectively at 12 centres around Australia from January 2007 to May 2010 as part of a longitudinal cohort study instituted by the Australian SSc Interest Group.

Patients were identified as having CHD if they reported percutaneous coronary intervention, coronary artery bypass grafting, angina or myocardial infarction. Data from the patient's most recent review were used to obtain a cross-sectional view of the cohort.

We compared the prevalence of CHD in our cohort with Australian population prevalence estimates from the National Health Survey 2007 – 2008[2]. Chi square and two-sample *t* tests were used to analyze differences between SSc patients with and without CHD.

Results: Of the 850 SSc patients included in the analysis, 88 had CHD. The prevalence of CHD in our cohort was therefore 10.3% (95% confidence interval 8.3%–12.4%). Patient characteristics are summarized in table 1).

Table 1. Demographics and cardiovascular risk factors in SSc patients with and without CHD

	CHD present (n = 88)	CHD absent (n = 762)	p-value
	N (%) or mean ± standard deviation		
Female	68 (77.3%)	667 (87.5%)	0.009
Subclass			
- limited	65 (73.9%)	510 (66.9%)	0.21
- diffuse	21 (23.9%)	231 (30.3%)	
- sine	0	2 (0.3%)	
- not documented	2 (2.3%)	19 (2.5%)	
Mean age	67.5 ± 9.7 years	58.3 ± 12.3 years	<0.001
Hypertension	59 (67.1%)	277 (36.4%)	<0.001
Hypercholesterolaemia	42 (47.7%)	145 (19.0%)	<0.001
Diabetes mellitus	12 (13.6%)	25 (3.3%)	<0.001
Family history of heart disease*	31 (60.8%)	162 (40.1%)	0.006
Ever smoked	51 (58.6%)	354 (47.3%)	0.047
Obesity (BMI ≥ 30 kg/m^2)	22 (25%)	145 (19.0%)	0.18
Age at diagnosis of SSc	50.8 ± 15.3 years	45.3 ± 13.9 years	0.001
Duration of SSc	16.4 ± 10.8 years	12.8 ± 10.2 years	0.004
Corticosteroid use ever	45 (51.1%)	314 (41.2%)	0.08
Pulmonary arterial hypertension	27 (30.1%)	112 (14.7%)	<0.001
Interstitial lung disease	28 (31.8%)	188 (24.7%)	0.15
SSc renal crisis	3 (3.4%)	34 (4.4%)	0.65
Antiphospholipid antibodies (anticardiolipin or anti-β_2-microglobulin)	25 (32.1%)	156 (25.2%)	0.20

* Family history data missing in 37 patients with CHD and 358 without CHD

On stepwise logistic regression hypertension, diabetes, smoking, age, duration of SSc and pulmonary arterial hypertension were still significant predictors of CHD.

The prevalence of CHD in our SSc cohort compared with the general population is shown in table 2. Stratified by age, prevalence was slightly higher in SSc patients, with the difference more marked in younger patients.

Table 2. Prevalence of CHD in SSc compared to the Australian population

Age group (years)	Prevalence of CHD in SSc cohort	Estimated population prevalence of CHD
35–44	1.4%	0.7%
45–54	4.6%	2.9%
55–64	9.8%	6.8%
65–74	15.4%	12.3%
75 and over	24.7%	19.9%

Conclusion: The prevalence of CHD in SSc has not been previously reported. Our data suggests a higher prevalence of CHD in SSc patients than in the general population, particularly in those less than 55 years of age. These data need confirmation by comparison with a closely matched cohort of controls with similar methods of CHD ascertainment. Further investigation is needed to determine which SSc-specific factors contribute to the aetiology of CHD.

Pulmonary Artery Diameter Is Associated with Pulmonary Hypertension in Patients with Systemic Sclerosis (SSc). Elena Schiopu[4], Ann J. Impens[4], Barry H. Gross[3], Fazleomar Mahmood[4], James R. Seibold[1] and Kristine Phillips[2]. [1]University of Connecticut Health Center, Farmington, CT, [2]University of Michigan, Ann Arbor, MI, [3]University of Michigan, Department of Radiology, Ann Arbor, MI, [4]University of Michigan, Scleroderma Program, Ann Arbor, MI

Background: Early diagnosis of pulmonary hypertension (PH) in scleroderma remains challenging. The purpose of this study is to compare imaging and non-invasive cardio-pulmonary testing with right heart catheterization (RHC) results in patients with SSc.

Method: 141 patients with SSc seen at University of Michigan between 1998 and 2010 were retrospectively identified with a RHC, at least one set of pulmonary function tests (PFT), echocardiogram and brain natriuretic peptide (BNP) within 6 months and a chest computed tomography (CCT) within 16 months. Abstracted data include: clinical functional assessment (WHO class), forced vital capacity (FVC), diffusion capacity (DLco) and total lung capacity (TLC) (% predicted), six minute walk distance (6MWD), right ventricular systolic pressure (RVSP) and presence of right ventricular enlargement (RVE) by Doppler echocardiogram. A blinded cardio-thoracic radiologist measured the diameter of the pulmonary arteries (DPA) on the available CCTs. Student's t test, chi-square test and ANOVA were used to determine group differences.

Results: The mean (SD) age at RHC was 57.3 yrs (11.4) with mean disease duration (from time of first non-RP symptom to RHC) of 10.2 yrs (8.5). 117 (83%) patients were female, and 92 (65.2%) had limited SSc. 75 (53.2%) patients were dead at the time of analysis. One patient (0.7%) was WHO class I, 18 (12.8%) were WHO class II, 113 (80.1%) of patients were WHO class III and 9(6.4%) were WHO class IV. In our cohort, 103 (73%) subjects had ILD as evaluated by the blinded radiologist, of which 85 (60.3%) were described as non specific interstitial pneumonitis (NSIP) and 18 (12.8%) as usual interstitial pneumonitis (UIP); 30 (21.3%) subjects had no parenchymal involvement and the rest of the CCTs were not evaluable due to technique or pleural effusions. 108 (76.6%) patients had PH by RHC criteria (mPAP of > 25 mmHg at rest or > 30 mmHg with exercise and PCWP < 15 mmHg). The mean measured DPA was 3.3 (0.4) cm and the CCT techniques most often used were high resolution (75.9%) and PE protocol (17.7%). There was no difference between the mean/SD DPA in females (3.2/.4) and males (3.3/.4). The mean/SD of the body mass index (BMI) was not significantly different between the groups with PH (27.7/6) and without PH (27.6/5.5). Mean differences between the PH and non-PH groups were:

	N (%) or Mean (SD)	
	PH N 108	Non-PH N 33
Limited Scleroderma	71 (65.7)	21 (63.6)
Gender (Females)	88 (81.4)	29F (87.8)
Time to RHC (years)	10.7 (8.9)	8.7 (6.9)
WHO class*		
I	0	1 (3.0)
II	8 (7.4)	10 (30.3)
III	91 (84.2)	22 (66.6)
IV	9 (8.3)	0
Number of deaths*	67 (62)	8 (24.2)
% FVC	68.23 (20.7)	64.7 (18.8)
% DLco	34.0 (13.3)	38.72 (14.2)
%FVC/%DLco*	2.3 (1.0)	1.8 (0.7)
%TLC	79.4 (20)	72.9 (20)
RVSP*	74.2 (25.5)	43.3 (15.5)
RVE*	83 (76.8)	9 (27.2)
BNP*	588.3 (903)	132.2 (337.5)
DPA (cm)*	3.4 (.4)	3.0 (.4)
mPAP (by RHC)*	43.8 (13.4)	22.1 (10.2)
6MWD*	263.6 (122.7)	361.8 (88.4)
ILD*		
None	28 (25.9)	2 (0.6)
NSPI & UIP	73 (67.5)	30 (90.9)

*$p < 0.05$

Conclusion: The results of the RHC were comparable to the echocardiographic and the hemodynamic parameters. Both an elevated ratio of %FVC to

%DLco and elevated BNP was seen in patients with PAH/PH. CCTs are routinely performed in assessment of lung involvement in SSc. These data suggest that measurement of DPA can be an useful adjunct in identifying patients at risk of PAH and PH in SSc. Prospective studies to assess the predictive value of the non-invasive cardio-pulmonary measures in SSc-PH are in progress.

Pulmonary Hypertension Assessment and Recognition of Outcomes in Scleroderma (PHAROS): Comparison of Outcomes in Subtypes of Pulmonary Hypertension. Robyn T. Domsic[6], Lorinda Chung[3], Mardi Gomnberg-Maitland[4], Jessica K. Gordon[2], Barbara M. Segal[5], Virginia D. Steen[1] and PHAROS Investigators. [1]Gerogetown University Medical Center, Washington, DC, [2]Hospital for Special Surgery, New York, NY, [3]Stanford University Medical Center, Palo Alto, CA, [4]University of Chicago Medical Center, Chicago, IL, [5]University of Minnesota, Minneapolis, MN, [6]University of Pittsburgh, Pittsburgh, PA

Background: PHAROS is a multi-center, longitudinal study designed to assess risk factors and outcomes in patients with systemic sclerosis (SSc) who have definite pulmonary hypertension (PH), or at high risk to develop PH. This study looks at the differences in clinical features and outcomes among SSc patients with different types of PH: pulmonary arterial hypertension alone (PAH), PH associated with interstitial lung disease (PH-ILD), and those with pulmonary venous hypertension (PVH).

Methods: Patients complete questionnaires every 6 months and are seen yearly for physician evaluation. Information collected includes New York Heart Association functional classification (NYHA), vital status, six minute walk distance (6MWD), hospitalizations, pulmonary function tests and medication use. Differences among groups at baseline and in follow-up were assessed by chi-square test. We defined a worsening of 6MWD as a decline of $> 15\%$. We assessed the impact of PAH subgroup on survival using multivariate Cox proportional hazards models.

Results: Of the 151 patients with PH enrolled, 97 have PAH, 30 PH-ILD and 24 PVH. Mean age at enrollment was 58 years (SD 11.7), and 84% were female. The frequency of patients with limited cutaneous disease was higher in PAH (73%), compared to PH-ILD (47%) or PVH (50%; p=.009). The median duration since onset of Raynaud was 8.9 years (interquartile range (IQR) 4.3, 16.0), and median duration of PHAROS follow-up 1.1 years (IQR 0.5, 2.5).

There was a nonstatistically significant difference in initial drug therapy among the PH subgroups (p=0.06), as depicted in Table 1. With follow-up there was no difference in the frequency of progression to combination drug therapy between groups.

Table 1. Initial PAH-specific drug therapies for PAH subgroups (p = 0.06)

	No therapy	Endothelial receptor antagonist	Phospo-diesterase inhibitor	Prostacyclin	Combination
SSc-PAH (n = 97)	24%	26%	33%	14%	3%
SSc-ILD (n = 30)	37%	7%	37%	10%	10%
PVH (n = 24)	50%	21%	25%	0%	4%

There was no significant difference in functional status at baseline among groups. However, in patients with one or more years of follow-up (n=79), 32% of PAH patients had worsening NYHA class, compared to 29% in PH-ILD and 7% in the PVH group (p=0.02). No difference in the frequency of worsening 6MWD was found (p=0.82), with more than 65% in all groups either stable or improved.

As of last follow-up there was no significant difference in risk of death associated with PAH subgroup after adjustment for age (p=0.54). Patients with PAH had a higher frequency of all-cause hospitalizations (55%) compared to PH-ILD (30%) and PVH (44%; p=0.05).

Conclusions: Analysis of the PHAROS cohort suggests that PAH patients have a higher frequency of hospitalization than those with PVH or PH- ILD, although there is no difference in age-adjusted survival. The majority of patients in all classes are functionally stable by NYHA class and 6MWD at one year of follow-up. Although half of the patients with PVH were not treated with PH-specific therapies, their outcomes are comparable or better than PAH and PH-ILD. Longer follow-up of the PHAROS cohort will further elucidate differences between groups.

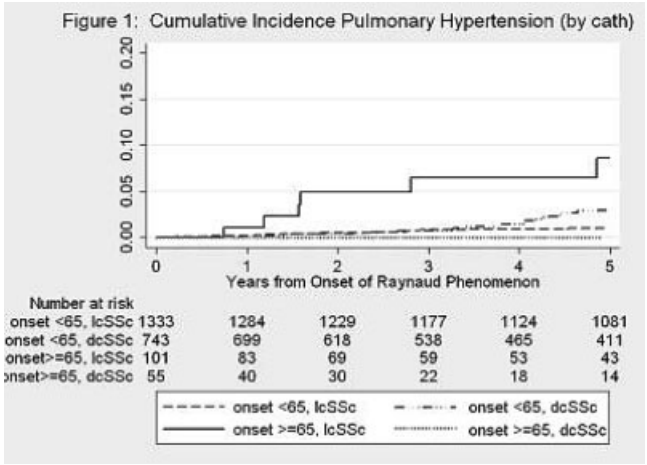
587

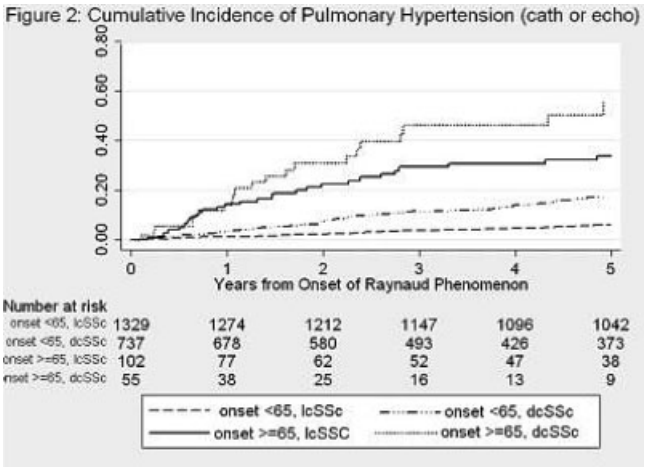
Pulmonary Hypertension by Age of Scleroderma Onset and Subtype. Rebecca L. Manno[2], Fredrick M. Wigley[1] and Laura K. Hummers[2]. [1]Johns Hopkins University, Baltimore, MD, [2]Johns Hopkins University, Baltimore, MD

Purpose: Pulmonary hypertension (PH) is a leading cause of death among scleroderma (SSc) patients. Historically, PH has been considered a late complication of SSc with predominance among those with the limited cutaneous subtype (lcSSc) and an older age of SSc onset. However, we hypothesize that the risk of PH will be the same among lcSSc and diffuse cutaneous (dcSSc) patients when SSc onset is defined at Raynaud phenomenon (RP) onset. We sought to determine the risk of pulmonary hypertension among a large cohort of SSc patients stratified by SSc skin subtype and age of disease onset.

Methods: Data were retrospectively reviewed from a comprehensive database at a University based Scleroderma Center. Patients were categorized by SSc subtype (lcSSc vs dcSSc), age of SSc onset (late-age onset $\geq$ 65years), and the presence of PH. Analyses were completed defining SSc onset in 2 ways: 1) onset of RP; 2) onset of first non-RP SSc symptom. PH was defined 2 ways: 1) mean pulmonary artery pressure $\geq$25 and pulmonary capillary wedge pressure $<$15 by right heart catheterization; 2) RVSP$\geq$40 mmHg by echocardiogram. Kaplan-Meier (KM) failure curves were generated to determine the cumulative incidence of PH. Cox proportional hazard models were generated to determine the risk of PH controlling for age of SSc onset, subtype, gender, race, and FVC. Sensitivity analyses were conducted excluding patients with FVC$<$60.

Results: 2282 patients were included in our analyses. With SSc onset defined by RP onset, 162 had late-age SSc onset (64% lcSSc, 32% +anti-centromere); 2118 had younger-age SSc onset (64% lcSSc, 28% +anti-centromere). Figure 1 depicts KM for PH by cath and figure 2 by cath or echo.





The risk of developing PH (by cath) was significantly greater (HR 4.49; 95% CI 2.22, 9.05) for those with SSc onset ≥65 years compared to younger-age onset. The risk of PH did not differ by SSc subtype (HR 1.19; 95% CI 0.82, 1.73). Sensitivity analyses excluding patients with FVC<60 yielded comparable results (late-age SSc HR 4.83; 95% CI 1.86, 13.41; dcSSc HR 1.46; 95% CI 0.88, 2.42). With SSc onset defined by first non-RP symptom, similar results were obtained results (late-age SSc HR 4.42; 95% CI 2.56, 7.63; dcSSc HR 0.96; 95% CI 0.66, 1.38).

Conclusions: Age of SSc onset impacts the risk of PH but SSc subtype does not. These data suggest benefit for routine screening for PH among all cutaneous SSc subtypes, especially those with late-age onset of disease.

Disclosure: R. L. Manno: None; **F. M. Wigley:** None; **L. K. Hummers:** None.

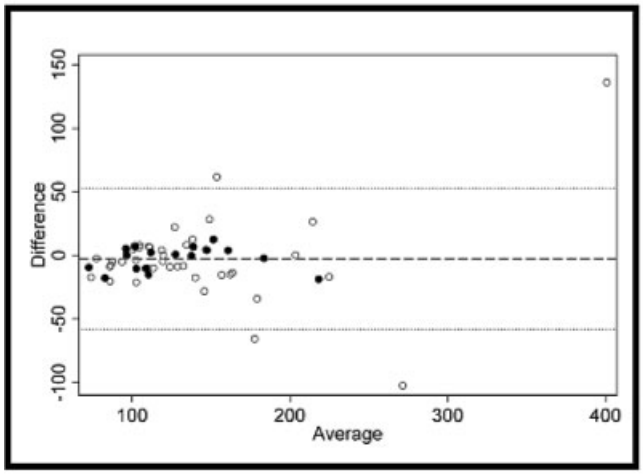
Reproducibility of Semi-Automated Quantitative Nailfold Capillaroscopy Measurements in Patients with Systemic Sclerosis. Andrea K. Murray[4], Tonia L. Moore[4], Andy Vail[1], Joanne Manning[2] and Ariane L. Herrick[3]. [1]Rheumatology Directorate, HealthMethodology Research Group, Manchester Academic Health ScienceCentre, The University of Manchester, Salford Royal Hospital, Salford, UK, [2]Salford Royal NHSFoundation Trust, Salford, [3]The University of Manchester, Manchester Academic Health Science Centre, Manchester, Salford Royal Hospital, Salford, Greater Manchester, United Kingdom, [4]The University of Manchester, Manchester Academic Health Science Centre, Manchester, Salford Royal Hospital, UK

Background: High magnification nailfold videocapillaroscopy allows measurement of capillary density and dimensions and therefore has the potential of being a non-invasive biomarker for systemic sclerosis (SSc)-related microvascular disease. However, quantifying abnormality brings enormous challenges: (a) in SSc, capillaries across any one nailbed are highly heterogeneous (many have very abnormal architecture) (b) measurement is subjective (c) current measurement methods are very time-consuming meaning that in practice only a small number of capillaries in any one nailfold are selected for study and these may be unrepresentative of the whole nailfold. Newly developed software allows rapid semi-automated quantification of capillary density and dimensions over the whole nailbed with results comparable to manual measurements. While this is likely to be a major advance, the system requires user input to identify and 'mark-up' the apex of each capillary in the image. This study aimed to assess the intra-and inter-observer variability and test-retest reliability.

Methods: Two nailfold images were taken from 60 patients with SSc over two visits. Two blinded observers familiar with capillaroscopy cropped image 1 independently to a standard size of 3 mm and then marked-up capillaries in order to assess inter-observer variability. One of the blinded observers then performed a repeat crop/mark-up on image 1 to assess intra-observer variability and crop/mark-up on image 2 to assess test-retest reliability.

Results: Reproducibility of independently cropped images was poor. Further investigation revealed that this was due to positioning of the cropped area. When images were categorised according to the amount of cropped area overlap, those with a high degree of overlap had statistically significantly improved reproducibility (example of Bland Altman plot shown in Figure below, solid circles representing high degree of overlap).



Conclusions: This study demonstrates the heterogeneity of nailfold architecture in patients with SSc and the importance of ensuring that quantitative measurements of nailfold capillaries are carried out on the same microvessels in longitudinal studies. The novel ability to make measurements across the whole bed and to compare current and previous visits is a significant advantage, as this ensures the same capillaries are measured at each visit. This fast, reliable method of quantifying microvascular disease could be a reliable outcome measure in future longitudinal studies including those of treatment response.

589

Risk Associated with African American Race in Relation to Prevalence of Cardinal Organ System Manifestations in Scleroderma. Elizabeth N. Le[3], Rebecca L. Manno[3], Laura K. Hummers[3], Fredrick M. Wigley[2] and Allan C. Gelber[1]. [1]Baltimore, MD, [2]Johns Hopkins University, Baltimore, MD, [3]Johns Hopkins University, Baltimore, MD

Purpose: Scleroderma is a severe multisystem rheumatic disorder with a broad spectrum of organ involvement. There are several known risk factors for particular organ system manifestations, including the cutaneous subset of disease (limited vs. diffuse) and age at disease onset. Whereas race has been related to risk for interstitial lung disease and diffuse cutaneous disease, there are few systematic examinations of race in relation to risk for each cardinal organ manifestation of scleroderma.

Method: A prospective clinical database was begun at a single university scleroderma referral center in 1990. Each patient satisfied at least one of the following three diagnostic criteria: (1) the ACR criteria for scleroderma; (2) 3 of 5 features of the CREST syndrome; or (3) a combination of definite Raynaud's phenomenon, abnormal nailfold capillaries and a scleroderma-specific autoantibody. Demographic data including age, sex, and race, together with cutaneous subtype (based on Leroy classification criteria), and smoking status were uniformly ascertained. Disease duration, from disease onset, at age of the first non-Raynaud's symptom, to evaluation at the Scleroderma Center was determined. Clinical data, including organ system involvement, were recorded using a uniform protocol at cohort entry, and updated every six months when available. The outcomes of interest were the Medsger severity scores [(MSS); J Rheumatol 1999;26:2159], determined for each cardinal organ system involved in scleroderma. The association of African American in comparison to Caucasian race with the MSS parameters were examined using logistic regression analysis, with adjustment for potential confounding by age at disease onset, sex, disease subtype, disease duration and smoking status (for pulmonary outcome).

Results: Between January, 1990 and June, 2009, a total of 2481 patients with scleroderma were enrolled. Overall, mean age at disease onset was 45.5 years. 63% of patients manifested the limited cutaneous subset; half were ever-smokers. In terms of the various MSS outcomes, the overall proportion with digital ischemia (score≥2) was 55%; for lung MSS ≥1 was 77%; heart MSS ≥1 25%; kidney MSS ≥1 18%; gastrointestinal MSS ≥2 40%; and

muscle MSS ≥1 was 24%. Importantly, in multivariate analysis, compared to the Caucasian members of the cohort, the African American members had a 50% increase in peripheral vascular disease, a >6-fold increase in lung involvement, 60% increase in heart, 70% increase in risk of kidney involvement, a 70% increase in gastrointestinal, and 90% increase in risk of muscle weakness.

MSS	Univariate OR	95% CI	Multivariate OR	95% CI
Peripheral Vascular	1.7	1.3–2.1	1.5	1.2–2.0
Lung	5.6	3.6–8.9	6.1	3.8–9.9
Heart	1.2	0.9–1.6	1.6	1.2–2.2
Kidney	1.4	1.1–1.9	1.7	1.2–2.2
Gastrointestinal tract	1.4	1.1–1.9	1.7	1.2–2.2
Muscle	2.0	1.5–2.6	1.9	1.4–2.4

Conclusion: These data imply that among patients presenting in rheumatology consultation for the evaluation and management of scleroderma, that African Americans are at notably increased risk to develop the full range of cardinal organ system features of disease.

Disclosure: E. N. Le: None; **R. L. Manno:** None; **L. K. Hummers:** None; **F. M. Wigley:** None; **A. C. Gelber:** None.

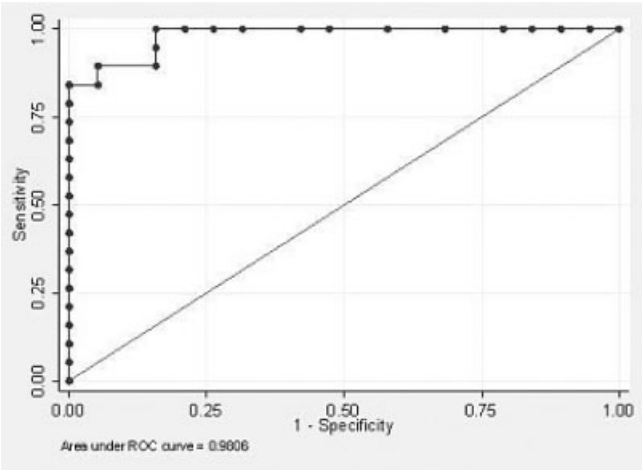
Role of N-Terminal Pro-BNP in Detecting Clinically-Significant Cardiac Involvement in Systemic Sclerosis Patients. Cecilia Chighizola[3], Benjamin Schreiber[2], Pier Luigi Meroni[3], Gerry Coghlan[1], Christopher P. Denton[4] and Voon Ong[1]. [1]Center for Rheumatology and Connective Tissue Diseases, UCL Medical School, Royal Free Hospital, London, United Kingdom, [2]Center for Rheumatology and Connective Tissue Diseases, UCL Medical School, Royal Free Hospital, London, 0', [3]Rheumatology Division, Department of Internal Medicine, Istituto G. Pini, University of Milan, Milan, Italy, [4]Royal Free Hospital, London, United Kingdom

Background: Cardiac involvement is common in Systemic Sclerosis (SSc) and is often clinically occult. However, it is recognised as a poor prognostic factor contributing significantly to mortality among these patients. Early detection of cardiac disease with non-invasive tools is therefore critical.

Aim: To assess the role of N-TproBNP in SSc related cardiac involvement in a retrospective cohort of patients.

Methods: 19 SSc patients (13 dcSSc and 6 lcSSc) patients with cardiac involvement were enrolled in this study. Cardiac involvement was defined as haemodynamically significant arrhythmias, pericardial effusion or congestive heart failure, requiring specific treatment. All patients had normal pulmonary artery systolic pressure and none had serum creatinine above 140 mmol/l. This group of patients was compared with 19 age- and sex-matched SSc patients without evidence of cardiac involvement or pulmonary arterial hypertension. Serum N-TproBNP levels were measured with the Roche Modular Analytics E-170 (Eleccys module) immunoassay. Normal N-TproBNP levels were less than 20 pmol/l. Unpaired t-test was used to compare N-TproBNP values between subgroups based upon presence of cardiac involvement. ROC curves were drawn to identify N-TproBNP levels which gave optimal sensitivity and specificity for diagnosis of SSc-related cardiac involvement. N-TproBNP levels were compared at presentation of cardiac involvement and at six month follow up using a paired t-test. Univariate mortality analysis was performed with Kaplan-Meier method, the level of significance of the differences among survival curves was assessed by Log-rank test

Results: Compared to those without cardiac involvement, N-TproBNP was significantly increased in SSc patients with heart involvement (mean±SD 14.9±14.5 pmol/l versus 1043±2053 pmol/l respectively, p=0.037; 95%CI 67,1989). Figure 1 shows a ROC curve of N-TproBNP that predicts the presence of heart involvement in SSc. A sensitivity of 100% was achieved at a cut-off N-TproBNP level of 28 pg/mL, with a specificity of 84% (95% CI 0.95–1). Moreover, a significant progressive reduction in N-TproBNP after the acute phase of cardiac involvement (mean±SD 301±330 pmol/l) was observed during 6 months follow-up (mean±SD 87±113 pmol/l; p=0.048, 95%CI 2.8,425). In addition, within the group with cardiac involvement, N-TproBNP levels were categorized as high if above the median value of 219 pmol/l; however, higher levels of N-TproBNP did not predict survival (p=0.959, at Log rank analysis).



Conclusions: These data suggest that N-TproBNP peptide may be a surrogate marker for cardiac involvement in SSc. It may selectively identify those patients with severe impairment of cardiac function. Further studies are required to evaluate the utility of N-TproBNP levels for cardiac assessment in SSc patients.

Scleroderma Autoantibodies and Disease Subtype Predict Pulmonary Hypertension Classification in the PHAROS Registry. Monique E. Hinchcliff[5], Aryeh Fischer[4], Nadera Sweiss[6], Maureen Mayes[7], Marcy Bolster[3], Virginia Steen[1] and PHAROS Investigators[2]. [1]Georgetown University, [2]Gerogetwon University, [3]Medical University of South Carolina, [4]National Jewish Health, [5]Northwestern University, [6]University of Chicago, [7]University of Texas-Houston Medical School

Background and Purpose: Pulmonary Hypertension Assessment and Recognition of Outcomes in Scleroderma (SSc), PHAROS, is a multi-center, prospective, observational study of SSc patients who are at high risk for pulmonary arterial hypertension (PAH) or who have definite pulmonary hypertension (PH) by right-heart catheterization (RHC). We sought to describe the relationship and predictive value of SSc-specific autoantibodies for pre-PAH and World Health Organization (WHO) PH classification: group 1 (PAH), 2 (pulmonary venous hypertension, PVH) and 3 (PH attributed to interstitial lung disease PH-ILD).

Methods: SSc patients with echo RVSP > 40mmHg, FVC/DLCO>1.6, FVC < 55% (Pre-PAH) or definite PH by RHC are enrolled in PHAROS. Objective (PFT, echo, and the presence of autoantibodies (ab) including anticentromere (ACA), anti-topoisomerase (Scl-70), an isolated nucleolar pattern on ANA testing (NUC), anti U1-RNP (U1RNP), RNA polymerase III (Pol III) and others) and clinical data (disease subtype, limited SSc (lcSSc) and diffuse SSc (dcSSc) according to the LeRoy criteria) are collected. Patients with mean pulmonary pressure (mPAP) ≥25 mmHg on RHC were classified according to WHO PH criteria. Statistical analyses were conducted using SPSS (Chicago, IL) and Bonferroni correction was used for multiple pair-wise comparisons.

Results: The majority of patients have lcSSc (65% l, 31% d, 4% other). Ab data were available on 322 of the 383 PHAROS patients. Patients with an isolated NUC ab were over represented in this registry compared to the usual scleroderma population and were more frequently entered as definite PH (groups 1–3) as opposed to Pre-PAH (p≤0.001). ACA and NUC patients more frequently had PAH compared to the Scl-70 patients who more frequently had PH-ILD. Patients with lcSSc and a positive NUC ab were more likely to have PAH (p=0.033). Patients with dcSSc and a positive Scl-70 had PH-ILD more commonly (p=0.025).

Conclusion: PHAROS is a multi-institutional registry that continues to provide insights into SSc-PH. Among this national SSc cohort of patients at high risk or with definite PH, we have shown that both SSc clinical phenotype and autoantibody profile predict WHO PH classification. Although less common in SSc in general, an isolated NUC ab is common in PH patients. Diffuse patients with a positive Scl-70 ab are less likely to have PAH and

more likely to have PH-ILD. In contrast, patients with lcSSc and a positive NUC ab are more likely to have PAH.

Clinical Implications: Scleroderma autoantibodies and disease subtype may be helpful in identifying patients who are more likely to have PAH or PH-ILD.

Antibody N (%)	All = 322	Pre-PAH	WHO 1 (PAH)	WHO 2 (PVH)	WHO 3 (PH)
ACA	86 (23)	51 (22)	27 (28)	6 (27)	2 (7)
Scl-70	52 (14)	35 (15)*	6 (6)*	2 (9)*	9 (30)*
Nuc	66 (20)	28 (12)*	29 (30)*	6 (27)*	3 (10)*
U1 RNP	21 (7)	13 (6)	8 (8)	0	0
Pol III	6 (2)	2 (1)	3 (3)	1 (5)	0
Other ANA	70 (22)	42 (18)	13 (14)	4 (18)	8 (27)

Scleroderma Lung Disease: Effect of Co-Existent Pulmonary Hypertension on Progression of Interstitial Lung Disease. Anupama Shahane, Joseph Parambil, Meng Xu and Soumya Chatterjee. Cleveland Clinic

Background: Pulmonary involvement is the leading cause of mortality in systemic sclerosis. The two most commonly seen patterns of lung disease, interstitial lung disease (ILD) and pulmonary hypertension (PH) often co-exist, with worse outcomes than either ILD or PH alone. We retrospectively studied patients with scleroderma lung disease to evaluate the effect of co-existent PH on progression of ILD.

Methods: Patients were identified from the Cleveland Clinic scleroderma database and the pulmonary hypertension database. Patients satisfied the ACR criteria for systemic sclerosis; pulmonary function tests and thoracic high resolution CT scans were used to identify ILD. PH was diagnosed on the basis of right heart catheterization. We described two cohorts of scleroderma patients: scleroderma with ILD alone (SSc-ILD) and scleroderma with both ILD and PH (SSc-ILD/PH). We further divided patients with ILD into limited and extensive disease based on extent of lung involvement on HRCT (Goh *et al*, Respir Crit Care Med, 2008). Disease progression was measured in terms of longitudinal values of forced vital capacity (FVC) and carbon monoxide diffusion capacity (DLco). We collected annual data for 6 years. Chi square or Fisher's exact test was used for comparison of categorical variables, and Wilcoxon rank sum test was used for continuous variables. Mixed model was used for longitudinal measures of FVC and DLco.

Results: We identified 86 patients with SSc-ILD (55 limited, 31 extensive) and 47 patients with SSc-ILD/PH (27 limited, 20 extensive). In our cohort, all subtypes of lung disease were more prevalent in females and Caucasians. Average duration of lung disease since time of diagnosis of scleroderma was 4 years (3.7–4.3 years). Significant difference was not noted in progression of patients with SSc-ILD in comparison with patients with SSc-ILD/PH ($p = 0.42$). Patients with limited ILD showed a trend towards faster disease progression in the presence of PH, but this was not noted in patients with extensive ILD ($p = 0.054$). Patients with extensive ILD had lower FVC and DLco at baseline and showed faster rate of progression ($p < 0.001$). Patients with SSc-ILD/PH had significantly faster decline in DLco compared to patients with SSc-ILD, in patients with both limited as well as extensive lung disease ($p < 0.001$). Moreover, extensive ILD was associated with faster rate of disease progression than limited ILD, irrespective of presence of PH ($p < 0.001$).

Conclusions: Our study showed that limited (but not extensive) ILD is likely to progress faster in the presence of PH. Also, patients with SSc-ILD/PH have faster rate of decline in DLco compared to patients with SSc-ILD. Lung disease is not only worse in extensive ILD patients but also progresses faster when compared to those with limited ILD, regardless of co-existent PH.

Sildenafil Increases Vasodilation in Systemic Sclerosis: An Interim Analysis from a Single Centre Pilot Study. Silvia Bellando-Randone, Irene Miniati, Serena Guiducci, Maria Letizia Conforti, Jelena Blagojevic, Ginevra Fiori, Francesca Bartoli, Francesca Nacci and Marco Matucci-Cerinic. Department of Biomedicine Section of Rheumatology University of Florence, Italy

Background: Vasculopathy is an early and prominent feature in systemic sclerosis (SSc) and it is reflected by Raynaud's Phenomenon (RP) and digital ulcers. Reduced nitric oxide levels have been proposed to play a role in the pathogenesis of vascular disease in scleroderma. Sildenafil represents an attractive candidate for the treatment of SSc-associated vasculopathy as a selective inhibitor of cGMP-specific phosphodiesterase type 5 and potent agent to increase the endogenous NO levels.

Objective: In this pilot study, the effect of sildenafil on RP was analysed. Primary outcome was the improvement of RP and changes in other clinical symptoms. This an interim analysis after 3 months of treatment.

Methods: Fourtyfive SSc patients were randomized in 3 groups: 15 treated with maximally tolerated sildenafil dose (20 mg three times daily), 15 with combination therapy (sildenafil and prostanoids i.v.) and 15 with prostanoids i.v. Symptoms were assessed by diary cards including a 10-point Raynaud's Condition Score, SF-36 and sHAQ: videocapillaroscopy was performed in all patients at baseline and every 3 months. Results were analysed with ANOVA using Bonferroni correction.

Results: After 3 months there was a statistically significant difference between the 3 groups for RCS ($p=0.03$). No significant differences were found for SF36 (all domains) and SHAQ. NVC pattern was unmodified in all patients.

Four patients (three treated with sildenafil, one with combination therapy) reported side effects leading to discontinuation of the study drug. Two patients on prostanoids and 1 patient on SILDENAFIL were switched to a combination therapy due to inefficacy.

Conclusion: s: This study indicates that sildenafil improves RP and associated symptoms and is a well-tolerated treatment in SSc patients. Long term results are necessary to confirm these results and investigate the effect on other outcome measures

Subclinical Atherosclerosis Is Increased in Systemic Sclerosis—A Case-Control Study. Karen M. Au[1], Maureen A. McMahon[1], Daniel E. Furst[3], Bevra H. Hahn[4], Nagesh Ragavendra[1], Amber Bechtel[1], Lori Sahakian[1] and Dinesh Khanna[2]. [1]UCLA School of Medicine, Los Angeles, CA, [2]University of California Los Angeles, Los Angeles, CA, [3]University of California Los Angeles Medical School, Los Angeles, CA, [4]University of California Los Angeles School of Medicine, Los Angeles, CA

Objective: Systemic sclerosis (SSc) is associated with vasculopathy and endothelial cell injury, which could potentially increase the risk of atherosclerosis. Carotid artery ultrasound can detect subclinical atherosclerosis by measuring carotid intima-media thickness (IMT) and presence of carotid plaque. Studies have suggested that IMT is elevated in SSc, but there is little evidence that plaque is more prevalent in SSc compared to healthy patients.

Normal high-density lipoprotein (HDL) is anti-inflammatory and prevents low-density lipoprotein (LDL) oxidation. While HDL is protective, an altered form known as pro-inflammatory high-density lipoprotein (piHDL) may increase atherosclerotic risk and may actually potentiate LDL oxidation. Serum piHDL is a novel marker of atherosclerotic risk in lupus and rheumatoid arthritis. The objective of the study was to determine 1) the prevalence of subclinical atherosclerosis (carotid plaque and IMT measurement) in SSc and 2) serum piHDL levels as a potential novel marker of atherosclerotic risk in SSc.

Methods: A cross-sectional study of 32 patients with SSc and 32 age-, sex-, and race-matched healthy controls in a single center was conducted. All subjects received bilateral carotid ultrasounds measuring plaque and IMT and were read by a single reader (NR) who was blinded to the diagnosis. Cholesterol studies and a cell free assay to measure presence of piHDL were performed.

Results: The average age of the patients was 48 (mean age SSc 48, controls 47) and included 15 limited SSc and 17 diffuse SSc subjects. Total cholesterol ($P=0.20$) and LDL ($P=0.13$) were similar between SSc and controls. SSc patients had lower HDL (SSc 54.2 vs. controls 63.4, $P=0.01$) and higher triglycerides compared to controls (142.3 vs. 110.1, $P=0.02$). Carotid plaque was significantly more prevalent in SSc patients compared to controls (14 SSc patients vs. 7 controls; $P = 0.043$). Presence of carotid plaque was equally distributed among limited and diffuse SSc patients (9 limited, 8 diffuse). Average IMT was higher in patients with SSc than controls (0.582 ± 0.11 vs. 0.557 ± 0.14; $P = 0.059$). SSc patients had similar rates of piHDL compared to controls (SSc 21.4%, controls 25%). piHDL was not

associated with plaque ($P=0.65$) nor with average IMT ($P=0.10$) in our SSc cohort.

Conclusion: Prevalence of subclinical atherosclerosis is greater in patients with SSc compared with healthy controls. This preliminary data suggests that pro-inflammatory HDL is not a marker of atherosclerosis in SSc.

Symptom Burden, Quality of Life and Attitudes toward Palliative Care in Patients with Pulmonary Hypertension with and without Systemic Sclerosis. Nicole M. Orzechowski[1], Keith M. Swetz[2], Tait D. Shanafelt[3], Jeff A. Sloan[3], Paul J. Novotny[3], Robert P. Frantz[3] and Michael D. McGoon[3]. [1]Dartmouth Hitchcock Med Center, Lebanon, NH, [2]Mayo Clinic, Rochester, MN, [3]Mayo Clinic

Background: Systemic Sclerosis (SSc) is a potentially devastating connective tissue disorder affecting multiple organ systems. Pulmonary hypertension (PH) can be a serious and life threatening complication of SSc. Little is known about health related quality of life (QOL) and the use of palliative care (PC) in patients with this complication. We sought to examine symptom burden, QOL and attitudes regarding PC in a large international sample of PH patients with and without SSc.

Methods: Patient members of four Pulmonary Hypertension Association listservs were sent an internet-based survey by email. Symptom burden and QOL were assessed using a standardized QOL assessment tool including the Linear Analog Self-Assessment (LASA) and the Cambridge Pulmonary Hypertension Outcome Review (CAMPHOR). Surveys were administered anonymously by a third party and the investigators were blinded to the identity of the respondents. PH patients with and without SSc were compared to assess any potential differences.

Results: Out of a total of 276 unique patient responses, 45 had PH associated with SSc. Primary PH accounted for 117, other lung disease 18, left heart failure 12, another condition 51, and uncertain 33. Patients with SSc were older both at the time of this survey and at the time of PH diagnosis ($p=0.0014$ and $p=<0.001$). Responders in both groups were predominantly female and Caucasian. Approximately 40% of patients in each group had LASA scores ≤ 5 which is considered profoundly low and clinically significant. Substantial numbers in both groups reported LASA scores≤ 5 for the physical well being, emotional well being, social activity, pain frequency, pain severity and fatigue components. Mean CAMPHOR score for total symptoms was near the 50th percentile for each group. Despite high symptom scores, no SSc patients and only four patients in the non-SSc group had a palliative care (PC) physician involved in their care. Reasons for this included confusion between PC and hospice, the misperception that medications would have to be stopped and patients' perceptions that they were not sick enough for PC. A minority of patients in each group completed a living will or discussed advanced care planning with their physician.

	Systemic Sclerosis N = 45	Others N = 231	p-value
Mean Age (years ± SD)	56.1 ± 13	47.5 ± 16	0.0014
Mean Age at PH Diagnosis (years ± SD)	52.2 ± 13	42.5 ± 17	<0.001
Female	41 (91.1)	194 (85.5)	0.31
Caucasian	42 (93.3)	192 (83.1)	0.08
LASA overall QOL ≤5	17 (37.8)	93 (40.3)	0.75
LASA Physical Well Being ≤5	29 (64.4)	125 (54.6)	0.22
LASA Emotional Well Being ≤5	16 (35.6)	94 (40.9)	0.50
LASA Social Activity ≤5	20 (45.5)	114 (49.8)	0.59
LASA Pain Frequency ≤5	30 (66.7)	138 (61.1)	0.47
LASA Pain Severity ≤ 5	31 (72.1)	159 (69.4)	0.72
LASA Fatigue ≤5	19 (42.2)	101 (43.7)	0.85
CAMPHOR total symptoms 0–25: High worse (SD)	11.5 (6.4)	12.7 (7.1)	0.26
Palliative Medicine MD involved in PH care	0	4 (1.7)	0.3739
Completed Living Will	18 (40)	75 (32.5)	0.3281
MD discussed advanced care	3 (20)	31 (31.3)	0.3721

All values are numbers (%) unless otherwise specified

Conclusions: A substantial proportion of PH patients with SSc have profound reduction in QOL, but they are no worse than patients with PH from other causes. Despite high symptom burden from PH, the use of PC was low, possibly due to patient or caregiver misperceptions. The integration of PC into the management of SSc patients with PH may provide an opportunity to improve QOL and requires further examination.

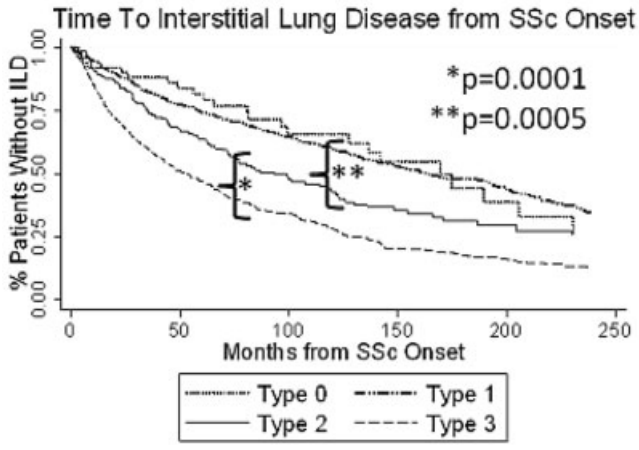
The Degree of Skin Involvement Predicts Distinct Interstitial Lung Disease Outcomes in Systemic Sclerosis. Tricia R. Cottrell, Fredrick Wigley, Robert Wise and Francesco Boin. Johns Hopkins University, Baltimore, MD

Purpose: Systemic sclerosis (SSc) is conventionally classified into limited and diffuse based on the extent of skin fibrosis. While this classification has some clinical utility and facilitates compatibility among patient groups for research purposes, the cutaneous involvement in SSc is heterogeneous and more specific skin subsets may be associated with unique clinical outcomes. In this study, we analyzed longitudinal data from a large cohort of well-characterized SSc patients to determine whether specific SSc skin subtypes can be associated with the development and severity of interstitial lung disease (ILD).

Methods: A retrospective analysis was conducted on a longitudinal cohort of 2054 SSc patients seen at the Johns Hopkins University Scleroderma Center between 1976 and 2010. Based on the maximum extent of skin fibrosis, 4 SSc subsets of patients were identified: Type 0 if no cutaneous sclerosis (sine scleroderma) was present; Type 1 if sclerosis was distal to the metacarpophalangeal joints with or without involvement of the face; Type 2 if skin changes were distal to the elbows or knees; Type 3 if sclerosis extended proximally to the elbows or knees. The primary outcomes were the presence of interstitial lung disease (ILD) defined as a forced vital capacity (FVC) < 80% of predicted with no evidence of obstructive lung disease, and time from disease onset (1st non-Raynaud's symptom) to development of ILD. Chi squared test and analysis of variance were used to compare cumulative frequency and severity of ILD, while Kaplan-Meier method, log-rank test and Cox proportional hazard ratio were used to compare ILD-free survival curves from SSc onset and to estimate the probability of developing ILD in the different disease subsets.

Results: The proportion of patients diagnosed with ILD significantly increased from type 0 to type 3 SSc subtypes ($p<0.0001$), while the average minimum FVC decreased ($p<0.0001$). Analysis of ILD free survival curves showed that over time, a greater extent of skin fibrosis was associated with a higher risk of developing ILD.



In particular, patients with type 2 SSc exhibited a distinct risk of ILD development (vs. Type 1 $p = 0.0005$; vs. Type 3 $p=0.0001$). This difference was supported also by the Cox proportional hazard ratio analysis demonstrating a significantly increased hazard of developing ILD for type 2 patients relative to type 1 (HR 1.5 [1.2–1.9], $p<0.001$), which was even higher for type 3 patients relative to type 1 (HR 2 [1.8–2.4], $p<0.001$).

Conclusions: The degree of skin involvement is predictive of different outcomes in SSc-ILD. In particular, SSc patients with an intermediate level of skin fibrosis (type 2), who normally are classified into the limited SSc group, exhibit a distinct risk profile for lung involvement and therefore their identification and characterization may be relevant in term of prognosis and proper clinical management.

The Effect of Gastric Acid Suppression with Esomeprazole on Treprostinil Diethanolamine Pharmacokinetics in Healthy Volunteers. Kristan Rollins[2], Susan Walker[2], Jennifer Kates[2], Kevin Laliberte[2] and Allison Lim[1]. [1]United Therapetutics, Research Triangle Park, NC, [2]United Therapeutics

Background: Treprostinil diethanolamine (TRE) is a prostacyclin analog currently being evaluated as a sustained release osmotic tablet for the treatment of digital ulcers in patients with systemic sclerosis (SSc). Esophageal manifestations of SSc are common requiring many patients to utilize acid suppressing therapies such as proton pump inhibitors (PPI). The use of acid suppressing therapies may alter the pharmacokinetics of concomitantly administered oral therapies via alterations in drug dissolution, absorption and metabolism. This study assessed the effect of steady-state esomeprazole induced gastric acid suppression on the pharmacokinetics of TRE.

Methods: This was a 9-day, single-center, open-label, single sequence study in which healthy volunteers were given a single dose of TRE SR 1 mg prior to and following repeated once daily oral dosing of esomeprazole 40 mg capsules over 7 days (Days 3–9). A single 1 mg oral dose of TRE was administered immediately following a 500 calorie meal on Days 1 and 8. Eighteen blood samples were obtained over 36 hours following each TRE dose. Plasma concentrations of treprostinil were quantified by liquid chromatography/mass spectrometry. Safety was assessed via adverse event reporting, clinical laboratories, physical exams, and ECGs.

Results: Fifteen male and fifteen female healthy volunteers with a mean age of 34 years (range 20–55 years) were enrolled. Concomitant administration of TRE and esomeprazole (test) following repeated esomeprazole dosing resulted in equivalent treprostinil exposure (Cmax and AUC) as compared to TRE dosing alone (reference) as described in Table 1. The most commonly reported adverse events included headache (8 subjects), flushing (2 subjects) and dizziness (2 subjects). There were no clinically significant treatment emergent changes in clinical laboratories, ECGs or vital signs.

Table 1. Preliminary Treprostinil Pharmacokinetic Parameters

Parameter	Least Squares Geometric Means		Ratio of Geometric Mean (Test/ Reference)	90% Confidence Interval
	Reference	Test		
C_{max} (ng/mL)	0.84	0.84	1.00	(0.85, 1.17)
AUC_{inf} (ng*hr/mL)	4.01	3.80	0.95	(0.87, 1.04)
AUC_{last} (ng*hr/mL)	3.93	3.79	0.96	(0.89, 1.05)

Conclusions: Esomeprazole-induced gastric acid suppression had no impact on single dose TRE pharmacokinetics in healthy volunteers.

The Pulmonary Arterial Hypertension Quality Enhancement Research Initiative (PAH-QuERI): Comparing Baseline Characteristics, Management and Survival in Patients with Idiopathic PAH (IPAH) to Patients with Systemic Sclerosis Related PAH (SSc-PAH). Philip J. Clements[2], Amparo Casanova[1], Tan Mary[1], Channick Richard[4], Valerie McLaughlin[6], Ron Oudiz[2], Lew Rubin[5], Tapson Victor[3] and Langer Anatoly[1]. [1]Canadian Heart Research Center, [2]David Geffen School of Medicine at UCLA, [3]Duke University Medical Center, Durham, NC, [4]Massachusetts General Hospital, [5]University of California at San Diego, [6]University of Michigan Health System

Purpose: To compare the baseline characteristics, management, and survival in patients with IPAH to patients with SSc-PAH in the prospectively-enrolled PAH-QuERI registry.

Methods: Between October 2005 and June 2007, physicians at 62 US specialist practices enrolled patients into the registry, entering diagnostic work-up, management and outcome data into an electronic data management system. Automatic queries were generated at each of the prescheduled follow-up visits if the tests recommended by American College of Chest Physicians' guidelines (2007) were not performed at least once.

Results: 287patients with IPAH and 253 with SSc-PAH were entered and followed for one year. At baseline, most of the clinical and laboratory characteristics of the two groups were similar, with only those listed in the table being judged clinically important and statistically different enough to warrant discussion. A few other variables (BMI, heart rate, hemoglobin) were statistically different but the differences were not deemed clinically important.

Both groups were composed largely of middle-aged (57 y/o) Caucasian women (see table). The patients with SSc-PAH were older at the time of PAH diagnosis (56 vs 53 y/o), were more likely to be ANA positive, had lower %DLCO, and more frequently had %FVC/%DLCO ratios $>$ 1.4 and/or DLCO $<$ 55%. The SSc-PAH patients were also more likely to have elevated BNP, shorter 6-minute walk distances (6-MWD), and lower mean pulmonary artery pressures (mPAP) and pulmonary vascular resistance (PVR) than patients with IPAH.

Table. Clinically interesting and statistically significant differences in variables at baseline between IPAH and SSc-PAH and in survival at 12 months

Baseline Variables	IPAH	SSc-PAH	p-value
Age of PAH diagnosis (years old)	53	56	0.001
Sex (% females)	77%	90%	<0.001
Abnormal ANA (%)	25%	85%	<0.001
%DLCO	62	44	<0.001
%FVC/%DLCO ratio >1.4 (median values)	34	67	<0.001
DLCO <55% (%)	35%	70%	<0.001
Abnormal BNP (>140 pg/ml) (%)	51%	64%	0.03
6-minute walk distance (6-MWD in meters)	356	305	0.001
Mean pulmonary artery pressure (mPAP in mm Hg)	48	40	<0.001
Pulmonary vascular resistance (PVR in Woods units)	8.95	7.01	0.02
Survival			
Mortality rate at one year (% death)	7%	17%	<0.001

During the one year follow-up period, both groups were managed with prostacyclin derivatives, endothelin-receptor antagonists (ERA) and/or phosphodiesterase-type-5 inhibitors (PDE-5i), singly or in combinations. There were minimal differences in how these drugs were administered over the year of follow-up, with these exceptions: SSc-PAH patients were more likely than IPAH patients to be treated with PDE-5i agents alone or with the combination of ERA and PDE-5i agents.

At 12 months, the mortality rate of the SSc-PAH patients (17%) was significantly greater than that of the IPAH patients (7%, $p < 0.001$).

Conclusion: In conclusion: 1) In this prospective registry of IPAH and SSc-PAH patients, the SSc-PAH patients at baseline were more likely to be older and female and to have lower %DLCO and more often had %FVC/%DLCO ratios $>$ 1.4 and DLCO $<$55%. Although they had better hemodynamics (lower mPAP and lower PVR), they were frequently "sicker" (elevated BNP and shorter 6-MWD). 2) patients with SSc-PAH were more likely to be managed with PDE5i alone or in combination with an ERA than IPAH patients. 3) Survival at one year was significantly lower in the SSc-PAH group than the IPAH group.

Goethe University, Frankfurt, Germany, [11]German Rheumatism Research Centre, Berlin, Germany, [12]Hannover Medical School, Department of Pneumology, Hannover, Germany, [13]Institute for Clinical Pharmacology, Medical Faculty, Technical University, Dresden, Germany, [14]Pediatric Rheumatology Clinic, General Hospital Eilbek, Germany, [15]Pfizer Ltd, Sandwich, UK, [16]Pfizer Ltd, Tadworth, UK, [17]Quanticate Ltd, Hitchin, UK, [18]Rheumatology A Department, RDU, Paris, France, [19]Service de Pneumologie et Reanimation Respiratoire, Centre des Maladies Vasculaires Pulmonaires, Hopital Antoine-Beclere, Université Paris-Sud, Clamart, France

Objective: To validate 6 minute walking distance (6MWD) as an outcome measure in patients with pulmonary arterial hypertension associated with systemic sclerosis (PAH-SSc) using the OMERACT filter of truth, discrimination and feasibility.

Methods: 6MWD was validated in PAH-SSc patients using data from randomized controlled clinical trials (SUPER-1 and STRIDE-1) and from an observational registry (CompERA-XL) reflecting clinical practice. All patients had PAH confirmed by right heart catheterization (RHC). Databases were assessed for the different aspects of the OMERACT filter. 6MWD was compared to pulmonary vascular resistance (PVR) obtained by RHC as the gold standard.

Results: A total of 57 PAH-SSc patients from trial data were available. Analysis of registry data was restricted to PAH-SSc patients where documented PVR and 6MWD were measured within a 30-day span (n=61) to allow for correlation analysis. In trials, both measurements were taken within 4 days. Regarding criterion validity, a linear correlation between 6MWD and PVR of −0.28 was found in the trials, −0.36 in the observational data. In trial data, 6MWD partially correlated with PVR in patients with moderate ($500 \leq PVR < 800$; $r = -0.28$) and severe ($PVR \geq 800$; $r = -0.33$) but not in mild ($PVR < 500$; $r = -0.03$) SSc-PAH. Change in 6MWD after 12 weeks of treatment correlated with change in PVR in the trials ($r = -0.25$). Regarding construct validity, 6MWD partially correlated with relevant dimensions of the SF-36 (e.g. physical functioning $r > 0.33$) in the trials, and discriminated for NYHA class and Borg index for both trial and observational data. Available data did not allow a reliable assessment of sensitivity to change over time (in placebo or untreated patients) or an assessment of reliability.

In comparison, 398 trial patients and 314 registry patients with IPAH were analyzed. Linear correlation of 6MWD and PVR was small ($r = -0.22$, $r = -0.06$). Correlation was better in mild and moderate than severe IPAH. Correlation of changes 12 weeks after treatment start was low ($r = -0.12$). 6MWD correlated with physical functioning of the SF36 ($r > 0.45$), and showed discriminating value for Borg index in both cohorts, for NYHA class only in trial data.

Conclusion: 6MWD and PVR have both demonstrated clinical utility in evaluating patients with PAH, but their relationship is unclear. Assessed by linear correlation between 6MWD and PVR, we found weak criterion validity in these cohorts of PAH-SSc patients. Due to differing correlation patterns between different stages of severity we could show only partial content validity. Construct validity was confirmed by the discriminating value for NYHA class and Borg index. Trial data were confirmed by registry data on most points. Notably, there were no major differences between patients with SSc-PAH and IPAH for the assessed OMERACT criteria. Limitations of this analysis include the small sample size, and retrospective, post hoc analysis of pooled data from different trials. However, taken together these data illustrate limitations of 6MWD as a single outcome measure in SSc-PAH clinical trials or clinical practice.

Adenosine A2A Receptor Occupancy Promotes Dermal Fibrosis by Modulating FLI1 and CTGF Expression. Hailing Liu[3], Edwin Chan[2], Patricia Fernández[2] and Bruce N. Cronstein[1]. [1]New York Univ Med Ctr, New York, NY, [2]NYU School of Medicine, [3]NYU School of Medicine, New York, NY

Background: Increased production of extracellular matrix in the skin is the hallmark of Scleroderma. We have previously reported that adenosine, a purine nucleoside produced in ischemic tissue, acting at A2A receptors, enhances dermal collagen production both in vitro and in a murine model of dermal fibrosis, although the mechanism by which adenosine receptor stimulation promotes collagen production is not clear. Fli1 is a known transcriptional repressor of fibrillar collagen genes and connective tissue growth factor (CTGF/CCN2) in dermal fibroblasts. To further clarify the mechanism by which A2A receptor stimulation induces dermal collagen accumulation, we explored the effects of A2A receptor occupancy on Fli1 and downstream mediators of fibroblast matrix production.

Methods: Primary human dermal fibroblasts were stimulated with the selective adenosine A2AR agonist CGS21680 (1μM) for varying time periods and message levels (real time-RTPCR) for fli1 and CTGF were quantitated. In addition we measured cell associated and supernatant levels of collagen I and nuclear levels of fli1 by Western Blot.

Results: Adenosine A2A receptor stimulation for 4 hours reduced Fli1 mRNA expression by 47±18% (4 hrs, $p<0.05$ vs. control, n=4) and reduced nuclear protein levels of Fli1 by 32±13% (24hrs, $p<0.05$, n=4). Because diminished nuclear fli1 should increase CTGF levels we next examined the effect of A2A receptor stimulation on CTGF mRNA and protein secretion. CTGF mRNA level was increased following A2A receptor stimulation for 8 hours by 3.7 fold.Consistent with the change in CTGF mRNA, CGS21680 stimulated a 4.7 fold increase in CTGF protein secretion at (24 hours) as well ($p<0.03$, n=4). As expected A2A receptor stimulation increased collagen I secretion (1.8-fold vs. control, $p<0.05$, n=3) and the increase in collagen production was completely abrogated by an antibody to CTGF (1.1+0.04 fold of control, $p<0.05$ vs.CGS, n=3) but not by control antiserum (1.6 +0.03fold of control, n=3).

Conclusion: A2AR occupancy promotes dermal matrix production by suppressing expression of the transcriptional repressor fli1 leading to an increase in CTGF expression which acts in an autocrine fashion to stimulate collagen production. These findings further suggest that modulation of A2AR function may be a novel therapeutic target for limiting fibrosis in such conditions as scleroderma.

Adipocyte-Targeted Wnt Activation Results in Spontaneous Dermal Fibrosis and Subcutaneous Lipoatrophy. Jun Wei[3], Denisa S. Melichian[2], Kazuhiro Kumora[2], Ormond Macdougald[4] and John Varga[1]. [1]Northwestern Univ Feinberg School, Chicago, IL, [2]Northwestern University Feinberg School of Medicine, [3]Northwestern University Feinberg School of Medicine, Chicago, IL, [4]University of Michigan

Background: Fibrosis and subcutaneous lipoatrophy are hallmarks of scleroderma, and are thought to reflect mesenchymal cell differentiation into

activated fibroblasts. The Wnts are a family of extracellular ligands and are involved in development and cell fate determinations. Canonical Wnt signaling drives preadipocyte differentiation into osteoblasts in part through negative modulation of PPAR-γ expression and function. Recent studies implicate abnormalities in the canonical Wnt pathway in scleroderma and pulmonary fibrosis. Because Wnt signaling has profound effects on regulating mesenchymal cell lineage, we examined the effect of adipocyte-specific ectopic Wnt10b expression on skin homeostasis and differentiation in transgenic mice.

Methods: Female transgenic mice harboring Wnt10b under the control of the FABP4 promoter were studied. Adiponectin levels were determined by ELISA. Dermal thickness was measured. Collagen accumulation in the skin was determined histochemical stains, and by colorimetric assays. Mast cells were identified by Astra Blue staining. Fibroblasts were explanted from the skin and evaluated in vitro at early passage. Gene expression was assessed by real-time qPCR and Western blot analysis.

Results: At six months of age, female FABP4-Wnt10b transgenic mice showed a marked loss of subcutaneous and visceral adipose tissue. Serum levels of adiponectin were >80% lower than in wildtype littermates. In the skin from Wnt10b transgenic mice, a dramatic increase in Wnt10b mRNA expression was noted, and mRNA level for axin 2 was significantly elevated. The dermis showed a >60% increase in thickness, with a striking reorganization of the collagenous matrix, and a >80% increase in soluble collagen content. Degranulating mast cells were seen in the reticular dermis and among muscle bundles in Wnt10b transgenic mice but not in wildtype littermates. mRNA levels for Type I collagen and α-smooth muscle actin were elevated. Explanted dermal fibroblasts showed elevated Wnt10b expression. Expression of the adipogenic markers PPAR-γ and FABP4 were reduced, whereas mRNA levels for Type I collagen α-SMA were elevated, compared to wildtype fibroblasts examined in parallel.

Conclusion: Ectopic Wnt10b expression targeted to adipocytes results in progressive loss of cutaneous and visceral adipose tissue accompanied by the spontaneous development of dermal fibrosis with increased expression of fibrotic markers. Dermal fibroblasts explanted from Wnt10b transgenic mice show sustained activation of Wnt10b-driven canonical signaling and upregulation of collagen gene expression in vitro, suggesting that ectopic Wnt10b drives a shifts in mesenchymal cell fate toward myofibroblasts by induction of fibrotic genes while simultaneously suppressing adipogenic gene expression. This shift appears to be driven, at least in part, by suppression of the adipogenic master regulator transcription factor PPAR-γ. The results implicate that Wnt signaling plays an important role in the pathogenesis of scleroderma. Modulating Wnt activity may therefore represent a novel therapeutic approach for the treatment of scleroderma.

Cadherin 11 Promotes Pulmonary Fibrosis through Production of TGF β and the Regulation of Epithelial to Mesenchymal Transition. Daniel J. Schneider[1], Minghua Wu[4], Thuy T. Le[2], Seo-Hee Cho[3], Michael B. Brenner[5], Michael R. Blackburn[2] and Sandeep K. Agarwal[4]. [1]Department of Biochemistry and Molecular Biology, University of Texas Health Science Center, Houston, TX, [2]Department of Biochemistry and Molecular Biology, University of Texas Health Science Center, [3]Department of Pediatrics, Pediatric Research Center, University of Texas Health Science Center, [4]Division of Rheumatology and Clinical Immunogenetics, The University of Texas-Houston Medical School, Houston, TX, [5]Division of Rheumatology, Immunology and Allergy, Brigham and Women's Hospital and Harvard Medical School

Background: A devastating component of autoimmune disorders including systemic sclerosis is pulmonary fibrosis (PF). PF is characterized by excess deposition of extracellular matrix by myofibroblasts. Epithelial to mesenchymal transition (EMT) is a potential source of myofibroblasts. Cadherin 11 (CDH11) may contribute to processes that parallel those seen in PF and EMT, thus we hypothesized that CDH11 is a key mediator of PF.

Methods: CDH11 expression was determined in lung tissue from idiopathic pulmonary fibrosis (IPF) patients with severe (n=10) and mild (n=10) airway restriction and in the mouse model of bleomycin (BLM)-induced PF. Utilizing CDH11 knockout (Cdh11 −/−) mice and CDH11-neutralizing antibodies, we characterized the contribution of CDH11 in the BLM model. An alveolar epithelial cell line, A549, was used to investigate the role of CDH11 in EMT.

Results: CDH11 expression was increased in patients with severe (1.6±0.1 Δ-ct) versus (vs) mild IPF (1.0±0.1 Δ-ct, p=0.004). CDH11 expression was localized to hyperplastic alveolar epithelial cells and alveolar macrophages in IPF patients and mice given BLM. Compared to wild type (WT), Cdh11 −/− mice given BLM showed reductions in histopathological evidence of lung fibrosis (Ashcroft score: WT 3.9±0.3 vs Cdh11 −/− 2.6±0.5, p=0.04) and reductions in soluble collagen (WT 342±41 μg/ml vs Cdh11 −/− 208±35 μg/ml, p=0.02). Furthermore, TGF-β levels were reduced in bronchoalveolar lavage (BAL) fluid (74±8 pg/ml) and BAL cell pellets (38±8 pg/ml) from Cdh11 −/− vs WT mice given BLM (214±11 BAL pg/ml, p<0.001) (106±16 cell pellet pg/ml, p=0.009). Similar reductions in lung fibrosis and TGF-β were obtained in WT mice given neutralizing CDH11 antibodies beginning 10 days after BLM. In vitro studies of A549 cells demonstrated Cdh11 upregulation by TGF-β and Cdh11 siRNA resulted in a reduction in EMT endpoints including TGF-β-induced collagen production and Snail2/Slug transcription.

Conclusion: We conclude that CDH11 contributes to pulmonary fibrosis through promotion of TGF-β production and the regulation of EMT. This suggests CDH11 may be a novel therapeutic target for PF.

603

Cadherin-11 in Systemic Sclerosis and Its Role in Dermal Fibrosis. Minghua Wu[3], Michael B. Brenner[1], Maureen D. Mayes[4], Frank C. Arnett[5], Filemon K. Tan[6] and Sandeep K. Agarwal[2]. [1]Brigham & Womens Hospital, Boston, MA, [2]Division of Rheumatology and Clinical Immunogenetics, University of Texas Health Science Center at Houston, Houston, TX, [3]Division of Rheumatology and Clinical Immunogenetics, University of Texas Health Science Center at Houston (UTHSC-H), Houston, TX, [4]University of Texas-Houston, Houston, TX, [5]UT Medical School, Houston, TX, [6]UT-Houston Med School, Houston, TX

Background: Cadherin-11 (Cad-11) is a mesenchymal cadherin initially identified in osteoblasts but subsequently found to be expressed on other cells including synovial fibroblasts where it confers a mesenchymal phenotype and promotes cellular invasion. Cad-11 has been reported to be increased during wound healing. Recently, Cad-11 was observed to be upregulated in scleroderma (SSc) skin in two independent microarray studies. These results led to the hypothesis that Cad-11 is a critical mediator of dermal fibrosis.

Methods: SSc and normal skin biopsies were used for qRTPCR to quantitate Cad-11 levels and for immunohistological (IHC) analyses to determine the expression pattern of Cad-11. Dermal fibroblasts were stimulated with TGFb and qRTPCR was used to determine if TGFb increased Cad-11 expression. To determine if Cad-11 is a mediator of dermal fibrosis, Cad-11 deficient (def) and wild type (WT) mice were compared using the bleomycin (bleo) induced skin fibrosis model. Anti-Cad-11 monoclonal antibodies (mAb) also were used to confirm these findings in the bleo-induced skin fibrosis model.

Results: Cad-11 transcript levels were increased in SSc skin biopsies (n=6) relative to healthy control skin biopsies (n=9). IHC analyses of skin biopsies demonstrated Cad-11 reactivity in the dermis of SSc biopsies, but not control biopsies, predominantly on fibroblast-like cells. TGFb upregulated Cad11 expression on cultured dermal fibroblasts from healthy controls and SSc patients. Using the bleo-induced dermal fibrosis model, Cad-11 def. mice had markedly attenuated dermal fibrosis as quantitated by skin thickness (Cad11 def:194±14 μm, WT: 255±17 μm, p=0.003), collagen levels (Cad11 def: 230±24 μg/mg, WT: 319±20 μg/mg, p=0.01) and myofibroblast accumulation in the lesional skin. Administration of two neutralizing anti-Cad-11mAb to WT mice resulted in a significant amelioration of collagen deposition and dermal thickness in bleo-induced dermal fibrosis. Lastly, Col1a1 and CTGF mRNA levels but not IL-6 levels were significantly decreased in lesional skin of Cad-11 def. compared to WT mice.

Conclusions: These results demonstrate that Cad-11 is a critical mediator of dermal fibrosis, and suggest that Cad-11 is a potential therapeutic target in SSc.

Dabigatran Etexilate, an Oral Direct Thrombin Inhibitor, Represses Fibrotic Changes in a Murine Model of Pulmonary Fibrosis. Galina Bogatkevich[3], Anna Ludwicka-Bradley[3], Paul J. Nietert[4], Joanne van Ryn[1] and Richard M. Silver[2]. [1]Boehringer Ingelheim, [2]Medical University of South Carolina, Charleston, SC, [3]Medical University of South Carolina, Charleston, SC, [4]Medical University of South Carolina

Rationale: Activation of the coagulation cascade and generation of thrombin has been extensively documented in pulmonary fibrosis, both in acute and chronic lung injury, including scleroderma and in animal models of lung injury. The oral direct thrombin inhibitor (DTI), dabigatran etexilate, modulates the coagulation cascade and inhibits thrombin-induced profibrotic signaling in lung fibroblasts, including scleroderma lung fibroblasts. This study tested whether thrombin inhibition by dabigatran etexilate attenuates bleomycin-induced pulmonary fibrosis in a murine model of lung injury.

Methods: Lung injury was induced in 6–8 week old female C57BL/6 mice by intratracheal instillation of bleomycin. Dabigatran etexilate was given as supplemented chow (10 mg/g chow) or as matching placebo beginning on day 8 following bleomycin. Two and three weeks after bleomycin instillation mice were euthanized, and lungs, bronchoalveolar lavage fluid (BALF) and plasma were collected. Lung collagen was measured by hydroxyproline assays; dabigatran concentration by LC-MS/MS; thrombin activity by fluorometric assays; TGF-β1 concentrations by ELISA; connective tissue growth factor (CTGF) and smooth muscle α-actin (α-SMA) were assessed by immunoblotting. The association between hydroxyproline levels in lung tissue and dabigatran concentration in plasma was tested using Spearman rank correlation test.

Results: In BALF we observed significant reduction of active thrombin and TGF-β1 from 46.05$\pm$19.4ng/ml and 54.9$\pm$6.1pg/ml in bleomycin + placebo-treated mice to 11.95$\pm$4.4ng/ml ($p< 0.001$) and 31.144$\pm$8.7pg/ml ($p<0.01$) respectively in bleomycin + dabigatran etexilate-treated mice. Dabigatran treatment was also associated with two-fold decrease in the absolute number of cells in BALF of bleomycin-treated mice. A quantitative evaluation of histopathology by Ashcroft scale demonstrated a significant decrease in fibrosis of dabigatran-treated mice (5.76$\pm$1.64 vs. 2.98$\pm$0.88, $p<0.05$). A strong negative correlation between hydroxyproline levels in lung tissue and dabigatran concentration in plasma was observed in mice with bleomycin-induced lung fibrosis ($R=-0.96$, $p=0.0005$). There was no correlation between hydroxyproline and dabigatran in control sham-injured mice. Additionally, dabigatran reduced CTGF 9-fold and α-SMA 2.5-fold in mice with bleomycin-induced lung fibrosis, whereas it did not interfere with basal levels of the proteins.

Conclusions: Inhibition of thrombin using the oral DTI dabigatran etexilate has marked anti-fibrotic effects in a bleomycin-induced mouse model of pulmonary fibrosis. Dabigatran etexilate treatment reduces collagens, TGF-β1, CTGF, and α-SMA induced by tissue injury, while not interfering with basal levels of these proteins in normal lung tissue. Our data suggest that dabigatran etexilate may be beneficial in the treatment of fibrosing lung diseases, e.g. scleroderma lung disease and idiopathic pulmonary fibrosis.

Endothelial Dysfunction and Abnormal Collagen V Deposition in Pulmonary Vasculature of Experimental Systemic Sclerosis Model. Roberta G. Marangoni[2], Edwin R. Parra[1], Ana Paula P. Velosa[3], Walcy R. Teodoro[3], Vera L. Capelozzi[1] and Natalino H. Yoshinari[3]. [1]Pathology Department, Faculdade de Medicina da Universidade de São Paulo, [2]Rheumatology Division, Faculdade de Medicina da Universidade de São Paulo, São Paulo, SP, Brazil, [3]Rheumatology Division, Faculdade de Medicina da Universidade de São Paulo

Purpose: We have recently described a collagen type V (COL V) rabbit experimental model that resembles the human systemic sclerosis (SSc). None of the profibrotic models for SSc to date have reproduced the vascular involvement observed in human disease. We therefore have evaluated in our model the intrapulmonary arteries for neovascularization (CD31 expression), endothelial apoptosis (caspase-3 induced), endothelial activity (endothelin-1 and VEGF expression) and COL V deposition.

Methods: Female rabbits from New Zealand lineage (n=6) were immunized with human COL V plus Freund's adjuvant. Animals immunized only with Freund's adjuvant (n=6) were used as controls. Two hundred and ten days after the first immunization, the animals were sacrificed and the lungs submitted to hematoxylin&eosin staining, electron microscopy, immunofluorescence, immunohistochemistry and morphometry.

Results: The histopathological analysis revealed a clear preponderance of intrapulmonary arteries with irregularity and wall thickness only in COL V immunized rabbits. Type V collagen was also increased and structurally altered. Ultrastructural analysis of same lungs showed increased rate of apoptosis, organelles with degenerative changes and cytoplasmic tumefaction of the endothelial cells which appeared detached from the basement membrane. Additionally, COL V group displayed increased expression of the immunomarkers for neovascularization, endothelial apoptosis and endothelial activation compared to controls ($p<0.01$).

Conclusions: Our experimental model reproduced the endothelial dysfunction and abnormal COL V deposition in pulmonary vasculature observed in SSc patients, confirming its suitability to study the vascular involvement of this disease.

606

Genetic Deletion or Pharmacologic Antagonism of LPA1 Ameliorates Dermal Fibrosis in a Mouse Model of Systemic Sclerosis. Flavia V. Castelino[3], Jon Seiders[1], Gretchen Bain[1], Chris King[1], James Swaney[1], Dan Lorrain[1], Jerold Chun[5], Andrew D. Luster[2] and Andrew M. Tager[4]. [1]Amira Pharmaceuticals, [2]Massachusetts General Hospital, Charlestown, MA, [3]Massachusetts General Hospital, Boston, MA, [4]Massuchusetts General Hospital, [5]Scripps Research Institute

Rationale: Systemic sclerosis (SSc) is a potentially fatal autoimmune disease of unknown etiology, characterized by progressive multi-organ fibrosis that is refractory to current therapies. We previously implicated the lipid mediator lysophosphatidic acid (LPA) in the pathogenesis of pulmonary fibrosis. Here, we studied the roles of LPA and two of its G protein-coupled receptors, LPA1 and LPA2, in dermal fibrosis using the bleomycin mouse model of SSc in mice deficient for these receptors. Additionally, we investigated the therapeutic potential of targeting LPA1, by using the novel LPA1-selective antagonist AM095 in this model.

Methods: Wild type (WT) and LPA1- and LPA2-deficient (LPA1 KO, LPA2 KO) mice received subcutaneous injections of bleomycin (10 μg/ml) or phosphate buffered saline (PBS) once per day. After 28 injections, full thickness 6 mm punch biopsies were obtained. Dermal thickness was measured between the epidermal-dermal and dermal-fat junctions using H&E stained skin sections. Collagen was visualized by Masson's trichrome stain, and quantified by hydroxyproline measurement. Myofibroblasts and cells responding to TGF-β, were identified in skin sections by immunohistochemical staining with anti-α-smooth muscle actin (α-SMA) and anti-phosphoSmad2 antibodies (p-Smad2), respectively. The LPA1 antagonist, AM095 or vehicle control was administered to bleomycin- or PBS-challenged C57Bl/6 mice by oral gavage twice daily on weekdays and once daily on weekends. AM095 or vehicle treatment was either administered concurrently with bleomycin or PBS, or initiated at 7 or 14 days after bleomycin, for total treatment durations of 28, 21 or 14 days, respectively. At the conclusion of these treatment schedules, dermal thickness and collagen content were assessed as above.

Results: LPA1 KO mice were markedly protected from dermal fibrosis. Comparing LPA1 KO and WT mice, genetic deletion of LPA1 attenuated bleomycin-induced increase in dermal thickness by 91% and hydroxyproline content by 90%. Dermal α-SMA+ and pSmad2+ cells were also markedly attenuated in bleomycin-challenged LPA1 KO mice. The number of α-SMA+ myofibroblasts increased by 70% in WT mice, but only by 5% in LPA1 KO mice. Similarly, bleomycin challenge increased pSmad2+ cells by 81% in WT mice, with no increase in LPA1 KO mice. In contrast, LPA2 KO mice were not protected from bleomycin-induced increases in dermal thickness and collagen content when compared to WT mice. Pharmacologic antagonism of LPA1 with AM095 also significantly attenuated bleomycin-induced dermal fibrosis. Although the greatest reductions in dermal fibrosis were seen with 28-day administration of AM095, both delayed treatment regimens significantly reduced dermal fibrosis as well.

Conclusions: These results suggest that LPA signaling through LPA1 but not LPA2 is required for bleomycin-induced dermal fibrosis, and is required for both myofibroblast accumulation and TGF-β-Smad signaling. Both

genetic deletion and preventive or therapeutic pharmacological inhibition of LPA1 attenuated bleomycin-induced dermal fibrosis. Targeting LPA1 therefore has the potential to be an effective new therapeutic strategy for SSc.

Inactivation of the Transcription Factor STAT4 Prevents Inflammation-Driven Fibrosis in Systemic Sclerosis Animal Models. Jerome Avouac[3], Barbara G. Fürnrohr[2], Michal Tomcik[4], Katrin Palumbo[2], Pawel Zerr[2], Angelika Horn[2], Clara Dees[2], Alfiya Akhmetshina[2], Christian Beyer[2], Oliver Distler[1], Georg Schett[5], Yannick Allanore[6] and Jorg H. W. Distler[7]. Objective: STAT4 is a transcriptional factor regulating various cytokines and in particular interferon type 1 and IL12-IL23 pathways. STAT4 has been recently identified as a genetic susceptibility factor to systemic sclerosis (SSc) and also to other autoimmune diseases. Our aim was to investigate the contribution of STAT4 in the development of a fibrotic phenotype in two different mouse model of experimental dermal fibrosis.

Methods: The role of STAT 4 was first evaluated in the mouse model of bleomycin-induced dermal fibrosis, a model for early, inflammatory stages of SSc. Mice deficient for STAT4 (stat4−/−) and wildtype littermates (stat4+/+) were injected with bleomycin or NaCl. Infiltrating leukocytes and T cells in lesional skin of STAT4−/− and STAT4+/+ mice were quantified respectively on hematoxylin and eosin stained sections and by immunohistochemistry for CD3. Th1 and Th2 cytokine levels were also measured in the serum or lesional skin samples of stat4−/− and stat4+/+ mice. The invalidation of STAT4 was also investigated in the tight-skin (tsk-1) mouse model, which serve as a model of later, less inflammatory stages of SSc.

Results: stat4−/− mice were protected from bleomycin-induced dermal fibrosis with reduced dermal thickening (65±3% reduction, p=0.03), hydroxyproline content (68±5% decrease, p=0.02) and myofibroblast counts (71±6% reduction, p=0.05). The numbers of leukocytes, especially infiltrating T cells, were also decreased in lesional skin of stat4−/− mice (respectively 62±4%, p=0.02 and 63±5%, p=0.02). Moreover, stat4−/− mice displayed in lesional skin decreased levels of cytokines involved in inflammatory and fibrotic processes such as IL-6 (50±4% decrease), TNFα (71±5%), INFγ (58±3%) and IL-2 (63±4%). Similar results were observed in the serum.

Consistent with a primary role of STAT4 on inflammation, STAT4 deficiency did not improve the fibrotic phenotype in tsk-1 mice. No differences in hypodermal thickness, hydroxyproline content and myofibroblasts counts were observed between stat4−/−/tsk-1 mice and their stat4+/+/tsk-1 littermates.

Conclusion: This is the first translational study demonstrating the role of the transcription factor STAT4, an established genetic susceptibility factor of SSc and different autoimmune diseases, in animal models of SSc. We herein demonstrate that STAT4 exerts potent profibrotic effects in inflammation-driven models of fibrosis. STAT4 indirectly regulates the activation of fibroblasts by promoting the infiltration of T cells into lesional skin and the production of inflammatory cytokines. These findings confirm the results of the genetic studies on the role of STAT4 in the development of SSc.

Induction of Peripheral Tissue Ischemia and Anti-Endothelial Antibodies after B Cell Adoptive Transfer from RNP-Immunized Mice. YunJuan Zang[3], Irina Fernandez[3], Maite Chavez[3], Laisel Martinez[1] and Eric L. Greidinger[2]. [1]Miami VA Medical Center, [2]Miami VA Medical Center and University of Miami Miller School of Medicine, Miami, FL, [3]University of Miami Miller School of Medicine

Background: We have previously developed a murine model of induced anti-RNP autoimmunity with clinical manifestations including interstitial lung disease and nephritis, in which disease manifestations were transferable to naive syngeneic mice by T cell or dendritic cell adoptive transfer. To pursue the hypothesis that autoimmune Raynaud's Phenomenon (RP) may be mediated by B cells, B cell adoptive transfer studies were performed.

Methods: C57BL/6 female mice transgenic for expression of HLA-DR4 were immunized with 70k and U1-RNA following our published protocol, and confirmed to have anti-RNP humoral responses by ELISA. Unimmunized syngeneic mice housed together with the immunized mice were used as control B cell donors. Two months after immunization, mice were sacrificed, spleens were collected and processed into RBC-depleted single-cell suspensions, and CD20+ cells were positively selected by AutoMACS. Four million cells per recipient were transferred via the tail vein into syngeneic 10 week old female mice. Recipients were followed clinically for up to two weeks after cell transfer. Loss of ear and tail tissue (thermoregulatory tissues in mice) was noted by personnel blinded to the treatment status of the mice, and documented photographically. Serum was collected from sacrificed mice, and organs were analyzed histologically. The immunoreactivity of collected sera was tested by immunofluorescence and immunoblot against HUVEC and Jurkat cells, and compared to reference human sera from patients with RP and controls.

Results: B cell adoptive transfer induced episodes of cyanosis and resulted in loss of ear and/or tail tissue in 14/17 recipients of B cells from RNP+ donors, but in 0/5 recipients of B cells from unimmunized donors (Fisher's Exact p = 0.002). No evidence of vasculitis or thrombosis was observed histologically. Like human RP sera but unlike human control sera or RNP+ B cell donor sera, the sera from mice with tissue loss had anti-endothelial reactivity, and induced morphological changes and cell death in HUVEC cultures. B cell recipients from RNP+ donors had lower titer anti-RNP responses than their respective B cell donors. Serum transfer from mice with tissue loss but not from RNP+ B cell donors also induced ear and/or tail tissue loss.

Conclusions: B cell adoptive transfer from RNP+ donors induces a novel murine model of Raynaud's Phenomenon. This model provides a novel link between the autoimmune and vasospastic manifestations of systemic autoimmune diseases, and specifically implicates B cells in RP pathogenesis.

Mice Lacking the Receptor-Like Protein Tyrosine Phosphatase CD148 Are Protected from Bleomycin-Induced Pulmonary Fibrosis. Tamiko R. Katsumoto[1], Kevin K. Kim[2], Alexis N. Brumwell[2], John X. Nguyen[2], Jing W. Zhu[2], Mark R. Looney[2], Harold A. Chapman[2] and Arthur Weiss[2]. [1]UCSF, South San Francisco, CA, [2]UCSF

Purpose: The molecular mechanisms underlying pulmonary fibrosis, one of the most morbid complications of scleroderma, remain incompletely characterized. Protein tyrosine phosphatases and kinases regulate the equilibrium of tyrosine phosphorylation signaling pathways important in cell growth and differentiation. Tyrosine kinases have been implicated in fibrosis, and studies testing the anti-fibrotic activity of tyrosine kinase inhibitors such as imatinib in scleroderma patients are underway. The receptor-like protein tyrosine phosphatase (RPTP) CD148 is widely expressed on various hematopoietic and non-hematopoietic lineages, including lung epithelial cells, endothelial cells, and fibroblasts. Given the importance of tyrosine phosphorylation pathways in fibrosis, we explored the role of CD148 in the bleomycin mouse model of pulmonary fibrosis.

Methods: Mice with a targeted deletion of the CD148 transmembrane domain (CD148KO) have been generated by our lab and are used in all studies described. Acute lung injury was measured using extravasation of radioactive iodine-labeled albumin and wet-to-dry ratios. Fibrosis was evaluated by both Masson Trichrome staining of lung sections as well as by the Sircol Collagen Assay (Biocolor).

Results: Following intratracheal instillation of bleomycin at a dose of 3 units/kg, WT mice showed significantly impaired survival, with 4 of 6 WT mice (67%) dying between 10–16 days, whereas none of the 8 CD148KO mice (0%) died (p=0.007). Masson Trichrome staining of lungs demonstrated markedly increased fibrosis in WT mice, whereas fibrosis was significantly attenuated in the CD148KO mice. At day #13 following a lower dose of bleomycin (2.5 U/kg), WT bleomycin-treated mice had a 4.2-fold increase in lung collagen content whereas CD148KO mice showed only a 1.7-fold increase in collagen (p=0.0009). Lung collagen levels in WT bleomycin mice (66.1+/−6.1 ug/ml) were significantly higher than in WT saline mice (15.8+/−0.8 ug/ml) (p=0.0008), whereas lung collagen levels in CD148KO bleomycin mice (46.1+/−8.2 ug/ml) vs. CD148KO saline mice (26.6+/−7.2 ug/ml) were not significantly different (p=0.157). The acute lung injury response at day #5 post bleomycin (2.5 U/kg) was equivalent between genotypes. Endothelial permeability was 1.7% +/−0.33% in WT saline mice vs. 1.5% +/−0.39% in CD148KO saline mice. Following bleomycin, the increase in endothelial permeability in WT mice to 3.9% +/−0.67% and in CD148KO mice to 3.9% +/−0.39% was equivalent between genotypes (n=4 mice per genotype).

Conclusion: Mice lacking CD148 phosphatase activity show improved survival. Attenuation of bleomycin-induced fibrosis does not appear to be the consequence of a diminished early acute lung injury response to bleomycin. Future studies will interrogate the specific cell types mediating this response, as well as elucidating the pathways regulated by CD148 underlying this phenotype. These data suggest that inhibition of the RPTP CD148 may present an attractive anti-fibrotic therapeutic strategy.

Noggin$^{+/LacZ}$ Heterozygous Mice Have Reduced Pulmonary Fibrosis in the Bleomycin Induced Model. Ellen de Langhe[2], Vanessa De Vooght[2], Frank P. Luyten[1] and Rik Lories[1]. [1]KU Leuven, Leuven, Belgium, [2]KU Leuven

Introduction: Noggin (Nog) is an extracellular antagonist of the Bone Morphogenetic Protein (BMP) signaling pathway. The BMP pathway plays an important role in embryonic development, postnatal growth, tissue homeostasis and disease. The molecular mechanisms underlying pulmonary fibrosis in diseases such as systemic sclerosis and idiopathic pulmonary fibrosis (IPF) are poorly understood. The role of the BMP antagonist gremlin in IPF has been published.

Objectives: We hypothesize that the BMP signaling pathway plays a role in fibrogenesis. Here we study the role of Nog and the BMP pathway in bleomycin induced pulmonary fibrosis using Nog$^{+/LacZ}$ heterozygous mice.

Material and Methods: Pulmonary fibrosis was induced in 8-week old male wild-type (WT) or Nog$^{+/LacZ}$ mice, both on the C57/Bl6 background by intratracheal instillation of 0.05U bleomycin (BLM) or phosphate buffered saline (PBS) as a control (WT: BLM n=23, PBS n=17; Nog$^{+/LacZ}$: BLM n=14, PBS n=7). 4 weeks after baseline induction invasive pulmonary function tests were performed using the Flexivent® SCIREC system. The mice were subsequently sacrificed and pulmonary tissue was collected for histopathology, immunohistochemistry and gene expression analysis. Pulmonary architecture was evaluated and scored on haematoxylin-eosin (H&E) sections using the validated Ashcroft score for pulmonary fibrosis. Total collagen content was quantified using the hydroxyproline quantification assay. Immunohistochemistry for phosphorylated Smad 1/5/8 was performed to demonstrate active BMP signaling during the process of fibrosis.

Results: Pulmonary fibrosis was successfully induced in the BLM treated groups, evident on H&E stainings and quantified by high Ashcroft scores. The increased nuclear staining for phosphorylated Smad 1/5/8 in the fibrotic areas indicated active BMP signaling. When pulmonary fibrosis was induced in the Nog$^{+/LacZ}$ mice, it was associated with an attenuated fibrotic response with a significant decrease in the Ashcroft score as compared to the WT controls, as well as a significantly decreased collagen content. This was further confirmed at the functional level by significantly higher lung compliance.

Conclusion: The BMP signaling pathway appears activated in bleomycin induced pulmonary fibrosis. When bleomycin is administered to Nog$^{+/LacZ}$ mice, partial loss of gene function is associated with an attenuated fibrotic response both at the histomorphological and at the functional level. Further experiments are needed to clarify whether this effect results from increased BMP signaling or from possible interactions with the TGFβ signaling pathway.

Nr4a1 Ameliorates the Pro-Fibrotic Effects of TGFβ in Systemic Sclerosis (SSc) and Might Be an Interesting Target for Anti-Fibrotic Therapies. Katrin Palumbo[1], Alfiya Akhmetshina[1], Pawel Zerr[1], Michal Tomcik[1], Angelika Horn[1], Clara Dees[1], Oliver Distler[3], Georg Schett[2] and Jorg H. W. Distler[4]. [1]Department of Internal Medicine III and Institute for Clinical Immunology, University of Erlangen-Nuremberg, Erlangen, Germany, [2]Friedrich Alexander Univ, Erlangen, Germany, [3]University Hospital Zurich, Zurich, Switzerland, [4]University of Erlangen, Erlangen, Germany

Background: Nuclear receptor 4 a 1 (Nr4a1) is a unique transcription factor which belongs to the superfamily of orphan nuclear receptors. Unlike most nuclear receptors, members of Nr4a receptors do not seem to require ligand binding for activation. Nr4a1 is known to be a regulator of macrophage gene expression in inflammation, cell death and cell growth. The aim of the present study was to investigate the role of Nr4a1 in TGFβ signaling and in the pathogenesis of SSc.

Methods: The expression of Nr4a1 in cells and tissue was analyzed by real-time PCR, Western Blot and immunofluorescence. Collagen synthesis was quantified by real-time PCR, SirCol- and hydroxyproline assay. The role of Nr4a1 in fibrosis and potential therapeutic implication were evaluated in three different mouse models: bleomycin-induced dermal fibrosis, tight-skin-1 (tsk-1) mice and mice infected with adenovirus overexpressing constitutively active TGFβ receptor I.

Results: The expression of Nr4a1 was significantly elevated in the skin of SSc patients compared to healthy controls. Moreover, mRNA levels of Nr4a1 were increased in cultured SSc fibroblasts. Stimulation with TGFβ strongly increased the mRNA and protein levels of Nr4a1 in cultured fibroblasts, indicating that TGFβ might drive the overexpression in SSc. siRNA-mediated knock-down of Nr4a1 in human fibroblasts potently induced the expression of collagen mRNA and protein. An increased release of collagen was also observed in murine fibroblasts isolated from Nr4a1 deficient mice. On the other hand, stimulation of Nr4a1 signaling, either by overexpression of Nr4a1 or by incubation with the Nr4a1 agonist Cytosporone B, strongly reduced the collagen synthesis in cultured fibroblasts. These data suggest that Nr4a1 is in the centre of a negative feedback loop, which restricts the pro-fibrotic effects of TGFβ in SSc. Consistently, mice lacking Nr4a1 were more sensitive to bleomycin induced fibrosis with 2 fold more pronounced dermal thickening, myofibroblast counts and hydroxyproline content upon challenge with bleomycin compared to wildtype mice. Moreover, AAV-TGFRI virus infected Nr4a1 deficient mice and tsk-1 mice lacking Nr4a1 showed also significantly increased fibrosis compared to control mice expressing Nr4a1. Next, we investigated, whether therapeutic activation of Nr4a1 by Cytosporone B prevents experimental fibrosis. Treatment with Cytosporone B completely prevented fibrosis in all mouse models and reduced dermal thickness, myofibroblast counts and hydroxyproline content to levels similar to control mice.

Conclusion: We demonstrate that Nr4a1 is upregulated in SSc in a TGFβ dependent manner. Nr4a1 negatively regulates the extracellular matrix (ECM) production by limiting the pro-fibrotic effects of TGFβ in vitro as well as in vivo. Thus, we first describe a negative feedback loop, in which the concomitant upregulation of Nr4a1 limits the pro-fibrotic effects of TGFβ in SSc. In addition, activation of Nr4a1 signaling by Cytosporone B might be a novel therapeutic approach for fibrotic diseases.

Osteopontin in Systemic Sclerosis and Its Role in Dermal Fibrosis. Minghua Wu[2], Daniel J. Schneider[1], Maureen D. Mayes[3], Shervin Assassi[2], Frank C. Arnett[4], Filemon K. Tan[5], Michael R. Blackburn[1] and Sandeep K. Agarwal[2]. [1]Department of Biochemistry and Molecular Biology, UTHSC-H, Houston, TX, [2]Division of Rheumatology and Clinical Immunogenetics, University of Texas Health Science Center at Houston, Houston, TX, [3]University of Texas-Houston, Houston, TX, [4]UT Medical School, Houston, TX, [5]UT-Houston Med School, Houston, TX

Background: Osteopontin (OPN) is a multifunctional cytokine produced during inflammation and tissue repair. OPN has been implicated in certain autoimmune diseases such as rheumatoid arthritis and as well as with fibrosis in disorders such as idiopathic pulmonary fibrosis and in mouse models of pulmonary fibrosis. Given the importance of autoimmunity and fibrosis in systemic sclerosis (SSc), we hypothesized that OPN is elevated in SSc patients and plays a critical role in the development of dermal fibrosis.

Methods: Plasma from a cohort of SSc patients (n= 319) and non-autoimmune disease controls (n= 144) were used to determine OPN levels by ELISA. Skin biopsies from SSc patients and healthy controls were used for immunohistological (IHC) analyses. To determine if OPN is a mediator of dermal fibrosis, OPN deficient (def) and wild type (WT) mice were compared in the bleomycin (bleo)-induced dermal fibrosis model.

Results: Circulating levels of OPN were elevated in SSc patients (47.9±3.6 ng/ml) compared to healthy controls (28.3±3.8ng/ml, p=0.0009). OPN levels were elevated in both patients with limited and diffuse disease as well as anticentromere, anti-topoisomerase I and anti-RNA polymerase III positive SSc patients relative to controls. Compared to controls, SSc skin biopsies expressed OPN that localized to both fibroblast-like cells and macrophages on IHC analyses. Similarly, skin biopsies from mice treated with subcutaneous bleo had increased levels of OPN compared to PBS injected mice. Interestingly, using the bleo-induced dermal fibrosis model, OPN def. mice had markedly attenuated dermal fibrosis as quantitated by skin thickness (OPN def: 253±14 μm, WT 318±12 μm, p=0.001), collagen levels (OPN def: 263±35 μg/mg, WT 420±46 μg/mg, p=0.01) and myofibroblast accumulation in the lesional skin. Furthermore, OPN def. mice had decreased dermal inflammation, including decreased number of Mac-3 positive macrophages. Lastly, Col1a1, IL-6, PAI-1 and CTGF mRNA levels were significantly decreased in lesional skin of OPN def. compared to WT mice.

Conclusions: These data demonstrate that OPN is a mediator of dermal fibrosis, and suggest that OPN may be a potential biomarker and/or therapeutic target in SSc.

Relevance of Epithelial Phenotypic Switching in the Pathogenesis of Systemic Sclerosis. Xu Shiwen[1], S. Sonnylal[3], A. Tam[2], R. Stratton[2], A. Leask[2], C. P. Denton[2], J. Norman[2] and D. Abraham[2]. [1]Rheumatology, London, United Kingdom, [2]Rheumatology, United Kingdom, [3]UT M. D. Anderson Cancer, Houston, TX

Systemic sclerosis (SSc) is a complex disorder of uncertain etiology characterised by progressive vascular and interstitial fibrosis. Recently, we found that epidermal compartment in SSc skin exhibits abnormalities, taking on an activated phenotype reminiscent of that during the wound healing response. Fibroblast-Epithelial cell interactions are believed important during normal tissue repair and aberrant cellular cues may underlie important aspects of scarring and fibrosis. Transgenic mice in which the fibroblast expressed a constitutively active TGFb type I receptor (ALK5) or which expressing CTGF, develop progressive tissue fibrosis most prominent in the skin and lung. Our *in vivo* data also suggests that activation of TGFb signalling or CTGF over-expression by fibroblasts not only causes stromal activation, but also pathological changes in the phenotype of adjacent epithelium. Here, we focus on the phenotypic profile of the SSc epithelium, the role of fibroblast-derived CTGF in epithelial switching into a mesenchymal-like phenotypic and the contribution this process may play to fibrogenesis.

Methods: Whole skin biopsies were obtained from SSc and controls. The epidermis was prepared from some of the skin biopsies, and processed for phospho-kinase profiling (Kinexus: Vancouver, Canada). Human and rodent type II epithelial cells lines (A549 and T2) were grown in grown in DMEM + 10%FBS. Epithelial cells were stimulated with TGFb after serum starvation in the presence and absence of siRNA for specific for CTGF. Markers of epithelial cells and fibroblasts including CTGF, snail, E-cadherin, aSMA, collagen type I and fibronectin were examined using western blot analysis.

Results: Phosphorylation arrays were performed on the epidermal tissue from SSc patients and healthy controls to identify signaling pathways activated in SSc epidermis. A number of EMT-related proteins were found to have elevated phosphorylation states in SSc tissues versus controls, including c-Met, Wee1 protein-tyrosine kinase, STAT3, Integrin-linked protein-serine kinase 1($p<0.05$). Further *in vitro studies,* A549 and T2 epithelial cells exposed to TGF-β develop a mesenchymal-like morphology and molecular markers associated with EMT (snail and CTGF). CTGF-specific siRNA dose-dependently suppressed TGFβ-induced snail and CTGF protein expression towards basal levels in A549 cells. Transgenic mouse fibroblasts over-expressing CTGF showed significantly higher expression levels for matrix genes and proteins including collagen type I, fibronectin and increased expression of aSMA.

Conclusion: In this study we show that phosphorylation array analysis revealed induction of EMT-like protein kinase signaling in SSc epidermis. Important growth factor, TGF-β promotes and triggers epithelial cells to undergo a phenotypic switch which is attenuated upon CTGF knock-down by RNA interference. Our data suggests that in SSc, the enhanced expression of TGFb signaling and CTGF expression is likely to indirectly contribute to disease pathogenesis by triggering epidermal cells phenotypic switching towards a mesenchyml cell-like programme.

S100A4 as a Novel Mediator of TGF-β Driven Dermal Fibrosis in Systemic Sclerosis. Michal Tomcik[4], Pawel Zerr[2], Katrin Palumbo[2], Barbara G. Fürnrohr[2], Jerome Avouac[3], Angelika Horn[2], Clara Dees[2], Alfiya Akhmetshina[2], Christian Beyer[2], Radim Becvar[7], Oliver Distler[1], Mariam Grigorian[6], Ladislav Senolt[7], Georg Schett[5] and Jorg H. W. Distler[8]. [1]Center of Experimental Rheumatology and Zurich Center of Integrative Human Physiology, University Hospital Zurich, Switzerland, [2]Department of Internal Medicine III and Institute for Clinical Immunology, University of Erlangen-Nuremberg, Erlangen, Germany, [3]Department of Internal Medicine III and Institute for Clinical Immunology, University of Erlangen-Nuremberg, Erlangen, Germany and Paris Descartes University, Rheumatology A Department Cochin Hospital, Paris, France, [4]Department of Internal Medicine III, University of Erlangen-Nuremberg, Erlangen, Germany and Institute of Rheumatology and Connective Tissue Research Laboratory, Department of Rheumatology of the First Faculty of Medicine, Charles University i, [5]Friedrich Alexander Univ, Erlangen, Germany, [6]Institute of Cancer Biology, Danish Cancer Society, Copenhagen, Denmark, [7]Institute of Rheumatology and Connective Tissue Research Laboratory, Department of Rheumatology of the First Faculty of Medicine, Charles University in Prague, Czech Republic, [8]University of Erlangen, Erlangen, Germany

Background: S100A4 (metastasis associated protein) is a calcium binding protein exerting regulatory functions in diverse biological processes. It promotes cancer progression and metastasis by regulating the remodelling of the extracellular matrix.

Objectives: The aim of this study was to investigate the contribution of S100A4 to the pathologic activation of fibroblasts in SSc and its role in the development of a fibrotic phenotype in a mouse model of experimental dermal fibrosis.

Methods: Activation of S100A4 in human skin and experimental dermal fibrosis was determined by real-time PCR, immunohistochemistry and western blot. Collagen synthesis of SSc and healthy dermal fibroblasts was quantified by real-time PCR and SirCol collagen assay. Bleomycin-induced dermal fibrosis, a model for early, inflammatory stages of SSc, was used to assess the role of S100A4 in vivo using mice deficient for S100A4 ($^{-/-}$) and wildtype littermates ($^{+/+}$).

Results: Increased expression of S100A4 was detected in the upper layer of the dermis of SSc patients and was clearly colocalized with alpha-smooth muscle actin-positive fibroblasts. The overexpression of S100A4 persisted in cultured SSc fibroblasts and might contribute to their activated phenotype. A similar increase in S100A4 expression was observed in the skin samples from mice challenged with bleomycin and tsk-1 mice, both on mRNA (3.5- and 15.5-fold increase, respectively) and protein level. TGF-β stimulation of both healthy and SSc fibroblasts led to an increased expression of S100A4 protein. Of particular interest, knockdown of S100A4 by siRNA fully abrogated the stimulatory effects of TGF-β on the collagen synthesis of SSc fibroblasts. In agreement with the role of S100A4 as a novel mediator of the pro-fibrotic effects of TGF-β, mice lacking S100A4 were protected from experimental fibrosis. In the model of bleomycin-induced dermal fibrosis, inhibition of S100A4 decreased dermal thickening by 53±2% ($p<0.01$), significantly reduced the hydroxyproline content by 30±4% ($p<0.01$) and the number of myofibroblasts by 254±16% ($p<0.01$). Reduced induction of dermal fibrosis in S100A4 $^{-/-}$ mice might result from inhibition of TGF-β signaling as evidenced by reduced nuclear accumulation of phosphorylated Smad 3 in the skin sections of S100A4 $^{-/-}$ mice treated with bleomycin compared to their wildtype ($^{+/+}$) littermates.

Conclusion: This is the first study reporting on the role of S100A4 in SSc. We demonstrate an upregulation of S100A4 in SSc in a TGF-β dependent manner, and that inhibition of S100A4 reduces collagen synthesis in activated SSc fibroblasts. Knockdown of S100A4 protected from fibrosis in the murine model of bleomycin-induced dermal fibrosis due to inhibition of TGF-β signaling. Thus, the S100A4 pathway could be an interesting novel target for the treatment of SSc.

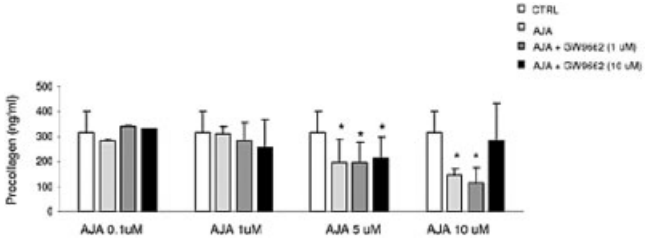
The Synthetic Cannabinoid Ajulemic Acid Targets Scleroderma Fibrosis. Estrella Garcia Gonzalez[3], Enrico Selvi[2], Balistreri Epifania[3], Alfiya Akhmetshina[1], Sauro Lorenzini[3], Kathrin Palumbo[1], Mauro Galeazzi[3] and Jorg W. H. Distler[1]. [1]Departement of Internal Medicine III and Institute for Clinical Immunology -Friedrich-Alexander University-Erlangen-Germany, [2]Rheumatology Unit - Departement of Clinical Medicine and Immunological Sciences-University of Siena, Siena, Italy, [3]Rheumatology Unit - Departement of Clinical Medicine and Immunological Sciences-University of Siena-Italy

Background: Substantial evidence supports the involvement of the endocannabinoid system in pathologic fibrosis and the capability of cannabinoids to modify fibrogenesis in scleroderma. Ajulemic acid (AjA) is a non-psychoactive, synthetic analog of tetrahydocannabinol (THC), the main psychoactive ingredient of Cannabis-sativa. AjA binds the peroxisome proliferator-activated receptor-γ(PPAR-γ), and PPAR-γ receptor activation modulates fibrogenesis. Therefore, we performed experiments to determine whether AjA can modify fibrogenesis in scleroderma.

Material and Methods: skin fibroblasts from scleroderma patients were cultured and treated with increasing concentrations of AjA (0.1, 1, 5 and 10 μM) in the presence or absence of the PPAR-γ irreversible antagonist GW9662 (1 and 10 μM) in order to evaluate procollagen production. Cell viability was evaluated using MTT assay and trypan-blue exclusion test. To evaluate AjA effect in vivo, three groups of DBA/2J mice (n=7 in each group) were studied. Group I and II received bleomycin subcutaneously (100 μl/ every other day) for 21 days. In addition to bleomycin, group II was treated orally with AjA (1 mg/kg) for 21 days. Group III only received subcutaneously 100 μl/day of NaCl 0.9%. At day 21 animals were sacrificed. Skin fibrosis was histologically evaluated by quantification of skin thickness and hydroxyproline content. As a marker of fibroblast activation,α-smooth muscle actin (α-SMA) was examined.

Results: AjA as well as the selective PPAR-γ antagonist GW9662 did not show any significant toxicity at the concentrations used. Addition of AjA to scleroderma fibroblasts significantly reduced supernatant procollagen concentrations in a dose-dependent manner. This effect was completely reversed by the PPAR-γ antagonist GW9662 (10 μM).



AjA treatment (1mg/kg/day for 21days) reduced markedly the dermal fibrosis induced by bleomycin in the animal model. Dermal thickness and hydroxyproline content appeared similar to the untreated control group. AjA treatment also reduced substantially the number of α-SMA positive cells in lesional skin.

Conclusions: we have demonstrated that AjA reduces fibrogenesis, at least in part, through a PPAR-γ mediated mechanism. These results and the demonstrated safety of AjA, suggest AjA as an interesting molecule targeting fibrosis in patients with scleroderma.

The Transcription Factor AP-1 Mediates the Pro-Fibrotic Effects of TGFβ and Contributes to the Development of Experimental Dermal Fibrosis. Jerome Avouac[3], Katrin Palumbo[2], Michal Tomcik[4], Pawel Zerr[2], Clara Dees[2], Angelika Horn[2], Alfiya Akhmetshina[2], Christian Beyer[2], Shunichi Shiozawa[5], Oliver Distler[1], Georg Schett[6], Yannick Allanore[7] and Jorg H. W. Distler[8]. Background: Tissue fibrosis caused by pathological activation of fibroblasts is a major hallmark of systemic sclerosis (SSc). The activation of the transcription factor AP-1, composed of members of Jun and Fos families, regulates cell proliferation, apoptosis, inflammation, wound healing and tumorigenesis. AP-1 is also one of the transcriptional targets of TGFβ signaling, one of the key growth factors in SSc.

Objectives: The aims of the present study were to investigate whether AP-1 contributes to the pathologic activation of fibroblasts in SSc and to evaluate the anti-fibrotic potential of AP-1 inhibition for treatment of SSc.

Methods: Activation of AP-1 in human skin was determined by real-time PCR for c-Jun and c-Fos and immunohistochemistry for N-terminal residues of human c-Jun. SSc and healthy dermal fibroblasts were stimulated with TGFβ and incubated with T5224, a small-molecule inhibitor of c-Fos/AP-1 (1). Collagen synthesis was quantified by real-time PCR and hydroxyproline assay. Differentiation of resting fibroblasts into myofibroblasts was assessed by staining for α-smooth muscle actin and stress fibers. To evaluate the anti-fibrotic potential of specific AP-1 inhibition by T5224 in vivo, we used the mouse model of bleomycin induced dermal fibrosis or attenuated adenoviruses overexpressing a constitutively active TGFβ receptor I.

Results: Increased levels of AP-1 were detected in the skin of SSc patients. The overactivation of AP-1 persisted in cultured SSc fibroblasts. Inhibition of AP-1 reduced the basal mRNA levels of col1a1 and col1a2 in SSc fibroblasts by up to 46$\pm$3% ($p<0.05$) but did not reduce the collagen synthesis in resting healthy dermal fibroblasts. Similar results were obtained on the protein level. Stimulation of healthy fibroblasts with TGFβ lead to AP-1 activation and inhibition of AP-1 abrogated the stimulatory effects of TGFβ on collagen synthesis. Inhibition of AP-1 also prevented the differentiation of resting fibroblasts into myofibroblasts. Consistently, inhibition of AP-1 exerted potent anti-fibrotic effects in different models of experimental fibrosis. In the mouse model of bleomycin-induced fibrosis, inhibition of AP-1 decreased dermal thickening by 53$\pm$3% ($p<0.05$). In addition, the collagen content and the number of myofibroblasts were significantly reduced (respectively 46$\pm$2% and 66$\pm$4%, $p<0.05$). In the TGFβRI model, selective inhibition of AP-1 also exerted potent anti-fibrotic effects and reduced dermal thickening, collagen content and myofibroblast counts by 70$\pm$5%, 52$\pm$3% and 51$\pm$2%, respectively ($p<0.05$). T5224 was well tolerated: no weight loss, alterations of the skin texture or affected activity were recorded during the whole treatment period.

Conclusion: We demonstrate that AP-1 is activated in a TGFβ dependent manner in SSc and that inhibition of AP-1 specifically reduces collagen synthesis in activated SSc fibroblasts. The specific AP-1 inhibitor T5224 efficiently prevented the development of dermal fibrosis in different mouse models of SSc and was well tolerated. Thus, AP-1 might be a promising new molecular target for the treatment of SSc.

The Triterpenoid CDDO Abrogates Canonical TGF-beta Signaling and Fibrotic Responses in Normal and Scleroderma Fibroblasts by Stabilizing the Anti-Oxidant Nuclear Factor-Like 2 (Nrf2). Kazuhiro Komura[2], Jun Wei[2], Gabriel Lord[2] and John Varga[1]. [1]Northwestern Univ Feinberg School, Chicago, IL, [2]Northwestern University Feinberg School of Medicine

Background: Scleroderma is characterized by excessive collagen accumulation and fibrosis in multiple organs. TGF-β stimulates collagen synthesis and is implicated in the pathogenesis of fibrosis. 2-Cyano-3,12-Dioxooleana-1,9-Dien-28-Oic acid (CDDO) is a synthetic triterpenoid that is known to activate peroxisome proliferator activated receptor (PPAR)-γ. We previously demonstrated that PPAR-γ ligands abrogated the stimulation of collagen synthesis induced by TGF-β in fibroblasts, by disrupting canonical TGF-β signaling in a PPAR-γ dependent manner. The objective of the current study is to address the anti-fibrotic effect of CDDO in fibroblasts.

Methods: The mesenchymal progenitor 3T3-L1 cell line was incubated with CDDO to induce adipogenesis. Expression of adipogenic markers was examined by real-time qPCR and immunofluorescence. Modulation of PPAR-g promoter activity was examined in foreskin fibroblasts incubated with CDDO. Induction of profibrotic gene expression by TGF-β was evaluated by real-time qPCR and Western analysis. PPAR-γ dependence was evaluated using GW9662 a PPAR-γ antagonist. Nrf2 expression and activity were examined by Western blot, immunofluorescence and antioxidant response element (ARE) reporter assays. Effects of Nrf2 on canonical TGF-β signaling were examined by transient transfection in foreskin fibroblasts. Skin fibroblasts from 6 patients with diffuse cutaneous SSc were incubated with CDDO and profibrotic gene levels were measured by real-time PCR and Western analysis.

Results: CDDO induced a marked adipogenic response in 3T3-L1 cells. Moreover, CDDO significantly enhances PPAR-γ transcriptional activity. CDDO abrogated TGF-βinduced stimulation of collagen and α-smooth muscle actin (α-SMA) expression in a dose-dependent manner, and abrogated the stimulation of Smad2/3-mediated transcriptional activity induced by TGF-β. These inhibitory effects were PPAR-γ–independent. CDDO also caused a marked accumulation and nuclear localization of Nrf2. Moreover CDDO stimulated Nrf2-dependent transcriptional activity. Ectopic Nrf2 was sufficient by itself to abrogate TGF-β stimulation of Smad-dependent transcription. In scleroderma fibroblasts, CDDO caused significant suppression of collagen gene expression at mRNA and protein levels, and attenuated the myofibroblast phenotype of these cells.

Conclusion: The triterpenoid and novel PPAR-γ ligand CDDO abrogates canonical TGF-β signaling and suppresses fibrotic responses in a PPAR-γ-independent manner. Nrf2, a master regulator of the antioxidant response, is activated by CDDO in normal fibroblasts, and appears to mediate the CDDO inhibitory process. Nrf2 thus is a novel target for anti-fibrotic therapy, and pharmacological modulation of the Nrf2 expression or activity might have a therapeutic potential in scleroderma.

Urantide Prevents and Alleviates Monocrotaline Induced Pulmonary Arterial Hypertension in Wistar Rats. Yifang Mei[1], Hong Jin[3], Hao Wang[2], Wei Tian[2], Yanping Zhao[2] and Zhiyi Zhang[2]. [1]The First Affiliated Hospital of Harbin Medical University, Harbin, Heilongjiang, China, [2]The First Affiliated Hospital of Harbin Medical University, Harbin, China, [3]The First Affiliated Hospital of Shantou University Medical College, Shantou, China

Background: Pulmonary arterial hypertension (PAH) is a serious complication of connective tissue disease (CTD). Urotensin II (UII) has been confirmed to be the most powerful vasoconstrictor greater than endothelin-1, which may play an important role on PAH development.

Objective: To observe the effects of urantide, an UII receptor antagonist, on monocrotaline (MCT)-induced PAH in rats.

Methods: 60 male Wistar rats were divided into six groups. For early treatment experiment, rats were divided into normal control group, MCT_{4w} model group(MCT+saline×3wks from the 8th day of MCT-injection) and urantide early treatment group (MCT+urantide 10μg/kg/d×3wks from the 8th day of MCT-injection). For late treatment experiment, rats were dived as controls, MCT_{6w} model group(MCT+saline×2wks 4 weeks after MCT injected once), and urantide late treatment group (MCT + urantide 10μg/kg/d×2wks 4 weeks after MCT injected once). The relaxation effects of urantide on the intralobar pulmonary artery rings of control and MCT 4wks model rats were investigated. Then, the mean pulmonary arterial pressures (mPAP) of rats in each group were measured by flow-directed pulmonary artery catheter. Pulmonary artery remodeling was detected by hematoxylin and eosin (HE) staining. The rats plasma endothelial nitric oxide synthase (eNOS) and nitric oxide(NO) levels in all six groups were assayed by ELISA kits.

Results: Urantide dose-dependently relaxed the pulmonary artery rings of PAH model and normal rats. Moreover, L-NAME blocked the dilation response of urantide. Urantide reduced the mPAP in both early and late treatment groups and inhibited the pulmonary vascular remodeling remarkably. eNOS and NO levels in plasma elevated in both early and late treatment rats with urantide infusion.

Conclusions: Urantide effectively alleviated MCT induced PAH, at least partly, through mediating NO releasing, which provided a novel therapy for PAH.

Visfatin/NAMPT in Interstitial Pneumonia of Patients with Systemic Sclerosis and Scleroderma Mice Model Induced by Bleomycin. Hirahito Endo[2], Tatsuhiro Yamamoto[1], Kaichi Kaneko[3], Yoshie Kusunoki[3], Natsuko Kusunoki[3] and Shinichi Kawai[3]. [1]Division of Rheumatology, Department of Internal Medicine, Toho University School of Medicine, Ohmori-nishi, Ohta-ku, Japan, [2]Division of Rheumatology, Department of Internal Medicine, Toho University School of Medicine, Ohmori-nishi, Oh-taku, Japan, [3]Division of Rheumatology, Department of Internal Medicine, Toho University School of Medicine

Scleroderma intestinal lung disease(SLD) is a leading cause of morbidity and motality in patients with systemic sclerosis. Excessive fibrosis and inflammatory cell infiltration is a main features. Nicotinamide Phosphoribosyl Transferase/Visfatin (NAMPT/Visfatin) is an adipokine and a proinflammatory cytokine. To evaluate the significance of NAMPT/Visfatin in the diagnosis and monitoring of SLD we analyzed the concentration of NAMPT/Visfatin in bronchoalveolar lavage fluid (BALF) and plasma levels in SLD. Moreover we analyzed the role of NAMPT/Visfatin on experimental interstitial pneumonitis induced by bleomycin.

Methods: NAMPT/Visfatin concentration of BAL fluids and plasma of patients with SSc and other CTD. 12 patients with SSc and 20 patients with other CTD-IP (PM/DM,RA). Concentration of NAMPT/Visfatin were measured by enzyme- linked immunoabsorbent assay. Expression of NAMPT/Visfatin in lung tissue detected by immunohistochemistry. Expression of NAMPT/Visfatin mRNA also detected by RT-PCR. We also analyzed the NAMPT/Visfatin expression on lung injury induced by bleomycin was investigated in mice.

Results: Plasma concentration of NAMPT/Visfatin in SSc were significantly higher than healty subject (SLD 5.38 $\pm$1.09, Control 2.38$\pm$2.60 ng/ml,$P<0.05$). NAMPT/Visfatin concentration in BALF of SLD were not significantly higher than that of other CTD (SLD11.8$\pm$6.3, CTD-LD18.9$\pm$4.4 ng/ml). NAMPT/Visfatin concentration in BALF were not correlated with total lung capacity, the diffusion capacity for carbon monoxide, whereas there were correlated of BAL lymphocyte counts and serum KL-6 levels. NAMPT/Visfatin detected in macrophage and pulmonary epithelial cells of biopsy tissues of interstitial pneumonitis of patients with SSc. NAMPT/Visfatin also detected in mice bleomycin induced interstitial pneumonitis at 3 weeks(serum IP 5.28$\pm$0.25,Control 1.8 $\pm$0.68ng/ml, $P<0.05$). NAMPT/visfatin detected in pulmonary epithelial cells, macrophage, and endothelial cells in murine IP lung tissues by immunohistochemical analysis. NAMPT/Visfatin also detected in BALF in mice IP (IP 0.40$\pm$0.06 ng/ml, Control 0.18$\pm$0.12ng/ml). NAMPT/Visfatin augmented the proliferation of cultured lung fibrobrast derived from interstial peumonitis lung tissue. NAMPT/Visfatin also induced Col I, IL-6, and MCP-1 mRNA in cultured lung fibroblasts.

Conclusions: These data suggest that Visfatin/NAMPT is a new therapeutic target of SLD.

Platelet C4d Is Associated with All-Cause Mortality in Patients with Systemic Lupus Erythematosus. Christine A. McBurney[5], Amy H. Kao[2], Abdus Sattar[3], Apinya Lertratanakul[6], Nicole L. Wilson[4], Rutman Sarah[6], Barbara Paul[6], Jeannine S. Navratil[6], Joseph M. Ahearn[1] and Susan Manzi[7]. [1]Wexford, PA, [2]Allegheny Singer Research Institute, Pittsburgh, PA, [3]Case Western University, [4]Magee Womens Hospital of UPMC, Pittsburgh, PA, [5]University of Pittsburgh Medical Center, Pittsburgh, PA, [6]University of Pittsburgh School of the Health Sciences, [7]West Penn Allegheny Health System, Pittsburgh, PA

Background: Platelets bearing complement C4d (P-C4d) are reported to be specific for a diagnosis of systemic lupus erythematosus (SLE) and are associated with ischemic stroke. We investigated the association of P-C4d with all-cause mortality and prevalent cardiovascular disease (CVD) events in our longitudinal cohort of patients with SLE.

Methods: We recruited 356 consecutive outpatients or inpatients with SLE since July 2001. Outcomes were all-cause mortality and cardiovascular events including myocardial infarction, coronary artery bypass graft, percutaneous coronary transluminal angioplasty, stroke, pulmonary embolism, deep vein thrombosis or other thrombosis. P-C4d status was determined by flow cytometry.

Results: Mean age was 44.4 years (range: 18 – 81 years), 92% were female, and 81% were Caucasian. Seventy SLE patients (20%) had positive P-C4d at baseline. PC4d-positive patients were more likely to have a history of renal disease, seizure disorder, hemolytic anemia, thrombocytopenia, anti-double stranded DNA (dsDNA) and/or antiphospholipid antibodies. Overall CVD event frequency was 21.6%. SLE patients with positive P-C4d had significantly more CVD events compared to those with negative P-C4d (35.7% vs. 18.2%, p=0.001). Positive P-C4d at baseline was associated with stroke, but not with other cardiovascular events (odds ratio 4.96, 95% confidence interval 1.75–14.06, p=0.003) after adjusting for age, race, smoking history, SLE disease duration, renal disease, dsDNA and antiphospholipid antibodies. The overall mortality was 3.9%. Causes of death were infection (n=4), cardiac arrest (n=2), congestive heart failure (n=1), cancer (n=2), hemorrhage (n=1), and unknown (n=4). Six of these 14 deceased patients had a history of cancer (ovarian carcinoma, lymphoma, lung cancer, anal squamous cell carcinoma). Positive P-C4d at baseline was associated with all-cause mortality (hazard ratio 7.92, 95% CI 2.13–29.48, p=0.002) after adjusting for age, race, sex, SLE disease duration, renal disease, cardiovascular event, cancer, dsDNA and antiphospholipid antibodies.

Conclusions: Platelet C4d is associated with all-cause mortality and stroke. Platelet C4d may be a prognostic biomarker as well as a pathogenic clue that links systemic inflammation, complement activation, and thrombosis and may represent a subset of patients with poor clinical outcomes.

β2-Glycoprotein Exists in a Distinct Molecular Post-Translational Oxidative State in the Antiphospholipid Syndrome: Novel Prognostic Assays and Insights into Antigenicity. Yiannis Ioannou[10], Jing-Yun Zhang[8], Miao Qi[11], Gao Lu[12], Jian Cheng Qi[11], De-min Yu[7], Herman Lau[6], Allan D. Sturgess[5], Panayiotis Vlachoyiannopoulos[4], Haralampos M. Moutsopoulos[3], Anisur Rahman[9], Pericleous Charis[9], Tatsuya Atsumi[1], Takao Koike[2], Bill Giannakopoulos[11] and Krilis A. Steven[11]. [1]Hokkaido University, Sapporo, Japan, [2]Hokkaido University, Japan, [3]Natl Univ of Athens Med Schl, Athens, Greece, [4]Natl Univ of Athens Med Schl, [5]St. George Hospital, Sydney, NSW, Australia, [6]St. George Hospital, [7]Tianjin Medical University, [8]Tianjin Medical University, University of New South Wales, [9]University College London, [10]University College London, University of New South Wales, [11]University of New South Wales, [12]University of New South Wales, Tianjin Medical University

Background: We have recently reported the novel finding that the major autoantigen in the antiphospholipid syndrome (APS), β2-glycoprotein I (β2GPI), exists in serum in a biochemically reduced state with free thiols (1). This study aims to characterise the oxidative molecular state of β2GPI with respect to free thiol content in APS and evaluate relevance to antigenicity.

Methods: Through a multi-centre collaborative effort (Sydney, Athens, London, Sapporo), a total of 502 patient samples were collected from APS patients and three control groups: 182 APS (93 had an additional autoimmune disease (AID), 189 AID controls (± persistent antiphospholipid antibodies (aPL) but no APS), 38 clinical event controls (vascular thrombosis, no AID) and 93 healthy controls. Each sample was assayed for total levels of β2GPI and relative amounts of β2GPI present with free thiols. This was performed as described previously (1) and based upon a sandwich ELISA system using a biotinylated free thiol binding reagent to capture proteins with free thiols on a streptavidin plate and detect β2GPI using a monoclonal anti-β2GPI antibody. Oxidised versus reduced β2GPI binding avidity to polyclonal patient anti-β2GPI antibodies was then assessed.

Results: Total levels of β2GPI were significantly increased in the APS group (216.7 ± 79.5 μg/ml, median ± SD, n=181) as compared to all of the three control groups studied (p≤0.0001). No differences were observed between the other three groups. The relative proportion of β2GPI in the biochemically reduced form expressed as a percentage of that observed with the in-house standard was significantly less in APS patients (median ± SD, 57.15% ± 23.5, n=177) as compared to healthy control (p≤0.001), AID disease control (p≤0.001) and clinical event control (aPL negative, p≤0.001) groups. Hence, β2GPI in APS patients is in an oxidised state relative to each of the other three control groups. Sub-analyses of the APS group with anti-β2GPI positivity reveals that APS patients with LA positivity harbour the lowest proportion of β2GPI with free thiols (anti-β2GPI + LA, 47.52% ± 22.96 (median ± SD, n=49) versus anti-β2GPI without LA 74.93% ± 17.86 (median ± SD, n=28), p≤0.001). IgG from 10 patients with APS was purified. β2GPI within plasma derived from healthy volunteers oxidised by pre-incubation with H2O2 was a significantly better inhibitor of anti-β2GPI activity than untreated serum (p≤0.001, n=10).

Conclusion: In APS patients, a greater proportion of β2GPI circulates in an oxidised versus reduced state relative to disease and healthy control groups. The finding that oxidised β2GPI harbours a greater avidity for patient derived anti-β2GPI antibodies coupled with the observation that APS patients have a greater antigenic load supports the theory that high amounts of oxidised β2GPI may lower the threshold for breaking tolerance, driving antigenicity and hence anti-β2GPI production in autoimmune susceptible patients.

Normal Monocyte and Fibrocyte Behavior in Scleroderma Is Restored by Caveolin-1 Scaffolding Domain (CSD) Peptide: Implications for Treating Scleroderma Lung Disease. Elena Tourkina, James Oates, Ann Hofbauer, Michael Bonner, Richard P. Visconti, Jing Zhang, Richard M. Silver and Stanley Hoffman. Medical University of SC

Purpose: Scleroderma (systemic sclerosis, SSc) is a complex autoimmune disease characterized by inflammation and fibrosis of the skin, lungs and other organs. Despite the accepted importance of the contribution of monocyte-derived fibrocytes in the development of lung fibrosis, their role in scleroderma is not clear. The aim of this study was to investigate the role of caveolin-1 on monocyte and fibrocyte migration into injured lung tissue in scleroderma and in the animal model of bleomycin-induced lung fibrosis.

Methods: Normal lung tissue was obtained from the Brain and Tissue Bank of Developmental Disorders; Scleroderma lung tissue was obtained from autopsy of patients at the Medical University of South Carolina (MUSC). The study was approved by MUSC's IRB for Human Subject Research. Monocytes (PBM) were isolated from blood of scleroderma and healthy donors using negative selection. Scleroderma patients fulfilled the preliminary ACR criteria for the classification of systemic sclerosis. Monocyte migration was assayed in Multiwell Chemotaxis Chambers, with or without priming with TGFβ and with or without treatment with caveolin-1 scaffolding domain (CSD) peptide and control peptides. Fibrocytes in human peripheral blood and mouse lungs were detected by flow cytometry. Protocols for bleomycin-induced lung injury and CSD peptide treatment were approved by MUSC's Institutional Animal Care & Use Committee. Ten-week old,

male CD1 mice received daily i.p. injections of CSD or control peptide throughout the entire experiment from the day prior to bleomycin treatment until the day of sacrifice. Mice were treated intra-orally with bleomycin or PBS vehicle. Seven days after bleomycin treatment, lungs were removed and analyzed.

Results: Fibrocytes were observed in lung tissue of scleroderma patients (n=7), but not healthy control subjects (n=4). Upregulation of fibrocytes (CD45+/Col+, CD45+/CXCR4+, and CD45+/CXCR4+/Col+) was observed in the peripheral blood of scleroderma patients (n=7) compared to healthy control subjects (n=9): 2.5 ± 0.3 % vs 1.0 ± 0.07 %; 3.0 ± 0.5 % vs 1.0 ± 0.08 %; and 0.74 ± 0.09 vs 0.4 ± 0.08 %, respectively. Scleroderma PBM also differed from control PBM in signaling and in function. On average, SSc PBM contained less than half as much caveolin-1 and three-fold more CXCR4 compared to normal PBM. The percentage of scleroderma PBM that migrated in response to the CXCR-4 ligand, CXCL12, was more than four-fold enhanced compared to normal PBM. When scleroderma PBM were treated with the CSD peptide to overcome their diminished expression of caveolin-1, CXCR4 expression and migration in response to CXCL12 were inhibited by at least 80%. Similar results were obtained in vivo in a mouse model. CSD peptide inhibited bleomycin-induced recruitment of CD45/CXCR4/Col-positive cells into injured mouse lung tissue by > 50 %.

Conclusion: Our results support the notion that using the CSD peptide to compensate for low caveolin-1 levels may be a useful treatment strategy for scleroderma and other inflammatory/fibrotic lung diseases.

Clinical, Radiographic and Biomolecular Features of B Cell Synovitis in Rheumatoid Arthritis. Serena Bugatti[2], Antonio Manzo[2], Barbara Vitolo[2], Chiara Fusetti[2], Roberto Caporali[2], Costantino Pitzalis[1] and Carlomaurizio Montecucco[2]. [1]Centre for Experimental Medicine and Rheumatology, John Vane Science Centre, William Harvey Research Institute, St. Bartholomew's and Royal London School of Medicine, London, [2]Chair and Division of Rheumatology, Laboratory of Rheumatology, University of Pavia, Fondazione IRCCS Policlinico San Matteo, Pavia, Italy

Objective: Despite the central participation of B lymphocytes in the autoimmune process of rheumatoid arthritis (RA), the biologic and clinical impact of the B cell compartment at the site of inflammation itself, i.e. the synovial membrane, has not been consistently established. The aim of the present study was to investigate whether synovial B cell follicles are associated to specific clinical and molecular features of inflammation, immunological activity and bone remodeling in RA.

Methods: Multiple synovial biopsies were collected from 67 consecutive RA patients and evaluated histologically and by immunohistochemistry (IHC). From 25 of the 67 patients, paired paraffin and RNA samples were available and used for histological/IHC analysis and quantitative real-time polymerase chain reaction. The degree of B cell infiltration was determined semi-quantitatively (0–3) based on the size and density of CD20+ B cell aggregates and correlated to: 1) histopathologic features; 2) clinical parameters of disease activity and radiographic damage; 3) molecular markers of inflammation, T and B cell immunologic activity, bone damage and bone repair.

Results: The CD20+ B cell score was significantly related to mRNA expression levels of CXCL13 (rho 0.8, $p = 0.0001$) and lymphotoxin-β (rho 0.7, $p = 0.0006$), confirming the validity of the histological assessment. The degree of synovial B cell infiltration was associated to histological features of inflammation, such as the total inflammatory score (rho 0.6, $p < 0.0001$) and sublining infiltration of CD68+ macrophages (rho 0.4, $p = 0.001$). However, no correlation with systemic markers of inflammation was found. Instead, large-size B cell aggregates (CD20+ B cell scores 2 and 3) were independently associated to radiographic erosive disease in a multivariate logistic regression model including disease duration and serum auto-antibodies (OR 7.99, 95% CI 1.83–34.83; $p = 0.006$). Higher degrees of B cell infiltration were closely associated to increased mRNA expression of markers of activation of T cells, such as interferon-γ ($p = 0.001$) and interleukin-17 ($p = 0.005$), and B cells, such as activation-induced cytidine deaminase (AID) ($p = 0.02$). Relevantly, samples characterized by large-size B cell aggregates also exhibited an increased RANKL/osteoprotegerin (OPG) ratio ($p = 0.008$) due to reduced OPG levels ($p = 0.02$) rather than to increased RANKL ($p = 0.2$). Confirming the association with unbalanced bone remodeling, the expression levels of bone morphogenetic protein-2 and -7 tended to be lower in the presence of higher scores of B cell infiltration ($p = 0.07$ and $p = 0.05$ respectively).

Conclusions: The presence of large-size B cell aggregates in RA synovium is independently associated to a more aggressive pattern/status of the disease characterized by a higher frequency of radiographic erosions and a molecular milieu of increased immunological activity and unbalanced bone remodeling. Our data provide novel cues for further pathogenic and prospective clinical studies assessing the relationship between the synovial pattern of lymphoid infiltration and inflammation/joint damage in RA.

Association of FRZB Variants with Hip Shape and Radiographic Hip Osteoarthritis: Preliminary Results. Julie Baker-LePain[4], Kali Luker[2], John A. Lynch[4], Neeta Parimi[1], Michael C. Nevitt[3], Mary Corr[6] and Nancy E. Lane[5]. [1]California Pacific Medical Center, [2]Stanford, [3]UCSF, San Francisco, CA, [4]UCSF, [5]Univ of California at Davis, Hillsborough, CA, [6]Univ of California-San Diego, La Jolla, CA

Background: Single nucleotide polymorphisms (SNPs) in the FRZB gene, which encodes the Wnt antagonist secreted frizzled-related protein 3 (sFRP3), are significant predictors of radiographic hip osteoarthritis (RHOA) (Lane, et al., A&R 2006). In addition to FRZB, another important predictor of incident RHOA is hip shape (Lynch, et al., O&C 2009). Since the Wnt pathway is a key regulator of joint development, we examined whether FRZB variants are associated with hip shape and to what extent the relationship between joint shape and RHOA is affected FRZB.

Methods: We performed a nested case-control study within the Study of Osteoporotic Fractures (SOF). Subjects were Caucasian women aged >= 65 years with supine pelvic radiographs at baseline visit and at follow-up (mean 8.3 years). RHOA was scored radiographically using a modified summary grade (scale 0–4). Cases (n = 451) were defined as subjects with no baseline radiographic hip OA (RHOA) in either hip at baseline and incident RHOA (summary grade ≥ 2) at follow-up. Controls (n = 601) had no RHOA at either time point. We determined hip shape at 2 sites: the proximal femur by active shape modeling (ASM) (Lynch et al., O&C 2009) and the acetabulum by the center-edge angle and acetabular depth. Genotyping for the rs288326 SNP of FRZB was performed using allele-specific polymerase chain reaction (PCR). Linear regression was used to determine the association of hip shape parameters with the presence of the rs288326 FRZB SNP.

Results: In preliminary analsis, we found that among controls, proximal femur shape (Mode 2 from ASM analysis) was associated with the rs288326 FRZB SNP (coefficient −0.18, 95% CI −0.35 to 0.03, $p = 0.05$) after adjustment for age and femoral neck BMD. The presence of the rs288326 allele modified the association between proximal femur shape Mode 2 and RHOA (p-value for trend = 0.01, see Figure). Similarly, in preliminary results (n = 202 cases and n = 512 controls), the rs288326 allele modified the association between acetabular depth/center edge angle and RHOA (p-value for trend < 0.001).

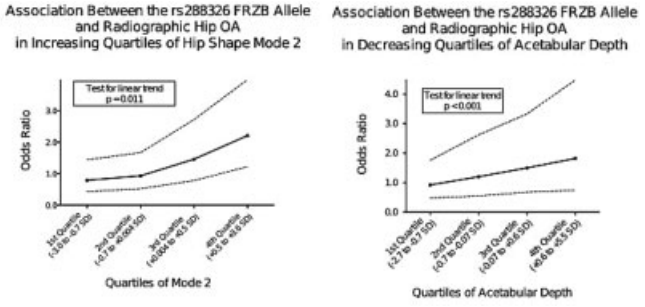

Figure. Quartiles of increasing proximal femur ASM Mode 2 or decreasing acetabular depth were created using control populations, and the association between the rs288326 FRZB allele and incident RHOA was examined in each quartile using logistic regression. Odds ratio with 95% CI is shown, together with p-value for test of linear trend. The referent group was subjects without the rs288326 FRZB allele.

Conclusions: Hip shape is known to be an important predictor of incident OA. In this preliminary analysis, we find that variants in the FRZB gene, a component of the Wnt pathway, may be involved in moderating the relationship between hip shape and OA. We hypothesize that Wnt pathway components play a key role in determination of joint shape, which in turn may predispose to development of osteoarthritis in a conducive architectural setting.

The Assessment of Health-Related Family Functioning in Systemic Lupus Erythematosus: Preliminary Validation of the SLE-FAMILY. Afton L. Hassett[6], Tracy Li[1], Diane C. Radvanski[3], Steven Buyske[2], Samuel A. Schiff[4] and Patricia P. Katz[5]. [1]Bristol-Myers Squibb, Princeton, NJ, [2]Rutgers University, [3]UMDNJ-Robert Wood Johnson Medical School, Union City, NJ, [4]UMDNJ-Robert Wood Johnson Medical School, [5]Univ of CA San Francisco, San Francisco, CA, [6]University of Michigan Medical School, Ann Arbor, MI

Background: Patients with systemic lupus erythematosus (SLE) often experience disabling symptoms that affect family relationships. To assess the impact of SLE on health-related family functioning we developed the SLE-FAMILY which evaluates six key domains: Fatigue (fatigue-related family activity impairment), Activities (general family activity impairment), Mental Health (emotional impact on family), Isolation (feelings of isolation from family), Love (loss of intimacy) and You (fulfilling family roles). The 6-item SLE-FAMILY has scores ranging from 1–7 with higher scores indicating worse family functioning. The major objectives of this study were to pilot test and achieve preliminary validation for the SLE-FAMILY.

Methods: 52 patients with SLE completed questionnaires including the 6-item SLE-FAMILY, SF-36, Sheehan Disability Scale (SDS), Fatigue Severity Scale (FSS), Multidimensional Scale of Perceived Social Support (MSPSS), Satisfaction with Life Scale (SWLS), Positive and Negative Affect Scale (PANAS) and the Systemic Lupus Activity Questionnaire (SLAQ). Data were analyzed for internal consistency reliability with Cronbach's alpha. Next, item statistics were calculated to assess the correlations between individual items and SLE-FAMILY total score. To evaluate convergent and discriminant validity, correlations between the SLE-FAMILY and the other measures were calculated.

Results: Mean age for the 52 participants was 36.8 (SD11.9) years with a mean duration of illness of 8.4 years (SD6.7). Most were female (88.5%). The SLE-FAMILY had good test-retest reliability (0.83) and internal consistency (0.67). However, reliability analysis of individual items revealed a weakness in the performance of Item 5. Raw data were reviewed and it was determined that 9 patients likely overlooked the reverse-scoring of Item 5, thus explaining its poor reliability. When the 9 patients were excluded from the analysis, alpha increased to 0.71, while test-retest reliability remained acceptable (0.78). Spearman's rho correlations supported the validity of the SLE-FAMILY as its total score was significantly related to SDS Family ($r=0.67$, $p<.001$) and SDS Social ($r=0.60$, $p<.001$); SLAQ ($r=0.68$, $p<.001$); PANAS negative subscale ($r=0.55$, $p<.001$) and FSS ($r=0.62$, $p<.001$). Similarly, the SLE-FAMILY total score was inversely related to relevant SF-36 subscales scores including: Social Functioning ($r=-0.55$, $p<.001$), Role Emotional ($r=-0.42$, $p=.005$), Role Physical ($r=-0.59$, $p<.001$) and Mental Health ($r=-0.48$, $p=.001$).

Conclusion: The SLE-FAMILY is a promising new instrument for the more robust measurement of family functioning. Additional pilot testing using revised scoring options for Item 5 and additional validation studies are underway.

Heart-Rate Recovery Immediately after Graded Exercise in Woman with Systemic Lupus Erythematosus. Danilo M. L. Prado[1], Fabio Baptista[1], Renata Miossi[1], Fernanda R. Lima[1], Ana Lucia S. Pinto[1], Eduardo F. Borba[3] and Eloisa Bonfa[2]. [1]USP, Sao Paulo, SP, Brazil, [2]USP, Sao Paulo, Brazil, [3]USP

Patients with systemic lupus erythematosus (SLE) are known to have lower heart rate variability suggesting impaired autonomic modulation. Heart-rate recovery after maximal graded exercise test has been identified as a strong independent predictor of cardiovascular and all-cause mortality in adults. Previous studies suggested that low heart-rate recovery is in part due to attenuated parasympathetic reactivation and sympathetic overactivity following the termination of exercise. Besides this knowledge, there is little information about this issue in SLE.

Purpose: To evaluate the heart-rate recovery after graded exercise in SLE.

Methods: Eighteen consecutive SLE women (SLE group) with low SLEDAI scores (1.0 ± 2.3) without cardiopulmonary involvement were selected and compared to 17 healthy women (control). All subjects performed a progressive treadmill cardiopulmonary test until exhaustion to determine the maximal aerobic capacity. Heart rate recovery at both one minute (ΔHRR1) and two minutes (ΔHRR2) were defined as the difference between heart rate at peak of exercise and at 1 and 2 minutes post exercise, respectively.

Results: Age (29.6 ± 1.3 vs. 26.2 ± 1.5 years, $p=0.10$) and Body-mass index (23.7 ± 0.8 vs. 21.8 ± 0.5 kg/m2, $p=0.09$) were alike between SLE and control group. SLE had significant lower peak workload (4.6 ± 0.1 vs. 5.6 ± 0.0 mph, $P=0.001$) and relative lower aerobic fitness [VO2peak] (28.3 ± 1.0 vs. 37.1 ± 1.2 mL.kg-1.min-1, $P=0.001$) compared to control.

	Heart Rate Recovery Post Graded Exercise		
	SLE	Control	P value
(ΔHRR1)	25.9 ± 1.5	32.7 ± 2.0	0.01
(ΔHRR2)	41.7 ± 1.6	52.1 ± 2.1	0.001

Values are means ± SE. ΔHRR1 - heart rate recovery at one minute; ΔHRR2 - heart rate recovery at two minutes. (Unpaired students T Test). $P < 0.05$ considered statiscally significant.

Conclusion: These findings demonstrated that woman with SLE had reduced heart rate recovery at first and second minutes after graded exercise compared to controls. Taken together, these data suggest abnormal restoration of autonomic nervous tone including a decrease in vagal tone and an increase in sympathetic activity after graded exercise in these patients.

Body Composition, Lower Extremity Strength, and Fatigue in SLE. Patricia Katz, Laura Julian, Jinoos Yazdany, Holly Wing, Sandi Kaplan, Laura Trupin and Ed Yelin. UCSF

Background: Fatigue is widely acknowledged as a major concern for individuals with rheumatoid arthritis, but less attention has been focused on fatigue in systemic lupus erythematosus (SLE). Additionally, there has been little research addressing the relationship of body composition and fatigue. These analyses examine the role of body composition and muscular weakness in fatigue among women with SLE.

Methods: All measures were collected during an in-person research visit. Fatigue was measured with the severity subscale of the Multidimensional Assessment of Fatigue (MAF), in which scores range from 1 (mild) to 10 (severe). Body composition was assessed by dual-energy x-ray absorptiometry (DEXA), which yielded measures of total, as well as regional (appendicular and trunk) body fat and lean mass, each of which was adjusted for height to create fat and lean mass indices (FMI; LMI). Lower extremity strength was assessed using a Biodex® Unit. Peak torque at knee extension and flexion at 150 degrees/second were used in these analyses. SLE disease activity was estimated with a modified version of the SLEDAI. Regression analyses, controlling for age, duration of SLE, and disease activity, modeled the effects of body composition and lower extremity strength on fatigue. (Knee extension and flexion were examined in separate models.) This analysis focuses on the 115 women for whom complete data were available. (30 women were missing either DEXA or strength testing data).

Results: Mean age was 48 (±12) years; duration of SLE was 16 (±9) years. Mean fatigue rating was 5.9 (±2.3); 30% rated fatigue severity at 7 or

greater. Mean total percent body fat was 41%. Mean peak torques at knee extension and flexion were 38 (±12) and 29 (±8) foot-pounds, respectively. Controlling for age, disease duration, and disease activity, neither total FMI nor LMI were significantly associated with fatigue severity. However, when appendicular and trunk FMI were examined separately, greater trunk FMI was significantly associated with greater fatigue (β=0.25, p=0.01). Muscle weakness was also significantly and independently associated with greater fatigue (extension: β=−0.04, p=0.03; flexion: β=−0.06, p=0.005).

Conclusions: A substantial portion of this group of women with SLE experienced severe fatigue. Both abdominal obesity and muscle weakness play an important role in fatigue among women with SLE.

Physical Exercise Improves Endothelial Function in Patients with Systemic Lupus Erythematosus. Edgard T. Reis Neto, Aline E. Silva, Carlos M. C. Monteiro, Luciano M. Camargo, Neusa P. Silva, Marcelo M. Pinheiro and Emilia I. Sato. Universidade Federal de São Paulo, Brazil

Background: Cardiovascular disease (CVD) is an important cause of morbidity and mortality in systemic lupus erythematosus (SLE). Endothelial dysfunction is implicated in the pathogenesis of premature atherosclerosis in SLE and there are studies showing improvement of endothelial function (EF) after physical exercise program in individuals with heart failure, diabetes and coronary arterial disease.

Objectives: to assess the effect of supervised physical exercise (SPE) on the EF, quality of life, fatigue, exercise tolerance and body composition in SLE patients.

Methods: prospective and controlled study in which women with SLE (18–45 years old) were allocated according to availability to participate in the exercise program in the exercise group (EG) or control group (CG). Intervention: SPE were performed 3 times a week for 16 consecutive weeks and consisted of 10 minutes of initial warm-up/stretching, 40 minutes of walking performed at a heart rate corresponding to the ventilatory anaerobic threshold (obtained with ergospirometric test), and 10 minutes of cooling-down. Patients were evaluated at baseline (T0) and after 16 weeks (T16) by high-resolution ultrasound of brachial artery in resting conditions, after reactive hyperaemia (flow-mediated dilation-FMD) and after oral glyceryl trinitrate (GTMD) for evaluating endothelial function; quality of life (SF-36 index); perceived exertion (Borg scale), fatigue (Krupp scale) and body composition (DEXA).

Results: Four hundred and eight patients were invited to participate in the study, 186 manifested interest but 109 were excluded due to exclusion criteria and only 21 were included in the study. Nineteen patients completed the evaluations (average age: 33.4±8.7 years and mean disease duration: 102.6±80.7 months). Twelve patients were allocated on EG and 7 on CG. Both groups were homogeneous and comparable at baseline regarding demographics variables. The average dose of prednisone was 8.5±12.9mg/day; 78.5% were using anti-malarials and 36.8% immune-suppressants. 15.8% had hypertension, 15.8% dyslipidemia and 21.8% had family history of coronary disease. In the EG we observed a significant increase in FMD (8.3±7.2% *vs* 16.4±8.9%, p=0.011) without changes in GTMD (21.3±6.1% *vs* 24,4±8.5%, p=0.334). In GC there was no increase in FMD (3.7±4.5% *vs* 5.6±4.6%, p=0.526) neither GTMD (26.1±6.2% *vs* 25.6±9.1%, p=0.884). In the EG we also found a significant improvement in exercise tolerance (11.8±2.1min *vs* 13.3±2.1min, p=0.02), maximum velocity (7.5±1km/h *vs* 8.3±1.1km/h, p=0.049), threshold velocity (5.5±0.6km/h *vs* 5.9±0.6km/h, p=0.011), functional capacity (66.2±23.8 *vs* 82.1±11.6, p=0.035) and vitality (72.9± 31.4 *vs* 78.8±19.7, p=0.007), with a tendency to improvement in fatigue (3.75±1,76 *vs* 2.49±1.13, p=0.06). None of these parameters changed significantly in the CG. There was no significant change in body composition in both groups.

Conclusion: despite the small number of patients, this is the first study demonstrating that SPE can improve endothelial function in SLE patients. Physical exercise can be a useful strategy to prevent CVD morbidity and mortality in these patients.

TNF and IL-6 Differentially Regulate the Production of DKK-1, a Master Regulator of Bone Remodelling, by Fibroblast-Like Synoviocytes. Nataliya Yeremenko[2], Karin Polzer[3], Gemma Righter[2], Radjesh Bisoendial[2], Jochen Zwerina[3], Georg Schett[3], Paul P. Tak[1] and Dominique Baeten[1]. [1]Academic Med Ctr/Univ of Amsterdam, Amsterdam, The Netherlands, [2]Division of Clinical Immunology and Rheumatology, Academic Medical Centre/University of Amsterdam, Amsterdam, The Netherlands, [3]Internal Medicine 3, Erlangen, Germany

Background: Different inflammatory joint diseases have distinct patterns of bone damage with pronounced erosions in rheumatoid arthritis (RA), a combination of bone destruction and formation in psoriatic arthritis (PsA), and dominant new bone formation in spondyloarthritis (SpA). Although the underlying molecular mechanisms remain poorly understood, blocking of Dickkopf-1 (DKK-1), an inhibitor of the Wnt pathway, reverses the bone-destructive pattern to a bone-forming pattern in experimental arthritis. In order to delineate the role of DKK-1 in the structural phenotype of SpA versus RA, we analyzed here the regulation of DKK-1 expression in the inflamed peripheral joint of different types of inflammatory arthritis *ex-vivo* and in fibroblast-like synoviocyte (FLS) cultures *in vitro*.

Methods: Synovial fluid (SF) was obtained from actively inflamed knee joints of RA (n=45), non-psoriatic SpA (n=38), PsA (n=33), and gout (n=17) patients. The concentrations of IL-6, DKK-1, TNF, and IL-1 beta were determined by ELISA. Synovial FLS lines were established from tissue samples obtained from patients with inflammatory synovitis including RA (n=5), SpA (n=6), PsA (n=6). Expression of DKK-1 was determined by ELISA in FLS cultures following stimulation with TNF, IL-1 beta, IL-6, LPS and oncostatin M (OSM). DKK-1 serum levels were assessed before and after IL-6R blockade in RA patients.

Results: SF DKK-1 levels were similar between the 4 disease groups with, however, a striking inter-individual variability within each cohort. As we previously demonstrated that DKK-1 production is strongly upregulated by TNF, we explored this inter-individual variability by correlating DKK-1 levels with pro-inflammatory cytokines levels in the inflamed joint. TNF and IL-1 beta levels were significantly higher in RA than SpA SF and did not correlate with SF DKK-1 levels, suggesting that other factors contribute to the regulation of DKK-1 in vivo. In contrast, there was a striking inverse correlation between DKK-1 and IL-6 in both RA and SpA. Exploring the functional impact of IL-6 on DKK-1 in vitro, DKK-1 production by RA, SpA, and PsA FLS was strongly induced by TNF (but not IL-1 beta) but clearly suppressed by IL-6 and OSM. This suppression was confirmed in dose-response experiments, although lower doses of IL-6 (10 ng/ml) have a stimulatory rather than inhibitory effect. Higher doses of IL-6 (50 ng/ml) were also able to reverse the TNF-induced upregulation of DKK-1 production by FLS. Preliminary data suggest that this regulation of DKK-1 production by IL-6 is also relevant in vivo as treatment with the anti-IL-6 R antibody, tocilizumab, induced a transient upregulation of DKK-1 serum levels in RA patients.

Conclusions: DKK-1 is abundantly expressed in the inflamed joint of both destructive and remodelling forms of arthritis. However, DKK-1 production by FLS is differentially regulated by TNF and IL-6 in vitro and in vivo. The relative balance between these factors in the arthritic joints may determine the pattern of inflammation-induced tissue remodelling.

Adipogenic and Osteogenic Switch in Differentiation of Human Mesenchymal Stem Cells (hMSCs) Is Triggered by Hypoxia in a HIF-1 Dependent Manner. Markus Wagegg[3], Timo Gaber[1], Ferenz Lohanatha[1], Manuela Jakstadt[1], Grit Kasper[2], Georg Duda[2], Paula Kolar[3], Gerd R. Burmester[4] and Frank Buttgereit[5]. [1]Berlin-Brandenburg Center for Regenerative Therapies (BCRT), [2]Charité University Hospital, Center for Musculoskeletal Surgery, Berlin, Germany, [3]Charité University Hospital, Department of Rheumatology and Clinical Immunology, Berlin, Germany, [4]Charité University Hospital, Department of Rheumatology and Clinical Immunology, Berlin, Germany, [5]Charite University Med-Berlin, Berlin, Germany

Background: Bone regeneration is often impaired in elderly people as well as in people suffering from autoimmune diseases such as rheumatoid arthritis (RA). Bone fractures initiate series of cellular and molecular events that commence with hematoma formation, induction of inflammatory cascades which regulate hMSCs recruitment and finally differentiation. Due to the disruption of supplying blood vessels, hypoxia and the induction of the transcription factor hypoxia-inducible factor (HIF)-1 are considered to have considerable influence on these events.

Objectives: Here, we analyzed the impact of hypoxia and HIF-1 on the adipogenic and osteogenic differentiation potential of hMSCs.

Methods: Human MSCs isolated from bone marrow were characterized for their ability to differentiate into adipogenic, osteogenic and chondrogenic lineage cells and for their expression of surface markers. Adipogenesis and osteogenesis were induced by respective conditioned media. The cells were cultured for 14 and 28 days under normoxia (20% O2 air fraction) and hypoxia (<2% O2 air fraction), respectively. Adipogenic differentiation was assessed by oil-red staining, osteogenic differentiation by von Kossa staining. Additionally, the expressions of the adipogenic gene peroxisome proliferator-activated receptor γ (PPARγ), and the osteogenic genes osteopontin (SPP1) and runt-related transcription factor 2 (RUNX2) were measured by real-time PCR. For defining the role of HIF-1, a knockdown of HIF-1α (the oxygen-sensitive α-subunit of HIF-1) by lentiviral transduction was performed, and the ability of the transduced MSCs to differentiate into adipogenic and osteogenic lineage cells was analyzed.

Results: Hypoxia led to the induction of HIF-1α, suppressed adipogenesis, and further enhanced osteogenesis in hMSCs. In case of adipogenesis, we observed a 13fold induction of PPARγ after 28 days under normoxia when compared to hypoxia. In the event of osteogenesis, SPP1 and RUNX2 were both found to be up-regulated under hypoxia when compared to normoxia (SPP1: 2fold; RUNX2 10.5fold; after 14 days). Furthermore, shRNA mediated knockdown of HIF-1α enhanced adipogenesis under both normoxia and hypoxia. In addition knockdown of HIF-1α suppressed hypoxia-induced osteogenesis.

Conclusion: We show that hypoxia considerably influences bone healing by promoting osteogenesis while suppressing adipogenesis of hMSCs in a HIF-1 dependent manner. Therefore, stem cell therapy in combination with chemically induced hypoxia might be a novel approach to improve fracture healing in elderly people with an impaired bone healing and in patients suffering from autoimmune diseases such as RA.

Mitochondrial 8-Oxoguanine DNA Glycosylase (Ogg1) Regulates the Cellular Function and Survival of Osteoarthritic Chondrocytes in Response to Catabolic Stresses in Osteoarthritis. Kazuo Yudoh[2] and Rie Karasawa[1]. [1]Kawasaki, Japan, [2]St. Marianna University School Medicine, Kawasaki City, Japan

Background: During the development of osteoarthritis (OA), mechanical and chemical stresses on articular cartilage change the stable cellular activities of chondrocytes and produce excess amounts of reactive oxygen species (ROS) as well as proinflammatory cytokines and chemokines. Studies have provided ample confirmation of the generation of ROS and the depletion of cellular antioxidants in degenerated articular cartilage. 8-Oxoguanine DNA glycosylase (Ogg1) repairs 8-oxo-7,8-dihydroxyguanine (8-oxoG), one of the most abundant DNA adducts caused by oxygen free radicals. In the mitochondria, Ogg1 is thought to protect against activation of the intrinsic apoptotic pathway in response to oxidative stress by augmenting DNA repair in a variety of cells. However, it still remains unclear whether mitochondrial Ogg1 regulates the chondrocyte function and cellular survival in osteoarthritic cartilage tissue.

Objective: The aim of the study was examined the potential involvement of mitochondrial Ogg1 in the pathogenesis of OA.

Methods: Ogg1 expression was investigated in human OA cartilage and rat OA cartilage by immunohistologic analysis. We studied whether IL-1beta and H_2O_2 induce Ogg1 expression in OA chondrocytes and analyzed the relationship between cellular apoptosis phenotypes and Ogg1 expression in human chondrocytes.

Results: We observed the decreased levels of Ogg1 in osteoarthritic chondrocytes in comparison with normal chondrocytes in animal models of osteoarthritis (OA) and patients with OA, suggesting the involvement of down-regulation of Ogg1 in the degeneration of articular cartilage in OA. We found that mitochondrial Ogg1 silencing using siRNA reduced chondrocyte activity and augments apoptosis in human osteoarthritic chondrocytes. In the previous studies, we have focused on nanocarbon particle, fullerene (C60), which acts a strong free radical scavenger, as an anti-oxidative agent, to prevent the degeneration of articular cartilage in OA. We have demonstrated that water-soluble fullerene has a potential as a protective agent against the catabolic stress-induced degeneration of articular cartilage both *in vitro* and *in vivo* OA models. In the present study, we found that C60 fullerene increased the expressions of Ogg1 in osteoarthritic chondrocytes.

Conclusion: Our recent study revealed the potential involvement of accumulation of 8-Oxoguanine, an oxidized form of guanine, and impairment of mitochondrial DNA repair enzymes in the pathogenesis of OA. These findings suggest that mt-hOgg1 prevents catabolic stress-mediated chondrocyte dysfunction and apoptosis that might be important in the maintenance of articular cartilage. C60 fullerene may have a therapeutic potential, as a nanomedicine, to protect against the degeneration of articular cartilage in OA.

Disclosure: K. Yudoh: None; **R. Karasawa:** None.

Advanced Glycation End Products (AGEs)-Induced Expression of IL-6 and IL-8 in Human Osteoarthritis Chondrocytes Correlates with the Induction of Endoplasmic Reticulum Stress. Zafar Rasheed, Nahid Akhtar and Tariq M. Haqqi. Department of Medicine, Metrohealth/CWRU, Cleveland, OH

Background: During aging, non-enzymatic glycation of protein and other molecules results in the accumulation of advanced glycation end products (AGEs) in articular cartilage. Here, we investigated (a) whether AGEs induce endoplasmic reticulum stress (ERS) in chondrocytes; (b) whether the induction of proinflammatory cytokine IL-6 and chemokine IL-8 is related to ERS; and (c) determined the signal transduction pathways required for the AGEs-mediated induction of ERS and the expression of IL-6 and IL-8 in chondrocytes.

Methods: Human chondrocytes were derived from OA cartilage by enzymatic digestion (OA chondrocytes) and were stimulated with AGE-modified BSA (AGE-BSA). Expression of IL-6 and IL-8 was determined by qRT-PCR and the production of IL-6 or IL-8 in the culture medium was quantified by ELISA. Western immunoblotting was used to analyze the expression of GRP78 and phosphorylation of eukaryotic initiation factor-2α (eIF2α),both markers of ER stress, IκBα degradation, and the activation of mitogen-activated protein kinases (MAPKs). Activation of nuclear factor (NF)-κB was determined using a highly sensitive and specific ELISA. Studies to elucidate the involved pathways were executed using transfection of OA chondrocytes with siRNAs specific for RAGE and eIF2-α and specific inhibitors of MAPKs and NF-κB.

Results: AGE-BSA induced the expression of the GRP78 with concomitant increase in the expression of IL-6 and IL-8. Transfection of OA chondrocytes with RAGE specific siRNAs inhibited the AGE-BSA-induced expression of GRP78, IL-6 and IL-8. In OA chondrocytes with SiRNA-mediated knockdown of RAGE, significant activation of MAPKs was not observed upon challenge with AGE-BSA. Inhibition of p38-MAPK (SB202190) blocked the AGE-BSA-induced expression of GRP78 in OA chondrocytes. Treatment of OA chondrocytes with SB202190 (p38 inhibitor) or PD98059 (ERK inhibitor) inhibited the AGE-BSA induced IL-6 or IL-8 mRNA and protein expression. Similar results were obtained when OA chondrocytes were treated with 2-aminopurine (an inhibitor of eIF2α). In contrast JNK inhibitor SP600125 had no effect on AGE-BSA-induced IL-6 expression but inhibited the expression of IL-8. NF-κB inhibitor Bay 11–7082 (IKKα/β inhibitors), Parthenolide (IKKβ inhibitor), NEMO-BDBP (IKKγ inhibitor) or MG-132 (proteasome inhibitor) potently suppressed the AGE-BSA induced IL-6 and IL-8 mRNA and protein expression in OA chondrocytes but had no effect on the expression of GRP78.

Conclusion: This is the first study to demonstrate that AGEs via RAGE mediated activation of p38-MAPK induce ER stress and stimulate the expression of IL-6 and IL-8 in OA chondrocytes. Our results also demonstrate that AGEs differentially induced the expression of IL-6 and IL-8 with expression of IL-6 was independent of the JNK activation but the expression of IL-8 required the JNK activation. Activation of NF-κB was an absolute requirement for ER stress-induced expression of both IL-6 and IL-8 but not of GRP78 via RAGE. Thus, our results provide important insights into the mechanisms of AGE-BSA-induced ER stress in human OA chondrocytes. Our data also suggests that AGEs-induced ER stress may contribute to the pathogenesis OA.

MicroRNA-199a-*Mediated Regulation of Cyclooxygenase-2 Expression in Human OA Chondrocytes. Nahid Akhtar[1], Zafar Rasheed[2] and Tariq M. Haqqi[1]. [1]Metrohealth Medical Center/CWRU, Cleveland, OH, [2]Metrohealth Medical Center/CWRU

Background: Recent evidence implicate the deregulated expression of microRNAs (miRNAs) in the pathogenesis of osteoarthritis (OA). Interleukin-1β (IL-1β)-induced expression of cyclooxygenase-2 (COX-2) correlates with the production of prostaglandin E_2 and cartilage degradation in OA. Here we determined the posttranscriptional regulation of COX-2 expression by miRNAs in IL-1β-stimulated human OA and normal chondrocytes.

Methods: Human chondrocytes were derived by enzymatic digestion of OA cartilage (OA chondrocytes) and cartilage from trauma patients with no history of OA (normal chondrocytes). Chondrocytes were stimulated with IL-1β (5ng/ml) *in vitro*. Total RNA was prepared using TRIZOL reagent and miRNAs were purified using the mirVANA system. Single stranded cDNA was synthesized using stem loop-specific primers and the expression of miRNAs of interest was quantified using TaqMan miRNA Expression Assay and their target mRNA was identified using bioinformatics. Transfection of OA chondrocytes with a 3'UTR reporter construct and pre-miRNAs was employed to verify the miRNA:mRNA interaction. OA chondrocytes transfected with pre-miRNAs and anti-miRNAs were analyzed for the expression of COX-2 mRNA and protein by qRT-PCR using specific primers and Western immunoblotting, respectively.

Results: IL-1β- stimulation of OA chondrocytes resulted in the down-regulation of two miRNAs- miR-101_3 and miR-199a*-that potentially target COX-2 mRNA. Kinetic analysis showed that in OA chondrocytes, expression of miR-101_3 was down-regulated at 6 h (2.1-fold $\pm$ 1.0; n=7) but no significant change was observed at 24 h (n=11) post stimulation. Normal chondrocytes showed down-regulation of miR-101_3 (1.7-fold $\pm$ 0.53; n=3) at 24 h but no change at 6 h post-stimulation with IL-1β. Expression level of miR-199a* in OA chondrocytes stimulated with IL-1β at 24 h (3.3-fold $\pm$ 1.5; n=11, $p<0.05$) and at 6 h (0.94-fold $\pm$ 0.86; n=7) inversely correlated with the COX-2 protein expression level. Similar results were obtained with normal chondrocytes stimulated with IL-1β. Significantly lower expression of miR-199a* was observed in freshly isolated OA cartilage compared to normal cartilage (n=5; $p<0.001$). Over-expression of miR-199a* in OA chondrocytes inhibited the IL-1β-induced expression of COX-2 protein significantly compared to control OA chondrocytes ($p<0.05$). Transfection of OA chondrocytes with miR-199a* inhibitor enhanced the IL-1β-induced expression of COX-2 protein. Co-transfection of OA chondrocytes with a luciferase reporter construct containing the 3'UTR of human COX-2 mRNA and pre-miR-199a* suppressed the luciferase activity significantly ($p<0.05$). No inhibition of luciferase activity was observed in OA chondrocytes transfected with negative control miRNA. Inhibition of NF-κB and p-38MAPK activation with specific inhibitors altered the expression of miR199a* in human OA chondrocytes suggesting the regulation of miR-199a* by activation of these pathways.

Conclusions: Our data implicate miR-199a* in the posttranscriptional regulation of COX-2 expression in OA chodrocytes and identify miR-199a* as a novel therapeutic target for the treatment/prevention of OA.

The Unfolded Protein Response (UPR) Is Impaired in Aging and Osteoarthritic Cartilage Chondrocytes. Matthew Husa[1], Ru Liu-Bryan[2], Shawn Grogan[3], Haitao Yang[2], Bing Yang[2], Martin Lotz[3] and Robert Terkeltaub[2]. [1]San Diego VA/UCSD, La Jolla, CA, [2]San Diego VA/UCSD, [3]Scripps Research Institute

Background: OA is clearly associated with cartilage aging, but these factors do not inevitably cause OA. To identify chondrocyte abnormalities that provide a foundation upon which OA is accelerated we studied the unfolded protein response (UPR), a fundamental means by which cells normally resolve stress. The UPR restores equilibrium to the stressed ER via a reprogrammed proteome rich in chaperones and protein folding catalysts. The UPR also regulates oxidative stress responses, inflammation, and cell fate (apoptosis vs. autophagy). The UPR is impaired in aging brain and liver, due to chronic oxidant damage to UPR protein mediators. Three UPR signaling/proteolytic cascades (IRE1-XBP1; ATF6; PERK- ATF4) are triggered by dissociation of distinct ER membrane proteins from the chaperone GRP78. Generation of the UPR-specific transcription factor XBP1s (spliced XBP1) is UPR-specific and pro-inflammatory. Each UPR cascade promotes terminal expression of CHOP, a sentinel of UPR activation. Triggering of cartilage pathology by loading the ER with misfolded transgenic mutant proteins (type X collagen, matrilin-3) has illustrated deleterious effects of UPR "gain of function" in cartilage. Conversely, "loss of function" of the UPR impairs bone and cartilage development. Furthermore, UPR impairment is linked with multiple aging/degenerative diseases, mediated by oxidative damage to UPR mediators and accumulation of misfolded proteins.

Hypothesis: Impaired activity of the UPR in articular cartilage chondrocytes is involved in the development and progression of OA.

Methods: Sections of human cartilage, and aging normal mouse cartilages (4–24 months) were analyzed by immunohistochemistry. Chondrocytes were isolated from graded human knee articular cartilages and compared for UPR mediators.

Results: Mouse knee cartilages demonstrated markedly decreased GRP78 and CHOP staining linked to aging. Immunohistochemistry of human knee cartilages demonstrated that in mild OA, the proportions of GRP78 and CHOP positive cells were reduced in the superficial zone (SZ), middle zone (MZ), and deep zone (DZ) compared with that in normal cartilage. In severe OA cartilages, GRP78 and CHOP expression became markedly increased, but only focally so in chondrocyte clusters in the MZ and DZ. Human knee chondrocytes demonstrated increased XBP1s mRNA and protein with more advanced OA. Last, consistent with a dysfunctional UPR in OA, the RNA microarray data showed flat GRP78 and CHOP expression in OA vs. normal cartilage, under conditions where there were spotty increases in chaperones and protein disulfide isomerase (PDI) expression, and marked increase in positive control chondrocyte hypertrophy markers (type X collagen, osteopontin).

Conclusions: We observed decreased expression by chondrocytes of the UPR mediators GRP78 and CHOP in aging mouse knee cartilages and in human cartilages with mild OA, suggesting that UPR impairment provides a foundation for OA development and/or progression in aging. Conversely, there was markedly increased GRP78 and CHOP expression in chondrocyte clusters in late stage OA, which suggests activation of the UPR is a component of cartilage regeneration and repair.

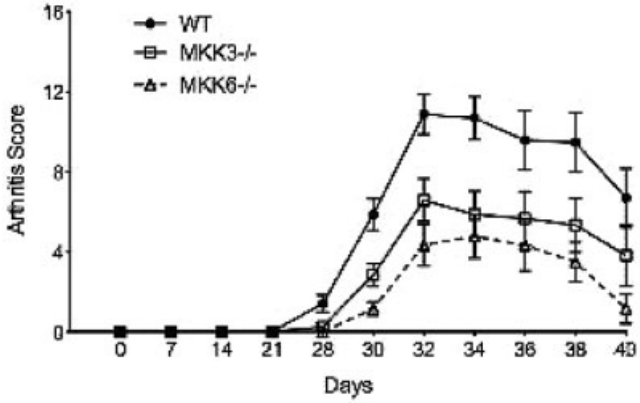
Decreased Collagen Induced Arthritis (CIA) Severity in MAPK Kinase 6 Deficient Mice: Pivotal Role of Th1 and Th17 Cytokines. Deepa Hammaker[1], Katharyn Topolewski[2], Meghan Edgar[2], David L. Boyle[1] and Gary S. Firestein[1]. [1]UCSD School of Medicine, La Jolla, CA, [2]UCSD School of Medicine

Purpose: MKK3 and MKK6 are upstream kinases that activate p38 MAP kinase and regulate distinct subsets of cytokines. Previous studies suggest that both kinases suppress innate immune responses and arthritis severity in passive K/BxN arthritis. However, their function in an adaptive model of inflammatory arthritis has is not known. This study evaluated whether these kinases play a role in collagen induced arthritis (CIA).

Method: Wild type (WT), MKK6−/−, and MKK3−/− mice were immunized on days 0 and 21 with type II bovine collagen in complete Freund's adjuvant. Joint histology was evaluated on synovitis, bone erosion, extra-articular inflammation and proteoglycan damage (max score=16). Serum anti-collagen antibodies were measured by ELISA. Cytokines in joints extracts and serum was determined by multiplex analysis. Splenocytes isolated 14 days after immunization were cultured with concanavalin A (Con A), type II collagen (CII), or medium and supernatants were assayed for cytokines.

Results: Arthritis severity was significantly lower in MKK6−/− mice than WT mice, while MKK3−/− mice had intermediate disease severity ($p=0.03$ for each compared to WT).



Scores of WT, MKK6−/− and MKK3−/− mice on day 35 were 12±1.5, 7±1.8, and 8±2.4, respectively. Histological evaluation showed significantly decreased bone erosion in MKK6−/− mice compared with WT mice (1.2±0.5 vs. 2.7±0.5, p=0.03). Decreased synovitis (50% inhibition), and proteoglycan loss (40% inhibition) were observed in MKK6−/− mice compared with WT mice. Surprisingly, inflammation and bone destruction were similar in WT and MKK3−/− mice. Anti-collagen antibodies levels in MKK6−/− mice were decreased by 45±12% compared with WT (p=0.004), but titers in MKK3−/− mice were the same as WT. Synovial IL-6, MMP3 and MMP13 gene expression was reduced by 66–79% in MKK6−/− mice compared with WT (p<0.02 for each). Expression of these genes was modestly reduced in MKK3−/− joints but did not reach statistical significance. T cell differentiation was evaluated by examining in vitro splenocyte cytokine profiles. IL-17 production in response to Con A and CII in MKK6−/− mice was reduced by 80±7% and 82±16% compared with WT and were normal in MKK3−/− cells (p≤0.03 for MKK6−/−). IFNγ production by Con A-stimulated splenocytes was inhibited by 85±5% in MKK6−/− compared with WT mice (p=0.025). IL-4 levels were not altered by MKK3 or MKK6 deficiency.

Conclusion: MKK6 deficiency suppressed CIA and joint destruction while MKK3 had an intermediate effect. Lower disease severity in MKK6−/− mice was due to decreased adaptive immune responses, especially the production of antibodies and Th1/Th17 cytokines. These data suggest that targeting MKK6 has a potential benefit in complex diseases involving adaptive immune responses like rheumatoid arthritis.

IL-7-Related TSLP: A Novel Potent Proinflammatory Mediator in Rheumatoid Arthritis That Activates Myeloid Dendritic Cells To Stimulate Th1 and Th17 Activity. F. M. Moret, C. E. Hack, K. M. G. van der Wurff-Jacobs, F. P. J. G. Lafeber and J. A. G. van Roon. Rheumatology & Clinical Immunology, University Medical Center Utrecht, The Netherlands

Background: The IL-7-related cytokine, thymic stromal lymphopoietin (TSLP), is well known for its potent activation of myeloid dendritic cells (mDCs) resulting in Th2-mediated immune responses. TSLP signals cells via the IL-7 receptor-alpha chain (IL-7Rα), shared with IL-7, together with a distinctive receptor subunit, the TSLP receptor (TSLPR). Recently, we have demonstrated that prevention of TSLPR signalling strongly reduces Th17-driven experimental arthritis and immunopathology. Furthermore, we have shown that administration of TSLP expands T and B cells and enhances severity of inflammation and joint destruction in collagen induced arthritis.

Objective: To determine the levels of TSLP and TSLPR in joints of rheumatoid arthritis (RA) patients and the capacity of TSLP to induce mDC-dependent T-cell activation.

Methods: TSLP was measured (by ELISA) in synovial fluid (SF) of patients with RA (n=44) and osteoarthritis (OA, n=20). CD1c+ mDC numbers and TSLPR expression on these cells were assessed by FACS analysis in paired samples of SF and peripheral blood (PB) from RA patients (n=7). mDCs, isolated from PB of patients with RA (n=8) as well as SF-derived mDCs were stimulated with TSLP for 24 hours and cytokine production was measured. Washed TSLP-activated mDCs were added to autologous CD4 T cells from PB in the absence of additional stimuli, cultured for 6 days and subsequently proliferation was measured. Additionally, T-cell cytokine production was measured upon restimulation with ionomycin/PMA.

Results: TSLP levels in SF of RA patients were increased compared to OA patients (mean 460 vs. 75 pg/ml, resp., p<0.01). mDCs numbers from SF were increased compared to PB (3.8% vs. 0.7%, resp., p<0.02). CD1c+ mDCs from SF and PB expressed substantial levels of TSLPR (SF: 76% positive cells, MFI 19 ± 3; PB: 70% positive cells, MFI 15 ± 2).

TSLP significantly stimulated production of chemokines TARC and MIP1α by mDCs from PB and SF (TARC; PB: from 4 to 89 and SF: from 323 to 629 pg/ml, MIP1α; PB from 1545 to 6293 and SF from 10185 to 14313 pg/ml). Upon incubation with TSLP, TSLPR-expressing mDCs from PB potently stimulated proliferation of autologous CD4 T cells (ratio T cell:DC 5:1, mean 15019 ± 1856 cpm) as compared to unstimulated mDCs (mean 960 ± 256 cpm). TSLP-mDCs from SF had a strongly increased stimulatory capacity (from 2195 ± 686 to 16615 ± 3162 at a ratio T cell:mDC 50:1). Upon restimulation, TSLP-mDC-activated CD4 T cells from PB produced increased levels of TNFα (3724 ± 972 vs. 11559 ± 1465 pg/ml), IFNγ (218 ± 142 vs. 738 ± 181 pg/ml), and IL-17 (27.9 ± 8.2 vs. 155 ± 66 pg/ml) in addition to IL-4 (1.4 ± 1.4 vs. 25.0 ± 11.3 pg/ml). Induction of TNFα was significantly higher in RA patients compared to healthy controls (p<0.05).

Conclusion: Our data indicate that increased intra-articular TSLP concentrations in RA potently activate TSLPR-expressing mDCs from RA patients to cause chemotaxis and activation of arthritogenic T cells. This suggests that TSLP and its receptor are novel therapeutic targets for RA.

Interleukin-12, Not the ITGAM Polymorphism (rs1143679), Correlates with Atherosclerosis Independent of Disease Activity in SLE. Manish Jain, Erin McDonnell, Jill P. Buyon and Robert M. Clancy. Department of Rheumatology, New York University School of Medicine

Background: Inflammation likely contributes to the increased prevalence of macrovascular disease in SLE. Dendritic cells (DCs) at sites of atherosclerosis may represent a double-edged sword, promoting plaque formation and restraining inflammation by inducing tolerance. Plasma IL-12 may represent a marker of DC activation, and its utility as a biomarker of macrovascular disease is underscored by the fact that in murine models, blockade of IL-12 function attenuates atherosclerosis. The integrin CR3 has been shown to decrease the release of IL-12 by DC. ITGAM polymorphism rs1143679 (exon-3 ITGAM gene, A allele frequency) encoding R77H in the alpha chain of CR3 (CD11b), is significantly associated with SLE. Accordingly, the hypothesis being raised is that macrovascular disease is linked to a skewing of DC phenotype towards activation as reflected by elevated levels of IL-12. A subgoal was to evaluate whether plaque was enriched in patients with the non-synonymous variant rs1143679.

Methods: IL-12 levels (ELISA) were measured in a previously reported cross sectional study of 116 SLE patients and 47 healthy controls in whom carotid ultrasonography was performed to evaluate Intimal Media Thickness (IMT) and the presence of carotid plaque. Complete history and physical were done to complete the SLEDAI in addition to chart review. Typing of ITGAM was performed by the allelic discrimination technique using assays and reagents optimized for the assessment of rs1143679.

Results: The mean level of IL-12 was significantly higher in SLE patients (109 ±87.9 pg/mL) than controls (67±26 pg/mL) (p=.0006). Among SLE patients, no correlation was observed between IL-12 levels and SLEDAI. SLE patients with plaque had significantly higher mean soluble IL-12 levels (130±104) than patients without plaque (93 ± 69 pg/mL) (p=.023). The top quartile of SLE patients based on IL-12 levels (29 patients) had a significantly higher prevalence of carotid plaque compared to the other SLE patients (18/29 patients or 62% versus 32/87 patients or 37%, p=.029). The mean common carotid artery IMT was higher in these top quartile SLE patients (.649 mm) versus those in the bottom three quartiles (.565 mm) (p=.037). The presence of anti-ds DNA antibodies was significantly enriched in the top quartile SLE patients (18/29, 62%) versus the remainder of SLE patients (33/87,38%) (p=.031). No differences were found for levels of cardiac CRP or complement. Representation of the rs1143679 ITGAM polymorphism was 19% within the cohort, consistent with published values in SLE (versus 10% hapmap). There were no differences in allelic frequency for patients based on plaque status or for patients with varied levels of IL-12.

Conclusion: This study highlights IL-12 as a surrogate marker for vascular damage with potential clinical applicability in monitoring patients,

particularly since it may be independent of disease activity. While CR3 has been shown to attenuate IL-12, in this cohort an association with the ITGAM variant was not observed. Although the source of IL-12 is yet to be identified in this cohort of patients, a potential link between DC and atherosclerosis in SLE should be considered.

Pro-Inflammatory Properties of IL-35 and Its Association with Disease Activity in Patients with Rheumatoid Arthritis. Maria Filkova[2], Hana Hulejova[3], Marketa Polanska[3], Lucie Andres Cerezo[3], Jiri Vencovsky[2], Karel Pavelka[4], Steffen Gay[1] and Ladislav Senolt[3]. [1]Center of Experimental Rheumatology, University Hospital and Zurich Center of Integrative Human Physiology (ZIHP), Zurich, Switzerland, [2]Institute of Rheumatology and Connective Tissue Research Laboratory, Department of Rheumatology of the 1st Faculty of Medicine, Charles University in Prague, Prague, Czech Republic, [3]Institute of Rheumatology and Connective Tissue Research Laboratory, Department of Rheumatology of the 1st Faculty of Medicine, Charles University in Prague, Czech Republic, Czech Republic, [4]Institute of Rheumatology, Department of Rheumatology of the 1st Faculty of Medicine, Charles University in Prague, Czech Republic, Czech Republic

Background: IL-35 is a heterodimeric member of the IL-12 family consisting of p35 (IL-12a) and EBI3 (IL-27b) subunits. Expressed in murine T-reg cells, IL-35 was shown to control colitis and inhibit collagen induced arthritis in mice. In contrast to mice, human T-reg cells do not express IL-35 and both subunits are expressed in activated T-eff cells. An up-regulation of EBI3/p35 following TNF-α and IFN-γ was observed in human aortic smooth muscle cells.

Objective: To analyze the levels of IL-35 in sera and synovial fluids of patients with rheumatoid arthritis (RA), osteoarthritis (OA) and healthy controls and to study its effect(s) on peripheral blood mononuclear cells (PBMC) and RA synovial fibroblasts (RASF) in vitro.

Methods: The levels of IL-35 in sera (RA: n=40, healthy controls: n=34), synovial fluids (RA: n=32, OA: n=30) and cell culture media were determined by commercially available ELISA. PBMC and RASF were stimulated with human recombinant IL-35 protein (25, 50, 100 ng/ml) or TNF-α (10, 50, 100 ng/ml) in vitro. Taq-Man RT-PCR was performed to analyse gene expression after 6 and 24 hours and ELISA assays were used to confirm the protein secretion after 24 hours of stimulation.

Results: The levels of IL-35 in synovial fluids were significantly higher in patients with RA in comparison to patients with OA (mean$\pm$SEM: 23 583$\pm$7 474, calculated after dilution; vs. 397.5$\pm$68.7 pg/ml, $p<0.0001$). In addition, local levels of IL-35 significantly correlated with the levels of serum CRP in both RA as well as OA patients ($r=0.504$, $p=0.004$ and $r=0.453$, $p=0.02$; respectively) and with the disease activity of patients with RA assessed by DAS28 ($r=0.440$, $p=0.014$). On the other side, serum levels of IL-35 were below the detection limit in the majority of RA patients as well as healthy controls. Gene expression of both subunits of IL-35, EBI3 and p35, as well as IL-35 in cell culture supernatants, was dose- and time-dependently induced by TNF-α in PBMC. Related results show that PBMC isolated from patients with RA secreted more IL-35 than those from healthy controls. IL-35 dose-dependently up-regulated the gene expression of IL-1β (up to 6.3 fold), IL-6 (up to 9.6 fold) and MCP1 (up to 22.4 fold) but not of TNF-α in PBMC. This pattern was also confirmed by ELISA. However, there was no effect of IL-35 on RASF with respect to the tested cytokines.

Conclusion: These data show for the first time, in contrast to the immunosuppressive function observed in mice, that locally up-regulated levels of IL-35 reflect the disease activity of RA. Furthermore, the results of this study support the concept that IL-35 has also pro-inflammatory properties.

MAPK Kinase 3 (MKK3) Regulates Osteoclast Differentiation and Activation. David L. Boyle[3], Meghan Edgar[4], Mario M. Zaiss[1], Georg Schett[2] and Gary S. Firestein[3]. [1]Department of Internal Medicine 3, University of Erlangen-Nuremberg, [2]Friedrich Alexander Univ, Erlangen, Germany, [3]UCSD School of Medicine, La Jolla, CA, [4]UCSD School of Medicine

Purpose: p38 MAPK inhibitors have modest efficacy in diseases like rheumatoid arthritis (RA), in part because exposure is limited by side effects. Two upstream kinases regulate p38 function, namely MKK3 and MKK6. These two MKKs have non-redundant functions and control expression of complementary subsets of pro-inflammatory cytokines. Deficiency of either MKK decreases inflammation in the passive K/BxN model of arthritis. To explore distinct functions of MKK3 and MKK6, we examined their relative contributions to joint damage and bone resorption by evaluating the differentiation and function of MKK deficient osteoclasts. The data could support developing MKK inhibitors for bone protection in RA and in osteoporosis.

Methods: BM monocytes from wild type (WT), MKK3$-/-$, and MKK6$-/-$ mice were differentiated with M-CSF (30ng/ml) and non-adherent cells subsequently cultured with M-CSF (30ng/ml) and RANKL (50ng/ml) for 5 days in the Osteologic Bone Cell Culture System. Osteoclast number and matrix resorption were determined by TRAP staining followed by light microscopy and automated image analysis. SB203580 was used at 3μg/ml. Gene expression and p38 phosphorylation were determined by qPCR and Western Blot analysis, respectively.

Results: The number of osteclasts generated from BM monocytes was similar in WT and MKK6$-/-$ mice. Surprisingly, MKK3$-/-$ osteoclast differentiation was lower than WT or MKK6$-/-$ (n=9, 33% inhibition, $P<0.004$). The p38 inhibitor SB203580 inhibited osteoclast differentiation by 74% ($P=0.001$). In vitro matrix resorption by osteoclasts was decreased by 46% by MKK3$-/-$ osteoclasts ($P=0.002$), while MKK6 deficiency had no effect compared with WT cells. p38 activation, as measured by determining relative P-p38/p38 ratios, for WT, MKK6$-/-$, and MKK3$-/-$ osteoclasts was 0.71$\pm$0.09, 0.54$\pm$0.05, and 0.09$\pm$0.02, respectively (n=3, $P=0.001$ for MKK3$-/-$). MMP13 expression was similar in all genotypes, but expression of the key bone resorbing proteinase cathepsin K was significantly lower in MKK3$-/-$ osteoclasts (67% inhibition; $P=0.0001$) but not in MKK6$-/-$ cells.

Conclusions: MKK3, but not MKK6, is required for osteoclast differentiation and activation, p38 phosphorylation, and cathepsin K gene expression. Selective MKK3 inhibitors could be targeted for RA in order to suppress bone erosions and inflammation while sparing p38 functions that might contribute to toxicity. In addition, an MKK3 inhibitor could have utility as an oral therapy for osteoporosis.

Tumor Necrosis Factor Inhibition Reduces the Incidence of Alzheimer's Disease in Rheumatoid Arthritis Patients. Richard C. Chou[2], Michael A. Kane[3], Shiva Gautam[1] and Sanjay Ghirmire[4]. [1]Beth Israel Deaconess Medical Center, [2]Dartmouth-Hitchcock Medical Center, Milton, MA, [3]Massachusetts General Hospital and Massachusetts Institute of Technology, Georgetown, MA, [4]Verisk Health

Objective: To investigate the relationship between different rheumatoid arthritis treatments and Alzheimer's dementia.

Background: A complication of chronic inflammation in rheumatoid arthritis (RA) is the deposition of amyloid proteins, resulting in secondary amyloidosis. Alzheimer's dementia (AD) is associated with the local deposition of beta-amyloid peptide in the brain, although the pathogenetic mechanisms of AD are unclear. The relationship between RA and AD has not been established.

Design/Methods: We reviewed medical and pharmacy claims data from January 2000 to November 2007 for a commercially insured cohort of 8.5 million adults throughout the US. We derived a subcohort of 42,193

patients with a pre-existing diagnosis of RA. In this subcohort, we conducted a nested case-control study of the incidence of AD. We excluded individuals with psoriatic arthritis, inflammatory bowel disease, previous stroke or previous AD. For each individual with newly diagnosed AD (cases) we matched up to 10 controls who did not have a prior diagnosis of AD and were free of AD during the exposure assessment period. Matching criteria included age, gender, duration of exposure assessment period and methotrexate treatment. We examined exposure to sulfasalazine, prednisone, three anti-tumor necrosis factor (TNF) agents (infliximab, etanercept, adalimumab) and rituximab.

Results: In this nested case-control study, a total of 165 patients with AD (cases) were matched to 1,383 controls without AD. Treatment with anti-TNF agents in RA was associated with lower risk for incident AD [adjusted odds ratio (OR) 0.440; 95% confidence interval (CI) 0.223–0.868; p=0. 0178). The risk of AD was not affected by exposure to sulfasalazine, prednisone or rituximab. The results were similar [adjusted OR 0.448; 95% CI 0.225–0.892; p = 0.0222) after adjustment for covariates, including hypertension, hyperlipidemia, diabetes mellitus, peripheral vascular disease, and coronary artery disease.

Conclusion: In this population of adults with RA, we observed that the risk of AD was reduced by TNF inhibitor therapy, but not by other disease modifying agents used for treatment of RA. Tumor necrosis factor may be an important component in the pathogenesis of AD.

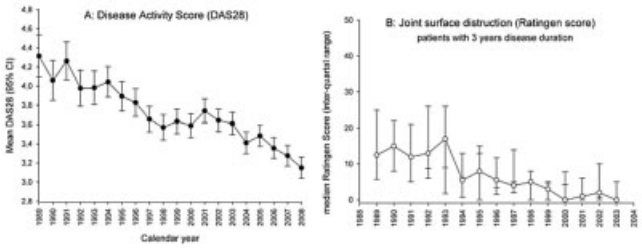
Major Improvements in Outcomes of Rheumatoid Arthritis Since the Biologic Era and beyond: An Historical Overview from 1989 until 2008 in a Large Inception Cohort of RA Patients. Wietske Kievit[1], Jaap Fransen[2], Maarten De Waal Malefijt[2], Alfons Den Broeder[3] and Piet van Riel[2]. [1]Radboud University Nijmegen Medical Centre, Nijmegen, The Netherlands, [2]Radboud University Nijmegen Medical Centre, [3]Sint Maartenskliniek

Background: Already since the early 80's there has been a movement towards intensified treatment for RA with an increasing use of methotrexate in higher doses up to 30 mg per week in individual patients and DMARD combination therapy.

Objectives: We hypothesized that the trend of better RA outcomes precedes the era of biologic response modifiers.

Methods: Data available from the period between 1989 and 2008 in the Dutch Nijmegen inception cohort was used, including DAS28, HAQ-DI, X-rays and orthopedic surgery. Patients with RA were regularly assessed at scheduled visits. For each individual patient, the average DAS28 and HAQ-DI scores for each calendar year were calculated. X-rays of hand and feet were taken annually and joint surface destruction was scored according to the Ratingen score (range 0–190) (data available until 2003). Population mean DAS28 and HAQ-DI over time were corrected for age, gender, rheumatoid factor and disease duration by means of repeated measures analysis (mixed models). Conditional means of DAS28 and HAQ-DI were plotted by calendar year. Median Ratingen scores were compared between calendar years non-parametrically. Orthopedic surgery was analyzed as incidence rates with 95% confidence limits based on a Poisson distribution. To describe treatment, the percentage of patients being treated with MTX or SASP, a biological response modifier, and the mean MTX dose per year were calculated.

Results: Per 2008, 992 RA patients were included, resulting in 8618 patient years. From 1989 onwards, the percentage of patients being treated with SASP decreased to 18% and the percentage of patients being treated with MTX increased to 62% in 2008. The percentage of patients being treated with a biologic was increased to 22% (166/765) in 2008. The MTX dose increased significantly from a mean dose (sd) of 6.7 (1.3) mg/week with a maximum of 7.5 mg/week in 1989 to a mean dose (sd) of 16.1 (5.5) mg/week with a maximum of 30 mg/week in 2008. The Figure A shows the mean DAS28 per calendar year conditional on disease duration, age, gender and rheumatoid factor. According to the repeated measures analysis the mean DAS28 and HAQ-DI were statistically significant higher ($p<0.008$) in all years compared to 2008, where mean DAS28 was 3.2 and the mean HAQ-Di was 0.47. Median Ratingen score for patients with 3 years disease duration decreased from 12.5 in 1989 to zero in 2003 (Figure B). Analysis of the incidence of orthopedic surgeries showed a trend towards lower rates of orthopedic surgery with non-overlapping 95% confidence intervals in the years 2006, 2007 and 2008 compared to almost all previous years.



Conclusion: The better controlled RA that we show is not only attributable to the introduction of anti-TNF, but also to the DMARDs (and especially MTX) which were largely available before the biologic era. We think that utilization of the available therapies can still be enhanced by tight control strategies.

Propensity-Adjusted Medication Effects on Survival in Rheumatoid Arthritis: 22-Year Follow-Up of 5629 Patients. Mary Chester Wasko[3], Abhijit Dasgupta[1], Helen Hubert[2], Bharathi Lingala[2], James Fries[2] and Michael Ward[1]. [1]NIAMS/NIH, Bethesda, MD, [2]Stanford University, Palo Alto, CA, [3]University of Pittsburgh, Pittsburgh PA

Background: Medications used to treat rheumatoid arthritis (RA) may affect mortality, though prescription patterns are influenced by patient demographics, comorbidities, and physician preference, all factors that change over time. The propensity for prescribing RA medications may influence the likelihood of drug use and thus also should be considered when evaluating if particular anti-rheumatic medications influence mortality in patients with RA.

Methods: Using a longitudinal multicenter observational database of 5629 RA patients followed biannually with the Health Assessment Questionnaire (HAQ) from 1981–2003, we calculated propensity scores at each HAQ for the use of methotrexate (MTX), prednisone (PRED), and anti-tumor necrosis factor (TNF) agents. Scores were time-dependent and based on RA duration at study entry, age, ethnicity, education level, gender, marital status, work status, body-mass index (BMI), pain and RA severity indices, comorbidities, other drug use, and phase of study. Time-varying Cox proportional hazards regression models were then constructed to determine the relationship between drug use and survival, adjusting for propensity score, age, BMI, HAQ-disability index, ethnicity, education level, gender, RA duration at entry, presence of any comorbidities, and concurrent use of MTX, prednisone, anti-TNF agents, hydroxychloroquine, other disease-modifying drugs, nonsteroidal anti-inflammatory drugs, and cyclooxygenase-2 inhibitors.

Results: Median age was 58y, 75% were women, 90% Caucasian, with median education 12 years. For MTX, PRED and anti-TNF users, median RA duration at entry was 5.7, 7.2, and 10.9y; 50%, 50%, and 39% had ≥1 comorbidity at baseline respectively. Overall, 1027 (18%) died during observation. MTX propensity increased over time, but PRED propensity was fairly constant. Time-varying Cox proportional hazards modeling adjusting for drug-specific propensity and covariates showed a strong protective effect for MTX on mortality (Hazard Ratio [HR]=0.27, 0.11–0.70 95% CI, $p<0.001$) but no statistically significant impact of PRED (HR=1.48, 0.69–3.17 95% CI, p=0.31) or anti-TNF (HR=0.59, 0.00–5e8 95% CI, p=0.96) on the outcome. However, the models for PRED without propensity score showed a significantly increased risk of mortality (HR=1.62, 95% CI 1.41–1.87, $p<0.001$).

Conclusions: Adjusting for propensity and other covariates, MTX use is strongly associated with reduced mortality in this RA cohort. These results underscore the important role of MTX in the management of patients with RA. Use of PRED is not associated with increased mortality in propensity-adjusted analysis, uniquely suggesting that factors associated with prescribing patterns play a role in the reported mortality rates for patients on PRED. Our findings do not indicate an increase in mortality with use of anti-TNF agents over 5 years of observation following introduction of these agents for commercial use.

Renal Dysfunction in Rheumatoid Arthritis Is Associated with Incident Cardiovascular Disease, Independently of Traditional Risk Factors: The CARRE Study. Alper M. van Sijl[3], Ingrid M. Visman[1], Inge A. M. van den Oever[1], Mike J. L. Peters[5], Alexandre E. Voskuyl[5], Ben A. C. Dijkmans[4] and Michael T. Nurmohamed[2]. [1]Jan van Breemen Institute, [2]Jan van Breemen Institute and VU Medical Centre, Amsterdam, The Netherlands, [3]Jan van Breemen Institute and VU Medical Centre, [4]VU Medical Centre, Amsterdam, The Netherlands, [5]VU Medical Centre

Background: Individuals with rheumatoid arthritis (RA), a chronic inflammatory disease, have an increased risk of developing cardiovascular disease (CVD), that persists after correction for traditional risk factors, e.g. smoking, hypertension, dyslipidemia, previous CV event or diabetes. Renal dysfunction is predictive of CVD in the general population but also in patients with diabetes or hypertension, independently of traditional CV risk factors. In these cases, low-grade inflammation is thought to have an essential role. To date, there have been no studies investigating the association of renal dysfunction with incidence of CVD in RA.

Methods: The CARRE study is a prospective cohort study of Dutch patients with RA aged between 50 and 75 years old, in which traditional CV risk factors, RA related factors and CV morbidity and mortality are investigated. CV events are defined as documented myocardial infarction, cerebrovascular accident, transient ischaemic attack, peripheral arterial reconstruction or coronary stent- or by-pass procedure. Renal function was assessed by the estimated Glomerular Filtration Rate (GFR) using the abbreviated Modification of Diet in Renal Disease (MDRD) formula. A GFR of less than 60 ml/min/1.73 m^2 is considered unfavourable. Multivariate Cox proportional hazard analyses were performed to determine the association between renal dysfunction and incident CV disease.

Results: 353 patients were followed for 3 years and 23 patients developed a CV event within this study period. Higher GFR (>60) was significantly associated with a lower risk for CVD, hazard ratio (95%-confidence interval): 0.185 (0.079–0.438). This association remained significant even after correction for: 1. Age, sex and previous CVD 2. Nodular disease and antihypertensive agents 3. Use of methotrexate, corticosteroids and non-steroidal anti-inflammatory drugs and 4. Traditional CV risk factors.

Conclusion: Renal dysfunction is associated with incident CV disease in RA, even after correction for traditional risk factors. These results indicate that a decreased renal function helps to identify RA patients at increased risk for future CV disease. Future studies should further investigate the relationship between chronic inflammation and renal dysfunction.

Table 1. Cox proportional hazard model for GFR and cardiovascular incidence

	Hazard Ratio	95%-Confidence Interval
Crude model	0.185*	0.079–0.438
Model 1	0.240	0.063–0.907
Model 2	0.174	0.039–0.776
Model 3	0.223	0.060–0.828
Model 4	0.125*	0.027–0.572

*p < 0.01. Results as hazard ratios (95%-confidence interval).
GFR-MDRD as categorical variable ≥60 and <60
Model 1: Adjustment for age, gender, previous CVD
Model 2: Adjustment for age, gender, previous CVD, nodular disease, use of antihypertensives
Model 3: Adjustment for age, gender, previous CVD, use of methotrexate, use of prednisone, use of non-steroidal anti-inflammatory drugs
Model 4: Adjustment for age, gender, previous CVD, systolic blood pressure, total cholesterol, triglycerides, prevalence of diabetes, current smoking and body mass index

Do Structural Damage and Inflammation Impact Physical Functioning Differently Based on Duration of Rheumatoid Arthritis? Martin J. Bergman[2], Sanjoy Roy[1], Naijun Chen[1] and Mary A. Cifaldi[1]. [1]Abbott Laboratories, Abbott Park, IL, [2]Arthritis and Rheumatology, Ridley Park, PA

Background: Impairment of physical function, caused by a combination of inflammation and structural damage, leads to eventual disability among patients with rheumatoid arthritis (RA). It has been suggested that the relative impact of inflammation and structural damage on physical function differ over time during the progression of the disease.[1] This study tests the hypothesis by assessing the relative associations of these two important factors with physical functioning among patients with RA.

Methods: Data from two trials of adalimumab—PREMIER (patients with early RA) and DE019 (patients with longstanding RA) —were pooled to assess the relationship of physical functioning (measured by the HAQ and the Physical Component Score [PCS] and Physical Functioning [PF] domain of the SF-36 questionnaire) with structural damage (measured by modified total Sharp scores [mTSS]) and inflammation (measured by C-Reactive Protein [CRP] levels). Baseline patient-level data were used from both trials regardless of treatment arm. Spearman's correlations were assessed between HAQ, PCS and PF with TSS and with CRP. Correlations were calculated separately for patients with duration of disease up to 3 years (early RA) and for those with more than 3 years (longstanding RA) across the two trials. Strengths of correlation between HAQ-TSS and HAQ-CRP were tested using Fisher's Z transformation technique.

Results: Combining patients from the two studies, there were 908 patients with disease duration ≤3 years and 507 with disease duration >3 years. The mean (SD) HAQ, TSS, and CRP values were 1.5 (0.6), 20.05 (20.3), and 3.73 (3.9) respectively in early RA, and 1.47 (0.6), 77.89 (55.9), and 1.69 (1.9) in longstanding RA. In early RA, all measures of physical functioning were correlated with CRP: Spearman's correlation coefficients with HAQ, PCS, and PF of 0.395, –0.288, and –0.357, respectively ($p<0.05$ for all). However, none of the physical function measures were correlated with TSS. In established RA, on the other hand, TSS was correlated with HAQ, PCS, and PF with coefficients of 0.238, –0.119, and –0.137, respectively. Correlations of the physical function measures with CRP were also significant in longstanding RA, but the strengths of such associations were weaker compared with those in early RA. Fisher's Z-transformed estimates of

correlation between HAQ and TSS increased significantly with longer duration of disease (0.034 vs. 0.242; p=0.0003), while it decreased significantly between HAQ and CRP (0.417 vs. 0.261; p=0.005).

Conclusion: This study shows that deterioration of physical functioning as a result of RA may be driven by inflammation earlier in the disease, but is driven more by structural damage as the disease progresses. This suggests that earlier treatment with appropriate therapy (that inhibits both inflammation and radiographic progression) prior to structural damage could dramatically improve long-term physical functioning and disability outcomes among patients with RA.

Common Vaccinations among Adults and the Risk of Developing Rheumatoid Arthritis; Results from the Swedish EIRA Study. Camilla Bengtsson[2], Meliha Kapetanovic[1], Henrik Källberg[2], Berit Sverdrup[2], Birgitta Nordmark[3], Lars Klareskog[3] and Lars Alfredsson[2]. [1]Institute for Clinical Sciences, Department of Rheumatology, Lund University, Lund, Sweden, [2]Institute of Environmental Medicine, Karolinska Institutet, Stockholm, Sweden, [3]Rheumatology Unit, Department of Medicine, Karolinska Institutet, Karolinska University Hospital, Stockholm, Sweden

Background: Vaccinations are among the events frequently considered as inciting agents for rheumatoid arthritis (RA), but no sufficiently powered epidemiological studies have been published addressing whether vaccinations commonly used in industrialised societies constitute risk factors for RA[1].

Objectives: To investigate whether common vaccinations given to adults were associated with an increased risk of RA, and whether vaccinations have different impact on two subsets of RA, characterized by presence/absence of antibodies to citrullinated peptides (ACPA). In addition we examined potential interactions between vaccinations and smoking and between vaccinations and HLA-DRB1 SE alleles regarding risk of ACPA-positive RA.[2]

Methods: Data from the Swedish population-based EIRA (Epidemiological Investigation of Rheumatoid Arthritis) case-control study encompassing 1998 incident cases aged 18–70 years and 2252 randomly selected controls, matched on age, sex and residency, was analysed. All cases were diagnosed by rheumatologists according to the ACR criteria of 1987. Those vaccinated within five years prior to disease onset were compared with those not vaccinated within five years before disease onset, by calculating odds ratios (OR) with 95% confidence interval (CI). Biological interaction, defined by departure from additivity of effects was evaluated between vaccination and smoking and between vaccination and HLA-DRB1 SE alleles.

Results: In total, 31% of the cases and 31% of the controls had been vaccinated. Vaccinations did neither increase the risk of RA overall (OR=1.0 (95% CI 0.9–1.1) nor the risk of ACPA-positive or ACPA-negative disease. Furthermore, there was no association between any specific vaccine (influenza, tetanus, diphtheria, tick-borne encephalitis, hepatitis (A, B, C together), polio, pneumococcus) and the risk of RA. Finally, no interaction was found between any vaccination and smoking or between any vaccination and SE alleles regarding risk of ACPA-positive disease.

Conclusions: Our results indicate that immunological provocation with common vaccines given to adults in their present form is not a major risk factor for RA, at least not vaccines administered within five years before onset of disease. In addition, the results indicate that active immunisation does not increase the risk of RA in individuals with established risk factors, i.e smokers or those carrying HLA-DRB1 SE alleles. These findings should be implemented among clinicians and health care providers in order to encourage common vaccinations according to recommended vaccinations schedule for adults.

Individually Tailored Exercise and Telephone-Delivered Cognitive Behaviour Therapy in the Management of Chronic Widespread Pain (CWP): Results from a Primary Care Based Randomised Controlled Trial. Gary J. Macfarlane[1], Chrysa Gkazinou[2], Marcus Beasley[2], Elizabeth A. Jones[2], Gordon J. Prescott[2], Phil Hannaford[2], Phil Keeley[3], Karina Lovell[3], Paul McNamee[2], Deborah P. M. Symmons[3], Steve Woby[3], John McBeth[3] and the MUSICIAN Study Team. [1]University of Aberdeen, Aberdeen, Scotland, United Kingdom, [2]University of Aberdeen, [3]University of Manchester

Background: Epidemiological and clinical studies have improved our understanding of the aetiology and consequences of chronic widespread pain. The challenge now is to use such information to improve outcome for patients. Despite recent innovations in pharmacological management, non-pharmacological therapies will remain the principal approach to improving quality of life in such patients. We aimed to determine whether exercise and/or cognitive behaviour therapy (CBT) would improve outcome in patients with CWP attending primary care.

Methods: We conducted a 2×2 factorial randomised controlled trial of an individually tailored exercise programme in community leisure facilities and CBT delivered by telephone (T-CBT). Interventions were of six months duration and were compared to usual care. Patients were recruited by means of a brief postal screening survey of all persons registered with 8 primary-care practices in the city of Aberdeen and suburbs of Manchester, United Kingdom. Patients were eligible if they satisfied the definition of CWP in the 1990 ACR criteria for fibromyalgia, reported disabling symptoms, had consulted their family doctor with symptoms in the past year and had no contraindications to exercise or a pain condition requiring other specific treatment. Severity of pain was measured by the Chronic Pain Grade (CPG) from I (low intensity) to IV (severely limiting). The outcome measure was a 7-point patient global assessment scale of change in symptoms since the time of recruitment from "very much worse" through "no change" to "very much better". A positive outcome was defined as "much better" or "very much better". Data were analysed as % reporting a positive outcome and logistic regression was used to describe the individual and combined effects of intervention(s) on outcome with results expressed as odds ratios (ORs) and 95% Confidence Intervals (CI).

Results: 14386 persons were screened of whom 878 were identified as potentially eligible for the trial. 442 individuals attended for assessment, were recruited to the trial and randomised to one of the four study arms. Participants had a median age of 58 years (IQR: 48–65), 69% were female and the distribution of CPG was: I 21%, II 38%, III 21%, IV 21%. At the end of the six month intervention period 361 provided outcome data (82%). The percentages reporting a positive outcome were: usual care 8%, T-CBT only 30%, exercise only 35% and both interventions 37% ($p < 0.0005$). T-CBT (OR 4.9 95% CI (2.0, 12) or exercise only (6.1; 2.5,15) resulted in improved outcomes but there was no significant additional benefit in receiving both interventions (OR combined multiplicative effect 0.22; 0.08, 0.67).

Conclusions: This study has demonstrated substantial and statistically significant improvement in the global assessment of their condition by patients with CWP who consult with their family practitioner and are provided with a 6-month exercise or T-CBT programme. This is the first trial of telephone delivered CBT in CWP. These results provide encouragement for patients with CWP that short-term improvement is possible in a substantial proportion with either of these interventions.

Non-Invasive Cortical Electrostimulation in the Treatment of Fibromyalgia. Jeffrey B. Hargrove[2], Robert M. Bennett[5], David G. Simons[1], Susan J. Smith[3], Sunil Nagpal[3] and Donald E. Deering[4]. [1]Emory University, [2]Kettering University, Flint, MI, [3]Michigan State University, [4]NeuroHealth Associates, [5]Oregon Health & Science Univ, Portland, OR

Purpose: The purpose of this study was to test the feasibility, efficacy and safety of an innovative form of non-invasive cortical electrostimulation (NICE) in the treatment of fibromyalgia (FM), where areas of the brain that may be involved in dysfunctional sensory processing were targeted.

Methods: A randomized placebo controlled, double-blind trial design was used to evaluate the efficacy of NICE in 77 FM patients (ACR 1990 criteria). Non-invasive leads were applied to the scalp with the aim of stimulating the centro-parietal area, including the somatosensory cortex. Monopolar electrical stimulation was used that employed high frequency carrier components to overcome skin and scalp impedance, and low frequency components designed to stimulate and modulate lower frequency cortical activity in the targeted areas. NICE consisted of 22 treatment sessions administered twice a week for approximately 11 minutes. As the signal is sub-threshold for cutaneous stimulation, the placebo arm (PL) was created by simply not delivering the signal. Patients were evaluated at baseline and no less than 7 days after completion of therapy. At both time-points all subjects completed the FIQ and a sleep VAS. A blinded investigator evaluated the number of positive tender points (TePs), and the summated tender point pain threshold (TPPT) was assessed using dolorimetry. The FIQ was re-administered at an average of 17 months post-termination of the study.

Results: Baseline demographic and clinical features were comparable in both treatment groups. Compared to PL, the NICE group had a significant improvement in the total FIQ score, pain VAS and sleep VAS scores. NICE group patients improved in the number of positive TePs (~ 43%), whereas the PL group did not change. The pain threshold (TPPT) for the NICE group improved 61% whereas the control group got slightly worse (−4%). Between-group analysis of TePs and TPPT scores showed significant improvement in the NICE arm compared to PL. Long-term follow-up showed a sustained improvement in the FIQ scores over baseline (average total FIQ scores: baseline 59, post-treatment 42; long-term 37; $p < 0.001$). NICE did not result in any significant adverse events.

Baseline to Post-Treatment Outcomes [Mean Raw Change (% change)]	NICE Group	PL Group
Number of positive TePs (range 0–18)	−7.4 (−43%), $p < 0.001$	−0.2 (0%), $p = 0.68$
Post-therapy group difference in number of positive TePs	−6.8 (41%, $p < 0.001$)	
Change in TPPT (range 9–72)	+19.7 (61%) $p < 0.001$	−3.1 (−4%) $p = 0.04$
Post-therapy group difference in TPPT	+20.8 (37%, $p < 0.001$)	
Post-therapy change in FIQ pain VAS (range 0–10)	−2.0 (30%) $p < 0.001$	−0.6 (9%) $p = 0.20$
Post-therapy group difference in FIQ pain VAS	−1.4 (23%, $p = 0.02$)	
Post-therapy change in total FIQ score (range 0–100)	−15.5 (25%) $p < 0.001$	−5.5 (9%) $p = 0.052$
Post-therapy group difference in total FIQ score	−6.5 (12%, $p = 0.03$)	
Percent of patients achieving 30% reduction in TePs	66%	5%
Percent of patients achieving 30% improvement in TPPT	71%	8%
Percent of patients achieving 30% improvement in Total FIQ	39%	20%
Percent of patients achieving 30% improvement in FIQ pain VAS	53%	29%

Conclusions: Using a cortical electrostimulation technique specifically designed to enhance signal penetration to centro-parietal brain regions, this study yielded clinically significant improvements in pain, tenderness and other typical features of FM. The treatment was well tolerated without significant adverse effects. This modality may augment current approaches to the treatment of FM.

Effect of Adding Milnacipran to Pregabalin for Managing Fibromyalgia: A Randomized, Open-Label, Controlled Study. Mildred V. Farmer[3], Joel M. Trugman[2], Yong Wang[2] and R. Michael Gendreau[1]. [1]Cypress Bioscience, Inc., San Diego, CA, [2]Forest Research Institute, [3]Meridien Research, St. Petersburg, FL

Purpose: Fibromyalgia (FM) is characterized by a multitude of symptoms that include chronic widespread pain, fatigue, stiffness, impaired physical functioning, sleep disturbances, cognitive dysfunction, and depressed mood. Medications used to manage FM often do not treat the full spectrum of symptoms that a patient with FM may experience. Patients may benefit from augmenting their current treatment regimen with medications that have complementary mechanisms of action. This randomized, open-label, controlled study evaluated the efficacy and tolerability of milnacipran 50 mg BID when added to pregabalin 150 mg BID or 225 mg BID in FM patients who had an incomplete response to pregabalin during a 4- to 12-week open-label run-in phase.

Methods: This was a randomized, controlled, open-label study. After the pregabalin run-in period, incomplete responders to pregabalin (patients with weekly recall VAS pain score ≥40 and ≤90 [0 to 100 scale], Patient Global Impression of Severity score ≥4 [ranging from "moderately ill" to "extremely ill"], and Patient Global Impression of Change [PGIC] score ≥3 [ranging from "minimally improved" to "very much worse"]) were randomized to pregabalin alone (n=180) or milnacipran added to pregabalin (n=184) for 11 weeks. The primary efficacy assessment was the percentage of PGIC responders at endpoint, defined as patients reporting a PGIC rating of "much improved" or "very much improved". The secondary efficacy assessment was the change from baseline in VAS 1-week pain recall score. Additional efficacy measures included SF-36 Physical and Mental Component Summary Scores (PCS and MCS, respectively), Multidimensional Fatigue Inventory (MFI), and Multiple Ability Self-report Questionnaire (MASQ). Treatment-emergent adverse events (TEAEs) occurring in the randomized treatment period were defined as AEs that were newly reported or increased in severity during the randomization period.

Results: The overall completion rate was higher in patients receiving milnacipran added to pregabalin (76.6%) than those receiving pregabalin alone (68.3%). At endpoint, milnacipran added to pregabalin treatment resulted in a significantly higher percentage of PGIC responders than pregabalin alone (46.4% vs 20.8%; $P<.001$). The addition of milnacipran to pregabalin also resulted in a significantly greater reduction in least squares mean weekly recall VAS pain score compared with pregabalin alone (−20.8 vs −6.4; $P<.001$). Patients receiving milnacipran added to pregabalin had significantly improved physical and mental function, fatigue, and cognition (SF-36 PCS and MCS, MFI, and MASQ, $P<.001$, all outcomes) than patients receiving pregabalin alone. During the randomized treatment period, the most common TEAE in patients receiving milnacipran added to pregabalin was nausea; peripheral edema and weight increased were most common in patients receiving pregabalin alone.

Conclusion: This open-label study is the first randomized controlled study to demonstrate that adding milnacipran to pregabalin therapy is both tolerable and effective in improving global status and reducing pain in patients with FM experiencing an incomplete response to pregabalin alone.

Hypothalamic-Pituitary-Adrenal Axis Response to Mental Stress Predicts Chronic Widespread Pain Onset—Results from the SPICE Study. Gareth T. Jones, Gordon D. Waiter, Marcus Beasley, Chrysa Gkazinou and Gary J. Macfarlane. University of Aberdeen, Aberdeen, United Kingdom

Background: The role of the Hypothalamic-Pituitary-Adrenal (HPA) axis stress response, as assessed by salivary cortisol, has been investigated in modifying risk of chronic widespread pain (CWP). It has been shown that, amongst those at high risk of CWP (high levels of adverse psychosocial factors), those with diminished diurnal variation and those who fail to suppress HPA axis function after a dexamethasone suppression test, are at particularly high risk of developing CWP.

The aims of the current study are (1) to determine the importance of HPA axis dysfunction in a general population sample; and (2) to examine the response of the HPA axis to mental, as opposed to pharmacological, stress.

Methods: Baseline: potential participants aged 25–70yrs, randomly selected from 4 primary care practices in Aberdeen, UK, were sent a postal questionnaire. They were asked: "Thinking back over the past month, have you had any pain that has lasted for one day or longer?" Those answering positively were asked to identify the location(s) of this pain on a body manikin. CWP was then determined as per the ACR-1990 classification for fibromyalgia.

Participants were then sent a saliva sampling kit, for 2 samples: approxi-

matly 1hr after waking (AM) and 1hr before going to bed (PM). In addition, a sub-group of respondents were invited into the laboratory and undertook a computerised version of the Stroop "Word-and-Colour" Test – a test known to induce mental stress among study participants. Salivary cortisol was assessed at baseline, and immediately post-Stroop.

Follow-up: new onset CWP was identified, by questionnaire, at 12 months.

Analysis: Poisson regression was used to examine the relationship between HPA axis function (salivary cortisol concentration, divided into tertiles for analysis) and new onset CWP. Thus, associations are expressed as risk ratios (RR) with 95% confidence intervals.

Results: Of 758 participants free of CWP, 461 (61%) participated at follow-up: 41 (9%) reported CWP. While, there was some evidence to suggest that higher AM cortisol was associated with a lower risk of CWP ($RR_{3rd\ vs\ 1st\ tertile}$: 0.6; 95%CI: 0.2–1.7), there was no association between between PM cortisol levels and the risk of CWP ($RR_{3rd\ vs\ 1st\ tertile}$: 1.2; 0.5–2.9); nor with AM-PM cortisol variation ($RR_{3rd\ vs\ 1st\ tertile\ of\ difference}$: 0.8: 0.3–2.1).

56 participants completed the Stroop Test, of whom 50 (89%) participated at follow-up. Those with the lowest stress response were more likely to report CWP than other individuals ($RR_{1st\ vs\ 3rd\ tertile\ of\ difference}$: 4.9; 0.6–39.5) and ($RR_{2nd\ vs\ 3rd\ tertile\ of\ difference}$: 3.6; 0.4–29.6).

Discussion: This is the first study to examine HPA axis function and CWP onset in the general population. The study is small, and the findings should therefore be interpreted with care. However, the results replicate findings from previous studies in high-risk samples and provide new evidence that persons with the lowest stress response to mental stress are at highest risk of CWP onset. Future work should examine this relationship in the context of —and possibly as a modifier of—environmental (psychosocial) stressors and, in particular, should determine the mechanisms underpinning this relationship.

Altered Resting Connectivity between Individuals with Fibromyalgia and Healthy Controls. Tobias Schmidt-Wilcke[2], Rupal Bhavsar[2], Daniel J. Clauw[1] and David A. Williams[1]. [1]University of Michigan, Ann Arbor, MI, [2]University of Michigan

Background: Fibromyalgia (FM) is a chronic pain condition characterized by widespread pain in addition to fatigue, disturbed mood, non-restorative sleep, and dyscognition. fMRI studies investigating brain activity in response to pressure and heat pain in FM have identified augmented activation of pain processing regions when exposed to these experimental pain stimuli. The use of functional connectivity (fc) to analyze "resting state" imaging data holds promise for revealing differences between FM and HC with regards to how brain regions differentially communicate with one another under conditions of spontaneous (i.e., chronic) pain versus these other studies which use experimentally-induced pain. Specifically, we were interested in whether individuals with FM differed from healthy controls (HCs) in resting state connectivity in the insular cortex (IC), a region that plays a critical role in pain perception and modulation and other regions associated with affect, cognition, and sensory experiences.

Methods: Using SPM8 and the SPM-based connectivity toolbox *Conn,* functional connectivity from resting state fMRI scans of 17 individuals with FM and 8 HCs used seed regions in the anterior, middle and posterior IC. After pre-procecessing (e.g., realignment, normalisation and smoothing) connectivity maps were generated indicating the temporal correlation of a given voxel with a seed region in the IC (i.e., in total, 6 connectivity maps). After Fisher z-transformation one and two sample t-tests were performed to determine IC connectivity both within and between groups.

Results: Highly correlated, low-frequency oscillations (< 0.1 Hz) between specific IC and cingulate cortex (CC) subdivisons were identified in both groups. Group differences were found in the connectivity of the left posterior IC and the left thalamus (i.e., hyperconnectivity in FM patients), the right IC and posterior mid-cingulate cortex/posterior cingulate cortex (i.e., hyperconnectivity in FM patients) and the right anterior IC and right middle frontal gyrus (hypoconnectivity in FM patients).

Conclusions: These data suggest that at rest, individuals with FM have stronger concurrent activations between brain regions known to participate in pain perception and modulation than do HCs. These data also add further support to the notion that central mechanisms play a critical role in the pain experience of individuals with FM.

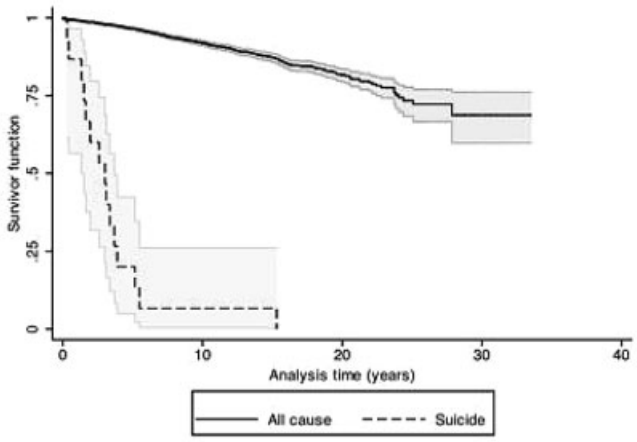
Mortality in Fibromyalgia: An 8,186 Patient Study over 35 Years. Frederick Wolfe[1], Afton L. Hassett[3], Brian T. Walitt[4] and Kaleb D. Michaud[2]. [1]National Data Bank for Rheumatic Diseases, Wichita, KS, [2]Univ of Nebraska Med Ctr, Omaha, NE, [3]University of Michigan Medical School, Ann Arbor, MI, [4]Washington Hospital Center, Washington, DC

Purpose: The issue of mortality in fibromyalgia (FM) is important because, if increased, it supports the seriousness of FM. One population based epidemiological study found that chronic widespread pain, effectively a criterion of the 1990 and 2010 ACR FM criteria, was associated with the risk of increased mortality, although that finding was not confirmed in another large population-based study. Reasons that mortality might be increased in fibromyalgia include substantial use of analgesics and anti-depressants, high levels of somatic symptoms, and high rates of depression. It seems possible that depression, socio-demographic characteristics or iatrogenesis could lead to increased mortality. The risk could also be increased if fibromyalgia is a representation of more extensive widespread pain or more severe symptoms. In this study we determined if mortality is increased among patients diagnosed with fibromyalgia.

Methods: We studied 8,186 fibromyalgia patients seen between 1974 and 2009 in 3 settings: all fibromyalgia patients in a clinical practice, patients participating in a longitudinal outcome study and patients invited to participate in the outcome study who refused participation. Internal controls included 12, 329 patients with osteoarthritis. Deaths were determined by multiple source communication, and all patients were also screened in the US National Death Index (NDI). We calculated standardized mortality ratios (SMR) based on age and sex stratified US population data, after adjustment for NDI non-response.

Results: There were 539 deaths, and the overall SMR was 0.90 (95% CI 0.61, 1.26). Among 1,665 clinic patients the SMR was 0.92 (95% CI 0.81, 1.05). Sensitivity analyses varying the rate of NDI non-identification did not alter the non-association. Adjusted for age and sex, the hazard ratio for fibromyalgia compared with osteoarthritis was 1.05 (95% CI 0.94, 1.17). The standardized mortality odds ratio compared with the US general population was increased for suicide, OR 3.31 (2.15, 5.11), for accidental deaths, 1.45 (1.02, 2.06), pneumonia 1.69 (1.12, 2.57) and septicemia 2.49 (1.61, 3.68), but not for malignancy 0.95 (0.76, 1.18).



Deaths were predicted by BMI, smoking, HAQ, fatigue, pain, mood and SF-36 in separate analyses adjusted for age and sex.

Conclusions: Mortality does not appear to be increased in patients diagnosed with fibromyalgia, but the risk of death from suicide and accidents was increased. The data are consistent with an in submission Danish study that reported no increase in overall mortality or cancer, but an increase in suicides.

Detection of Specific Markers Using Proteomics: Our Research on the Marker in Patients with Kawasaki Disease (KD). Rie Karasawa[3], Mikiya Fujieda[1], Kazuhide Ohta[2] and Kazuo Yudoh[3]. [1]Department of Pediatrics, Kochi Medical School, Kochi University, Japan, [2]Department of Pediatrics, National Hospital Organization Kanazawa Medical Center, [3]Institute of Medical Science, St. Marianna University School of Medicine, Kawasaki, Japan

Purpose: Anti-endothelial cell antibodies (AECA) are thought to be involved in pathophysiology of vasculitis. However, target molecules of AECA have been poorly identified, which hampers understanding of roles of AECA in detail. We tried to detect and identify target proteins of AECA comprehensively by proteomics. Further, we investigated clinical importance of the identified autoantigens in patients with KD.

Methods: We separated proteins extracted from HUVEC and HeLa cells respectively by 2-dimensional electrophoresis and then transferred them onto membranes. By WB using serum samples from patients with vasculitis, we detected autoantigens that were positive only in the HUVEC samples but not in the HeLa cell samples. We next identified the detected proteins by peptide mass finger-printing and characterized antigenecity by preparing recombinant autoantigens and antibodies to them.

Results: One of the identified 63 proteins was found peroxiredoxin2 (Prx2), an anti-oxidative enzyme. IgG antibodies to Prx2 were detected in 60% of the patients with KD, but not in healthy controls. IgM antibodies to Prx2 were detected in 10% of the KD patients, but also in 7% of healthy controls. IgA antibodies to Prx2 were not detected in both groups. Interestingly, IgG antibodies to Prx2 were detected in all the tested KD patients with coronary artery lesions. In contrast, IgM and IgA antibodies to Prx2 weren't detected in them. IIF staining revealed existence of Prx2 on the cell surface of HUVEC and WB using cell lysate proved expression of Prx2 not only in HUVEC but also in other endothelial cells (ECs), including human coronary artery endothelial cells(HCAEC). Anti-Prx2 antibodies also increased various inflammatory cytokine secretions significantly, in particular, IL-6 in HUVEC and G-CSF in HCAEC. IL-6 secretion of ECs stimulated with serum samples of patients with high anti-Prx2 titers was detected. WB using cell lysate and conditioned medium from ECs stimulated by H_2O_2 showed elevated expression levels of Prx2. Further, the addition of anti-Prx2 antibodies to the ECs resulted in increased concentration of H_2O_2 in the cell lysate. We measured Prx2-specific IgG titers on the pre- and posttreatment (within a week after therapy) in KD patients treated by IVIG. As a result, the titers on the posttreatment was higher than them on pretreatment in almost all tested KD patients.

Conclusions: IgG antibodies to Prx2 would be a useful marker for KD. Anti-Prx2 antibodies may have a pathogenic role in KD via inflammatory cytokine production and inhibition of anti-oxidative activity of Prx2 by binding Prx2 on ECs.

Specific Subgroup of New-Onset Systemic Juvenile Idiopathic Arthritis without Overt Macrophage Activation Syndrome Shares Similar Gene Expression Signature with a Distinct Subset of Familial Hemophagocytic Lymphohistiocytosis. Keith A. Sikora, Ndate Fall, Michael G. Barnes, Janos Sumegi, Alexandra H. Filipovich and Alexei A. Grom. Cincinnati Children's Hospital Medical Center, Cincinnati, OH

Background: Systemic juvenile idiopathic arthritis (sJIA) is a rheumatologic condition characterized by quotidian fevers, evanescent rash, lymphadenopathy, serositis, and arthritis. One of its feared complications is the macrophage activation syndrome (MAS), characterized by marked hyperferritinemia, pancytopenia, fever, hepatosplenomegaly, and presence of hemophagocytosis within the bone marrow, which closely resembles the primary hystiocytic disorder familial hemophagocytic lymphohistiocytosis (fHLH). The aim of this study was to compare the gene expression signatures of patients with new-onset sJIA, but without overt MAS, to HLH gene expression signatures.

Methods: Peripheral blood mononuclear cells (PBMCs) from 14 untreated new-onset sJIA without overt MAS, 11 fHLH patients, and 27 healthy controls were isolated from whole blood. Purified RNA was labeled using the Nugen Ovation RNA amplification and labeling system, and gene expression profiles were generated using the Affymetrix HG-U133 Plus 2.0 GeneChip. The list of differentially expressed genes was generated using Student's *t*-test, with Bonferroni-corrected P values less than 0.05 considered significant. Four of the 11 fHLH patients had known mutations in either their perforin or MUNC13-4 genes.

Results: A list of genes differentially expressed in systemic JIA was used in the hierarchical clustering analysis of samples obtained from healthy controls and patients with sJIA and fHLH. This analysis revealed distinct gene expression patterns among the sJIA and HLH patients, separating them into subgroups. One specific subgroup of sJIA patients (n=9) clustered together with a particular subgroup of HLH patients (n=4). This sJIA subgroup was characterized by an increase in peripheral CD34+ cells, increased peripheral myeloid precursors, and a general upregulation of cell cycle genes. Highly increased serum ferritin was another characteristic feature of this group. The patients in this corresponding HLH subgroup were more likely to have a rapidly progressive course of HLH and an identifiable mutation in either their perforin or MUNC13-4 gene.

Conclusions: There exists a distinct subgroup of new-onset sJIA, but without overt MAS, that displays a gene expression pattern that is shared with a specific subgroup of rapidly progressive, relapsing, and mostly mutation positive HLH patients. This subgroup of sJIA is characterized by an increase in peripheral CD34+ cells, increased peripheral myeloid precursors, and a general upregulation of cell cycle genes, perhaps reflecting increased turnover of hematopoietic cells.

A Genome-Wide Association Study for Juvenile Idiopathic Arthritis Identifies Chromosome Region 3q13 near the T Cell Receptor Co-Stimulatory Molecule CD80. Susan D. Thompson[1], Miranda Marion[10], Marc Sudman[2], Paula S. Ramos[10], Wendy Thomson[8], Anne Hinks[8], J. Peter Haas[7], Sampath Prahalad[4], John F. Bohnsack[9], Carol Wise[6], Marilynn G. Punaro[5], Carlos D. Rose[3], Mary Ryan[2], Monica Tsoras[2], Michael Wagner[2], Mehdi Keddache[2], Timothy Howard[10], Carl Langefeld[10] and David N. Glass[1]. [1]Childrens Hospital Med Ctr, Cincinnati, OH, [2]Cincinnati Children's Hospital Medical Center, [3]duPont Hospital for Children, Wilmington, DE, [4]Emory Children's Center, Atlanta, GA, [5]Texas Scottish Rite Hospital for Children, Dallas, TX, [6]Texas Scottish Rite Hospital for Children, [7]University of Greifswald, [8]University of Manchester, [9]University of Utah, Salt Lake City, UT, [10]Wake Forest University

Objective: Juvenile idiopathic arthritis (JIA) is a complex genetic trait. Like other autoimmune diseases, JIA has strong HLA associations, and is often found in families with a history of other autoimmune diseases. Furthermore, many of the loci associated with JIA are shared across several autoimmune diseases. Here we report a large genome-wide association study of oligoarticular and polyarticular rheumatoid factor negative forms of JIA.

Methods: The Discovery Cohort consisted of 814 JIA cases, 658 local controls and 2400 out-of-study controls from the Non-Gain Schizophrenia Study who self-identified as Non-Hispanic, European ancestry. The Replication Cohort consisted of 1621 cases and 1630 controls representing five independent JIA case and control sample collections originating from the United Kingdom (CAPS and BSPAR study group), Germany, Utah, Delaware or Texas. Additional out-of-study controls were available for the UK cohort (Wellcome Trust Case Control Consortium, n=5984) and used in the replication analysis. For the Discovery Cohort, genotyping was done using the Affymetrix SNP Array 6.0 and tests for association were adjusted for potential confounding affects of population structure via covariates in logistic regression models. Analyses were repeated adjusting for key HLA associations. Ten SNPs representing five loci, which to our knowledge have not yet been reported in JIA, were selected based on statistical evidence and biologic information and genotyped by Taqman or Sequenom chemistries in the Replication Cohort. Association testing and meta-analyses were performed.

Results: Testing for genome-wide association in the Discovery Cohort identified multiple loci outside the MHC region associated with JIA. Previously identified loci associated with JIA and overlapping with other autoimmune disease associations include PTPN22 (rs6679677, $p=1.98\times10^{-12}$,

rs2476601, $p=1.90\times10^{-13}$ and rs2488457, $p=6.74\times10^{-8}$), and PTPN2 (rs1893217, $p=1.60\times10^{-9}$ and rs7234029, $p=1.86\times10^{-10}$). Novel loci with consistent findings in both the Discovery and Replication cohorts are shown in the table and include c3orf1, IL15, and REEP3.

		Discovery Cohort				Replication Cohort				Meta Analysis
		MAF			OR	MAF		p-value	OR	
SNP	Chr Gene	JIA	Ctrls	p-value	[95%CI]	JIA	Ctrls		[95%CI]	p-value
rs6766899	3q13.33 CD6AP	0.26	0.22	3.62E-04	1.26 [1.11-1.43]	0.24	0.22	0.0464	1.18 [1.04-1.36]	3.15E-04
rs4688011	3q13.33 C3orf1	0.24	0.19	1.88E-06	1.37 [1.21-1.57]	0.21	0.19	0.0037	1.1 [1.01-1.21]	5.20E-07
rs13139575	4q31.21 IL15	0.44	0.48	2.44E-04	0.73 [0.62-0.86]	0.45	0.46	0.0249	0.92 [0.84-0.99]	1.07E-04
rs12411988	10q21.3 REEP3	0.18	0.13	1.17E-07	1.57 [1.33-1.84]	0.14	0.13	0.0953	1.07 [0.96-1.21]	1.92E-05

Conclusions: We provide strong evidence in both the Discovery Cohort and Replication Cohort for a novel autoimmune disease and JIA association with 3q13, a region containing the TCR co-stimulatory molecule CD80. Fine mapping and integration with gene expression data is underway to further define this locus.

Gene Expression Profiling in Peripheral Blood Mononuclear Cells Predicts Disease Flares in Children with Polyarticular Juvenile Idiopathic Arthritis Who Have Achieved Clinical Remission on Medication. Nicholas Knowlton[2], Mark Barton Frank[2], Nicholas E. Armstrong[1], Kaiyu Jiang[1], Yanmin Chen[1], Jeanette Osban[2] and James N. Jarvis[1]. [1]Dept of Pediatrics, U of OK College of Medicine, [2]Oklahoma Medical Research Foundation

Background: Children with polyarticular juvenile idiopathic arthritis (JIA) patients pursue variable clinical courses, even after disease control has been achieved. Developing biomarkers to identify which children can come off therapy and which children need continued or more aggressive therapy has been elusive.

Objective: To better understand the underlying biology of disease flares in polyarticular, RF-negative juvenile idiopathic arthritis (JIA), and to determine the feasibility of developing gene array-based prognostic biomarkers to guide therapy in this disease.

Methods: We performed gene expression profiling and *in silico* pathway analysis on peripheral blood mononuclear cells (PBMC) of 17 children with RF-negative polyarticular JIA at the time they achieved inactive disease (ID) status. Of these children, 8 subsequently experienced a disease flare within 11 months of achieving ID status, while the remaining 9 experienced sustained disease control over observation periods ranging from 18 months to 6 years. Computational analyses were undertaken in an attempt to distinguish the 2 groups.

Results: Gene expression profiling identified 103 genes that distinguished the Flare and No-flare groups. Gene expression profiling comparing children in ID/CRM who were fated to flare with those who were not ("baseline specimens") showed distinct differences between the two groups. The group fated to flare was already distinguishable from the group that remained stable at the time of baseline sampling. One hundred forty-four genes were differentially expressed between the two groups, all of which were over-expressed in children fated to flare. *In silico* modeling demonstrated that the differentially expressed genes could be incorporated into 4 large, linked networks. These networks incorporated genes associated with MAP kinase signaling, type 1 interferon production, and genes regulating the cell cycle. Furthermore, the gene expression profile remained largely stable in each group over the 5–15 month period over which the patients were followed. That is, comparison of the "flare" group at the time they achieved ID/CRM with the same patients at the time of their flare revealed only a single gene whose expression differed from the baseline sample. Similarly, children who remained stable also demonstrated a stable gene expression profile. In addition, network analysis suggests a role hepatocyte nuclear factor 4a (HNF4a), a transcription factor not previously identified in leukocytes, in maintaining treatment response in JIA.

Conclusions: Although the number of patients studied here is small, this work demonstrates the feasibility of developing prognostic biomarkers in JIA. These findings also cast light on the nature of the inflammatory networks that sustain the disease process in polyarticular JIA even when the illness clinically appears to be inactive.

Levels of beta2-Glycoprotein-I May Reflect a Protective Effect on the Development of Heart Block in Fetuses Exposed to Maternal Anti-Ro Antibodies. Joanne H. Reed, Tom P. Gordon, Robert M. Clancy and Jill P. Buyon. New York University School of Medicine

Purpose: Identification of congenital heart block (CHB) in a fetus predicts with near certainty that the mother, who may have a rheumatic disease or be asymptomatic, will have autoantibodies to a 60kD Ro protein (Ro60). Injury is thought to be initiated by surface binding of maternal anti-Ro60 autoantibodies to apoptotic cardiocytes during physiological remodelling of the fetal heart. The low penetrance of disease suggests that a factor in the microenvironment of the fetal hearts which remain unaffected may inhibit binding of maternal anti-Ro60 autoantibodies. The plasma protein beta2-glycoprotein I (β2GPI) is a potential candidate since it binds to Ro60 on the surface of apoptotic cells and inhibits opsonization by anti-Ro60 autoantibodies. The current study evaluated the opsonization of fetal apoptotic cardiocytes by IgG from mothers of infants with CHB in the presence or absence of β2GPI and determined whether fetal levels of β2GPI correlate with CHB.

Methods and Results: To test the role of β2GPI as a protective factor in CHB, in vitro studies were conducted on human fetal apoptotic cardiocytes (induced by staurosporine or loss of anchorage). Flow cytometry analysis revealed dose-dependent binding of β2GPI to apoptotic cardiocytes. IgG from a mother of a child with CHB (CHB IgG), but not IgG from a healthy control, bound the apoptotic cardiocytes (mean fluorescence intensity, MFI 3,998 vs 462). In the presence of β2GPI, the binding of CHB IgG to apoptotic cardiocytes was significantly inhibited in a dose-dependent manner (range 20–64%). Enzyme linked immunosorbent assay (ELISA) was used to measure levels of β2GPI in the umbilical cord blood from unaffected (n=25) and CHB (n=28) anti-Ro exposed infants. β2GPI levels were lower in CHB children (mean units 234 ± 17) compared to those unaffected (365 ± 29 SEM), ($p = 0.0004$). Ventricular rates were positively correlated with levels of β2GPI ($r = .512$, $p=0.042$). Among the cord blood samples, four twin pairs discordant for CHB, were assessed for β2GPI levels. In each pair, the twin with CHB had lower levels of β2GPI (169 ± 12) compared to the healthy twin (283 ± 20 however, this trend did not reach significance. β2GPI levels tended to be higher in those fetuses delivered by C-section but were not associated with maternal use of dexamethasone. Children with a higher weight at birth had significantly higher levels of β2GPI ($r=.51$, $p=0.01$) consistent with the observation that the neonates with CHB had significantly lower birth weights than those who were unaffected. Fetal β2GPI levels were not associated with gestational age at birth. β2GPI levels were not significantly associated with the requirement for a pacemaker.

Conclusion: Lower levels of fetal β2GPI are associated with CHB in anti-Ro60-positive mothers. β2GPI may protect the developing fetal heart from injury by binding to Ro60 on apoptotic cardiocytes and preventing opsonization by maternal anti-Ro60 autoantibodies. Factors such as infection, inflammation, or a genetic predisposition could reduce β2GPI levels in the fetus, thereby promoting conditions where the fetal heart is vulnerable to autoantibody-mediated tissue injury.

Pathogenic Consequences of Mutations of *NLRP12* Gene. A New Cold-Induced Autoinflammatory Disease. Silvia Borghini[2], Sara Tassi[1], Sabrina Chiesa[3], Francesco Caroli[2], Sonia Carta[1], Roberta Caorsi[3], Marco Di Duca[2], Denise Lasiglié[3], Alberto Martini[3], Isabella Ceccherini[2], Anna Rubartelli[1] and Marco Gattorno[3]. [1]Institute for Cancer Research, Genoa, Italy, [2]Lab of Molecular Genetics, G. Gaslini Institute, Genoa, Italy, [3]Rheumatology Unit, G. Gaslini Institute, Genoa, Italy

Purpose: mutations of the *NLRP12* gene have recently been described in patients affected with a new Autoinflammatory disease. NLRP12 belongs to the NLRPs family and its role in the activation of the inflammasome and regulation of NF-kB activation is currently being under investigation. We report about the clinical features and pathogenic findings of 4 patients carrying a novel p.D294E missense mutation of the *NLRP12* gene affecting the Walker B sequence of the protein crucial for ATP binding.

Patients and Methods: Four individuals, carrying the p.D29E NLRP12 mutation were analyzed. NF-kB activity was evaluated in *NLRP12*-mutated monocytes after 24 hour of TNF stimulation using TransAM NFkB p65 Kit. IL-1β secretion, production of ROS and activation of antioxidant systems in resting conditions and after PAMPs stimulation were also assessed. *In vitro* analysis of the NLRP12 mutation effect on NF-kB activity was performed after co-transfection of a *luciferase*-NF-kB promoter reporter construct with the mutant and wild type NLRP12 expression plasmids in HEK293 cells.

Results: the p.D294E mutation segregates in association with a particular sensitivity to cold exposure (especially arthralgia and myalgia), but not always with an inflammatory phenotype (urticarial rash or fever). The p.D294E mutated protein did maintain the same inhibitory activity shown by wt NLRP12. Unexpectedly, this was also observed when the already reported p.Arg284X nonsense mutation (Jéru et al., 2008) was analyzed in the same system. Consistently, NLRP12-mutated monocytes showed neither increased levels of p65 NF-kB activity nor higher amounts of IL-1b secreted. However, the kinetics of PAMP-induced IL-1b secretion was significantly accelerated, and a high production of ROS and an upregulation of antioxidant systems were demonstrated, in patients carrying NLRP12 mutations compared to healthy controls.

Conclusions: Even with a variable range of associated manifestations, the extreme sensitivity to cold exposure represents the main clinical hallmark of individual carrying the p.D294E mutation of the *NALP12* gene. The regulation of NF-kB activity does not seem to be affected in NLRP12-mutated patients. Redox alterations and accelerated secretion of IL1b may be responsible for the mild autoinflammatory phenotype observed

ACR Concurrent Abstract Sessions
Rheumatoid Arthritis - Clinical Aspects: Preclinical RA and Early RA
Monday, November 8, 2010, 2:30 PM–4:00 PM

658

Application of the New ACR/EULAR Classification Criteria for Rheumatoid Arthritis to At-Risk Populations May Identify RA Prior to Clinical Presentation. Jason R. Kolfenbach[5], Lezlie Derber[5], Kevin D. Deane[9], Jan Hughes-Austin[4], Michael H. Weisman[3], Jane Buckner[2], Ted R. Mikuls[11], James R. O'Dell[8], Peter K. Gregersen[6], Richard M. Keating[1], Jill Norris[10] and V. Michael Holers[7]. [1]Oak Park, IL, [2]Benaroya Research Institute at Virginia Mason, [3]Cedars-Sinai Medical Center, Los Angeles, CA, [4]Department of Epidemiology, Colorado School of Public Health, University of Colorado Denver, [5]Division of Rheumatology, University of Colorado at Denver, Aurora, CO, [6]N Shore Univ Hosp Rsch Ctr, Manhasset, NY, [7]Univ of Colorado School of Med, Aurora, CO, [8]University of Nebraska Medical Center, Omaha, NE, [9]University of Colorado at Denver, Aurora, CO, [10]University of Colorado Denver, Aurora, CO, [11]University of Nebraska Medical Center, Omaha, NE

Objective: The proposed ACR/EULAR classification criteria were developed in part to identify early RA. Applying the new criteria to at-risk populations prior to evaluation in the health care setting may identify a unique cohort in which to study the evolution of very early symptomatic RA. We have established prospective cohorts of subjects at potentially higher risk for RA based on genetic risk factors as part of the SERA study (Studies of the Etiology of RA). The purpose of the current analysis was to identify and characterize a cohort within these populations with 'definite RA' according to the newly proposed criteria.

Methods: We have established a cohort of first-degree relatives (FDRs) of probands with RA. FDRs without RA by the 1987 ACR criteria undergo a joint exam and have laboratory data obtained. Identical data is collected on a second at-risk DR4-enriched population containing parents of children with high risk HLA alleles and/or Type I diabetes. The proposed RA criteria were applied to subjects in these cohorts with swelling suggestive of synovitis in $\geq$ 1 joint on clinical exam after exclusion of findings attributed to alternative diagnoses (e.g. trauma, osteoarthritis). Data regarding joint distribution, duration of symptoms, antibody status and presence of elevated inflammatory markers were used to apply the new criteria. Descriptive statistics were calculated for the identified cases.

Results: 1790 subjects were available for analysis. 153 subjects (8.5%) had synovitis in $\geq$ 1 joint on clinical exam. 21 subjects (1.17%) had 'definite RA' according to the proposed algorithm. 17/21 (81%) subjects were female with a mean age of 48.9 years old. 6/21 subjects (28.6%) were positive for rheumatoid factor (RF), one (4.8%) was positive for anti-cyclic citrullinated peptide antibody, and 11 (52.4%) had elevated levels of CRP. Median swollen and tender joint counts were 3 and 11, respectively. The average total score in the 21 subjects was 6.76. The mean scores for joint involvement, serology, acute phase reactant and duration were 4.33, 0.9, 0.52 and 1.0, respectively (Table 1).

Table 1. Relative contribution of Clinical & Serologic factors to the designation of 'Definite RA' by the newly proposed ACR/EULAR Classification Criteria for RA*

Patient	1	2	3	4	5	6	7	8	9	10	11	12	13	14	15	16	17	18	19	20	21

Score $\geq$ 6 indicates 'definite RA' according to the proposed algorithm
*Scores derived from a single visit in which the subject achieved a score $\geq$ 6. Some subjects have additional visits 3 subjects with >1 visit with a score $\geq$ 6; first is depicted.

Conclusion: Individuals with 'definite RA' according to the new criteria can be identified in these unique at-risk populations. A score $\geq$ 6 was driven primarily by joint involvement with the majority stemming from tender rather than swollen joints, a finding which may indicate an earlier phase of RA development than individuals presenting for clinical care. The identification of these subjects in a research rather than clinical setting may allow us to study an earlier phase of RA than possible in usual clinical practice. These subjects will be followed prospectively with multiple modalities including serial joint evaluations and biomarker assessments to evaluate the relationship between the new RA criteria and the longer-term evolution of RA.

The Revised 2010 ACR/EULAR Diagnostic Criteria for Rheumatoid Arthritis Identify Many More Patients Who Are Eligible for Treatment and for Clinical Trials. Vivian P. Bykerk[5], Gilles Boire[2], Boulos Haraoui[4], Carol A. Hitchon[8], Ed C. Keystone[9], J. Carter Thorne[6], Diane S. Ferland[3], Janet E. Pope[7] and CATCH Investogators[1]. [1]Canada, Canada, [2]CHUS - Sherbrooke University, Sherbrooke, QC, Canada, [3]Hopital Maisonneuve Rosement, Montreal, LaSalle, QC, Canada, [4]Institut de Rhumatologie, Montreal, QC, Canada, [5]Mt Sinai Hospital, University of Toronto, Toronto, ON, Canada, [6]Southlake Regional Health Care, Newmarket, ON, Canada, [7]St Joseph Health Care London, London, ON, Canada, [8]University of Manitoba, Winnipeg, MB, Canada, [9]University of Toronto, Toronto, ON, Canada

Background: The 2010 revised ACR/EULAR criteria for the classification of RA were developed to enable earlier diagnosis. These criteria identify patients with RA likely to have persistent and/or erosive inflammatory arthritis. The revised criteria have not been validated in North American

patients or shown to identify patients who would be eligible for clinical trials that recruit for patients with a DAS28 of ≥ 3.2.

Objectives: To determine what proportion of patients with recent onset early inflammatory arthritis (IA) of < 1 year duration the revised ACR/EULAR criteria newly identify as having rheumatoid arthritis. To determine if these newly identified patients would be eligible for clinical trials in early RA.

Methods: Baseline (BL) data collected from patients (n=1146) enrolled into the Canadian Early Arthritis Cohort (CATCH) study, a multi-centre observational prospective "real world" cohort of patients with early IA recruited since July 2007 were analysed for this study. Inclusion Criteria were: age >16, symptom duration 6–52 weeks of persistent synovitis, ≥2 effused joints or 1 swollen MCP/PIP + ≥1 of: + RF, +anti-CCP, AM stiffness >45 minutes, response to NSAIDs, or a painful MTP squeeze test. The new 2010 ACR/EULAR criteria were applied to determine what proportion of patients with EIA fulfill the new criteria at BL. Most patients were treatment naive or had only received a few weeks of DMARDs. Patients newly identified as having RA by the new criteria were evaluated for disease activity and the proportion of patients with a DAS28 ≥3.2 were considered as potentially being eligible treatment of for an early RA clinical trial. Patients previously used for criteria development were excluded from this analysis.

Results: BL characteristics were: mean age 52±16 years, 73% female, median symptom duration 5.5 months, mean DAS28 ESR 4.9±1.6; 27% were initially treated with oral glucocorticoids and 50% treated with MTX. 26% (226/874) already had erosions at BL. 57% of patients were eligible for this analysis. Of the remaining 648 patients, 68% (N=441) of patients met 1987 ACR criteria for RA at BL. 31% (N=201) of patients had undifferentiated IA (UIA). Of these 74% (N=478) had a score of ≥ 6 on the new criteria. Of the 68% of patients who met old criteria, 82%(N=362) met new criteria. Of the UIA patients remaining, 57%(N=115) could now be diagnosed with RA using the new criteria. These patients had a mean (DAS28=4.0). 79% of the formerly UIA patients now meeting the new criteria had a DAS28 of ≥3.2.

Conclusions: Based on data from a Canadian cohort, revised ACR/EULAR 2010 criteria can identify a substantial number of new patients previously being designated as UIA as having RA. The majority of these patients would be eligible for clinical trials in ERA. Most of patient who fulfill the 1987 ACR criteria also fulfill the revised 2010 criteria.

660

A Novel Diagnostic Marker for RA, Anti-MCV. Rong W. Zablocki[1], Annette Van der Helm-van Mil[3], Tom Huizinga[3] and Srinivas Rao[2]. [1]Cypress Bioscience Inc, San Diego, CA, [2]Cypress Bioscience Inc, [3]Leiden University Medical Center, The Netherlands

Purpose: Early identification of undifferentiated arthritis (UA) patients at greatest risk for developing rheumatoid arthritis (RA) may facilitate better treatment. Rheumatoid factor (RF IgM) and antibodies against cyclic citrullinated peptide (anti-CCP) are widely used in diagnosing RA. It has been suggested that the enzyme-linked immunosorbent assay (ELISA) to detect mutated, citrullinated vimentin (anti-MCV) may have a different diagnostic spectrum versus anti-CCP. The purpose of the current study was to evaluate the diagnostic performance of combinations of these biomarkers in UA-RA patients.

Methods: Clinical and laboratory data were analyzed from a 470 patient subset of the previously described 570 patient Leiden Early Arthritic Clinic cohort (A. Van der Helm-van Mil, et al., 2007). These patients presented with UA, and a fraction (n=153) progressed to RA within 1 year, based on the fulfillment of the American College of Rheumatology (ACR) criteria. Anti-MCV, Anti-CCP2 and RF IgM tests were performed. A positive result for a combination was defined as resulting when all constituents were positive; a negative result of any constituent was defined as the combination negative. The sensitivity, specificity, positive predictive value (PPV) and negative predictive value (NPV), as well as their 95% confidence intervals (CI), were calculated for each individual biomarker as well as their combinations.

Results: Table 1 presented the diagnostic performance of the biomarkers and their combinations. Overall, anti-MCV demonstrated the highest sensitivity (63%) and NPV (82%), though at the cost of reduced PPV (60%). Combining Anti-CCP2 and Anti-MCV barely reduced sensitivity comparing to Anti-CCP2 alone (52% vs. 53%), and exhibited a favorable balance in sensitivity/specificity and in PPV/NPV. Further, the sensitivity diagram (at right) revealed that anti-CCP2 did not provide additional information (sensitivity=0%) in the context of both RF IgM and anti-MCV being positive. However, anti-MCV and RF IgM still respectively retained 10% and 5% sensitivity despite positivity of the other 2 assays.

Conclusions: Anti-MCV showed the highest sensitivity and NPV. Nearly all Anti-CCP2 positive RA patients were also Anti-MCV positive, though not vice versa, reinforcing the notion that the diagnostic spectrum of the 2 assays is not identical. In the context of positive results for both anti-MCV and RF IgM, anti-CCP2 became redundant in term of sensitivity. In summary, incorporating anti-MCV as an adjunctive diagnostic tool to prognosticate future RA in patients who present with UA enhances sensitivity.

Table 1. Performance of the biomarkers in UA-RA patients (N=470)

Biomarkers	Sensitivity % (95%CI)	Specificity % (95%CI)	PPV % (95%CI)	NPV % (95%CI)
Anti-CCP2	53 (45-61)	88 (84-91)	69 (60-76)	80 (75-83)
RF IgM	48 (41-56)	84 (79-88)	59 (50-67)	77 (72-81)
Anti-MCV	63 (55-70)	80 (75-84)	60 (52-67)	82 (77-85)
Anti-CCP2 & Anti-MCV	52 (44-59)	91 (87-94)	73 (64-81)	80 (75-83)
Anti-CCP2 & RF IgM	42 (34-50)	93 (90-95)	74 (64-83)	77 (72-81)
Anti-MCV & RF IgM	42 (35-50)	92 (88-94)	71 (61-80)	77 (72-81)
Triple-Combination	41 (33-48)	93 (90-96)	75 (64-83)	76 (72-80)

Smoking Is a Predictor of Very Early Presentation with Rheumatoid Arthritis. David W. Sharpley[1], Sarang Chitale[2], Cristina Estrach[2], Robert N. Thompson[2], Robert J. Moots[2] and Nicola J. Goodson[2]. [1]Academic Rheumatology Department, Aintree University Hospitals, University of Liverpool, Liverpool, Merseyside, United Kingdom, [2]Academic Rheumatology Department, Aintree University Hospitals, University of Liverpool

Background: Starting disease modifying anti-rheumatic drug (DMARD) treatment very soon after rheumatoid arthritis (RA) symptoms develop may significantly alter the disease course in early RA (eRA) (1). Early arthritis clinics (EAC) have been set up to allow for rapid assessment and initiation of DMARD therapy for eRA. Symptom duration varies in eRA patients with some presenting with very early RA (veRA), defined as a symptom duration ≤12 weeks. These veRA presenters may differ from eRA patients with longer symptom duration at presentation.

Aim: The aim of this study is to identify predictors and disease characteristics associated with veRA presentation to an EAC.

Methods: New attendees at an EAC between May 2006 & March 2010 with eRA or probable eRA by ACR-EULAR 2010 criteria were identified. Symptom duration (weeks), smoking status, disease activity score (DAS-28), baseline radiograph & ultrasound findings, ESR, rheumatoid factor (RF) & anti-citrullinated protein antibody (ACPA) status, and other variables were recorded at presentation. Univariate, age & gender adjusted, & multivariate logistic regression were performed to identify predictors of very early presentation. Stratified analysis by ACPA status was also performed.

Results: 225 patients with eRA or probable eRA had a median age of 59 yrs [IQR 48, 70]. 140 (62%) female, 157 (70%) ACPA positive & 164 (73%) RF positive patients were identified. 189 (84%) had eRA by ACR-EULAR 2010 criteria & 89 (40%) presented within 12 weeks. Age & gender adjusted analyses revealed that, compared to later eRA presenters, veRA patients had higher ESR titres, tender & swollen joint counts & DAS-28 scores, but were less likely to be ACPA positive at presentation. Multivariate modelling identified smoking, ACPA negative status and ESR as independent predictors

of veRA presentation (Table 1). ACPA stratified analyses revealed that the association between smoking & veRA presentation was considerably stronger in ACPA negative patients (OR 15.55, 95% CI 1.61, 149.70) compared to that seen in ACPA positive patients (OR 2.23, 95% CI 1.11, 4.46).

Table 1. Multivariate model predicting veRA presentation

Presentation with veRA	Odds Ratio	95% Confidence Interval	
Age	1.00	0.98	1.02
Gender	1.12	0.62	2.02
Current smoker	2.76	1.45	5.25
ACPA positive	0.32	0.17	0.62
ESR	1.02	1.01	1.03

Conclusions: Smoking is associated with very early presentation and this association appears to be influenced by ACPA status in eRA. Interestingly, veRA patients were less likely to be ACPA positive at baseline. This may represent very early capture of patients prior to the development of ACPA.

Those with veRA had more active disease but less joint damage on ultrasound investigation. These veRA patients may benefit from early DMARD therapy to prevent joint damage and treatment within the window of opportunity may alter their disease course. It is interesting to note that in established RA, smoking is associated with more severe radiological, disability and mortality outcomes. Early remission induction in veRA presenters who smoke could improve these long-term outcomes.

Long-Term Remission in Daily Clinical Practice: Excellent 2 Year Results with Treatment To Target in Very Early Rheumatoid Arthritis, Results of the DREAM Remission Induction Cohort. Marloes Vermeer[5], Ina H. Kuper[5], Monique Hoekstra[1], Hein J. Bernelot Moens[6], Marcel D. Posthumus[4], Herman L. M. Brus[3], Piet L. C. M. van Riel[2] and Mart A. F. J. van de Laar[5]. [1]Isala Klinieken, Zwolle, The Netherlands, [2]Radboud University Nijmegen Medical Centre, Nijmegen, The Netherlands, [3]TweeSteden Ziekenhuis, Tilburg, The Netherlands, [4]University Medical Center Groningen, Groningen, The Netherlands, [5]University of Twente and Medisch Spectrum Twente, Enschede, The Netherlands, [6]Ziekenhuisgroep Twente, Almelo/Hengelo, The Netherlands

Background: Remission is the primary target of treatment of rheumatoid arthritis (RA). Clinical trials have proven that systematic monitoring of disease activity and adjusting medication on the basis of the disease activity outcome is effective in reaching this goal. Therefore, in current guidelines and recommendations on RA it has been advocated to treat RA to target. However, aiming for remission is not yet implemented and data on inducing and achieving remission in daily clinical practice are limited. The objective of this study was to evaluate disease activity in very early RA patients in daily clinical practice after 2 years of applying a tight control treatment strategy.

Methods: Since January 2006, 534 newly diagnosed patients with early RA (clinical diagnosis of RA, symptom duration ≤ 1 year) were enrolled in the Dutch Rheumatoid Arthritis Monitoring (DREAM) remission induction cohort study. Treatment adjustments (4–8 weekly) were based on the DAS28, aiming at DAS28 < 2.6. The medication protocol consisted of initial MTX, addition of SSZ, exchange of SSZ by anti-TNF in case of insufficient response. Primary outcome was the disease activity according to the DAS28, EULAR response criteria and ACR criteria for clinical remission after 1 and 2 years. Additional outcomes included time to first remission and sustainability of remission.

Results: Baseline characteristics were as follows: mean (SD) age 57.7 (13.9) years, 62.8% female, 56.6% RF positive, 62.4% anti-CCP positive, median (IQR) symptom duration 15 (8–26) weeks, mean (SD) baseline DAS28 5.0 (1.1) and 82.8% of patients fulfilled the ACR classification criteria for RA. Of all patients, 1 year follow-up data was available in 392 patients and 2 year data in 210 patients. At 1 year (n=392), 55.1% of patients achieved DAS28 remission, 64.8% had a good EULAR response and 45.1% satisfied the ACR remission criteria (Table 1). At 2 years (n=210), 64.3% of patients achieved DAS28 remission, 75.7% had a good EULAR response and 54.4% satisfied the ACR remission criteria (Table 1). Median (IQR) time to first DAS28 remission was 22 (12–37) weeks. In more than 60% (127/210) of patients sustained DAS28 remission (≥ 6 months) was observed during the first 2 years of follow-up. The majority of patients achieved remission on conventional DMARDs (mono or combination therapy). Results were independent of the definition of RA (i.e. clinical diagnosis/ACR 1987 criteria) or presence of traditional prognostic factors for RA (i.e. RF/anti-CCP).

Table 1. Clinical outcomes alter 1 and 2 years.

	1 year (n = 392)	2 year (n = 210)
DAS28		
Remission (DAS28 < 2.6)	216 (56.1)	135 (64.3)
Low (2.6 ≤ DAS28 ≤ 3.2)	62 (15.8)	37 (17.6)
Moderate (3.2 < DAS28 ≤ 5.1)	103 (26.3)	32 (15.2)
High (DAS28 > 5.1)	11 (2.8)	6 (2.9)
EULAR response		
Good	254 (64.8)	159 (75.7)
Moderate	102 (26.0)	35 (16.7)
None	36 (9.2)	16 (7.8)
ACR remission	143/317 (45.1)*	93/171 (54.4)*

Values are presented as number (%). *ACR remission could not be evaluated in all patients, due to missing values for morning stiffness.

Conclusion: This study shows that long-term remission is a realistic goal in very early RA patients in daily clinical practice. Implementation of a tight control treatment strategy results in rapid and high remission rates, regardless of the definition used. The management of very early RA patients in clinical care can go beyond the control of signs and symptoms, and should aim at remission.

663

The Association of Joint Damage and Treatment Response with ACPA Status in Recent Onset RA. M. van den Broek[3], N. B. Klarenbeek[4], M. L. Westedt[1], H. D. Boom[5], P. J. S. M Kerstens[2], T. W. J. Huizinga[4], B. A. C. Dijkmans[6] and C. F. Allaart[4]. [1]Bronovo Hospital, The Hague, The Netherlands, [2]JBI, Amsterdam, The Netherlands, [3]LUMC, Leiden, The Netherlands, [4]LUMC, Leiden, The Netherlands, [5]Spaarne Hospital, Hoofddorp, The Netherlands, [6]VU Medical Centre, Amsterdam, The Netherlands

Objective: To compare clinical and radiological response to disease activity score (DAS) steered treatment in patients with recent onset RA who were positive or negative for anti-citrullinated protein antibodies (ACPA).

Methods: In the BeSt study, 508 recent onset RA patients were randomized to 4 treatment strategies, aimed at a DAS ≤2.4: sequential monotherapy, step-up combination therapy, initial combination therapy including prednisone and initial combination therapy including infliximab. Chances of damage progression >5 (Sharp/vd Heijde score (SHS)) in 1 year, and >25 in 5 years, and rate of (drugfree) remission were compared for ACPA positive and ACPA negative patients, using logistic regression analysis. Functional ability over time, measured with the Health Assessment Questionnaire (HAQ), was compared using linear mixed models. The analyses were adjusted for gender, smoking habits and baseline age, DAS, and SHS

Results: At baseline, ACPA positive patients (N=297) had more radiographic damage than ACPA negative patients (N=183): median SHS 4.0 (IQR 1.0–10.5) vs 1.5 (IQR 0–6.1), and a lower DAS (4.3 for the ACPA positive group, vs 4.6, $p<0.001$) and HAQ (1.3 vs 1.5, $p=0.02$). More ACPA positive patients were male ($p=0.01$) and more were smokers ($p=0.01$). DAS reduction was achieved similarly in ACPA positive and ACPA negative patients in all treatment groups (figure). After 1 year of follow-up, the Odds ratio (OR) of SHS progression >5 was 3.27 (95% C.I. 1.68–6.35) for ACPA positive patients. After 5 years the OR of progression >25 was 5.95 (95% C.I. 2.02–17.52). Over time, there were no significant differences in HAQ between ACPA positive and negative patients. Odds ratio of ever achieving remission was 1.09 (95% C.I. 0.63–1.88) for ACPA positive patients, and of achieving remission during at least 1 year 0.75 (95% C.I. 0.49–1.16)). However, ACPA positive patients did have a lower chance of ever achieving drugfree remission (OR 0.46 (95% C.I. 0.28–0.72)) and a higher chance of restarting medication (OR 8.47 (95% C.I. 3.09–23.25)).

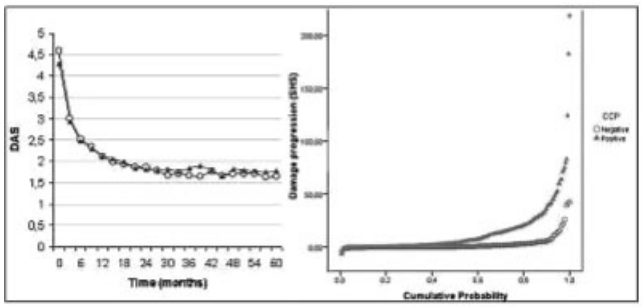

Figure. DAS over time and probability plot depicting radiographic progression (change in SHS) for ACPA positive and ACPA negative patients in 5 years.

Conclusion: Not the chance of remission, but the chance of (persistent) drugfree remission was lower in ACPA positive patients compared to ACPA negative patients. Treatment response was similar in both groups, irrespective of initial treatment and baseline characteristics. However, more ACPA positive patients had significant radiographic damage progression. This may suggest that, in ACPA positive patients, treatment decisions should be based on disease activity, but also on damage progression.

ACR Concurrent Abstract Sessions
Spondylarthropathies and Psoriatic Arthritis - Clinical Aspects and Treatment - Imaging

Monday, November 8, 2010, 2:30 PM–4:00 PM

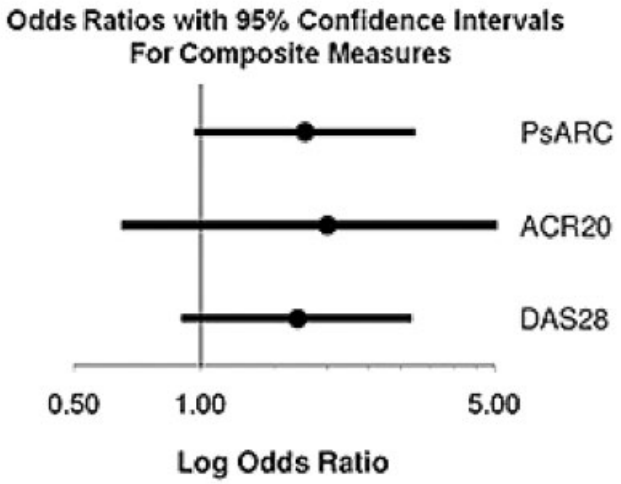
664

Methotrexate Is Not Disease Modifying in Psoriatic Arthritis: The MIPA Trial. Gabrielle H. Kingsley[3], Anna Kowalczyk[4], Helen Taylor[4], Fowzia Ibrahim[4], Jonathan C. Packham[2], Neil J. McHugh[7], Diarmuid M. Mulherin[1], George D. Kitas[8], Kuntal Chakravarty[6], Brian D. M. Tom[5], Peter J. Maddison[9] and David L. Scott[4]. [1]Cannock Chase Hospital, Cannock, United Kingdom, [2]Haywood Hospital, Stoke on Trent, UK, [3]Kings College London, London, United Kingdom, [4]Kings College London, UK, [5]MRC Biostatistics Unit, University of Cambridge, UK, [6]Queens Hospital, Romford, UK, [7]Royal National Hospital for Rheumatic Diseases, Bath, UK, [8]Russells Hall Hospital, Dudley, UK, [9]Sport, Health and Exercise Science, University of Bangor, UK

Background: Methotrexate (MTX) is widely used as a disease modifying drug (DMARD) in psoriatic arthritis (PsA) without definitive supporting clinical trial evidence. We tested its effectiveness in the first large multicentre randomised controlled trial (RCT) of MTX in active PsA (MIPA).

Methods: A 6-month double-blind RCT compared oral MTX (15mg/week) with placebo in patients with active PsA. The primary outcome measure was the PsA Response Criteria (PsARC); other composite measures included ACR20 and DAS28. We analysed changes in individual measures including "disease modifying" (joint counts, HAQ, ESR and CRP) and "symptom modifying" (global assessments and pain) measures, skin and nail scores.

Results: 462 patients were screened and 221 recruited. 71/109 (65%) of those who received MTX and 77/112 (69%) of those who received placebo completed 6 months therapy. 19 patients (11 MTX, 8 placebo) withdrew for toxicity and 22 (8 MTX, 14 placebo) for inefficacy. No significant treatment effects were seen on PsARC, ACR20 and DAS28 at 3 or 6 months using intention to treat logistic regression analysis (including multiple imputations for missing data and adjustment for age and sex).



There were also no significant treatment effects on tender and swollen joint counts, ESR, CRP, HAQ, pain and nail scores using ordinal linear regression analyses (adjusted for age, sex, baseline scores and disease duration). Patient and physician global scores and skin scores did improve with MTX compared to placebo but at 6 months only ($p=0.03$, $p=0.02$ and $p=0.02$). Separate analysis of polyarticular and oligoarticular PsA subsets also showed no treatment effect for PsARC, ACR20 and DAS28 at 3 or 6 months.

Conclusions: Contrary to general opinion, MTX does not act as a DMARD in PsA but has only borderline "symptom modifying" properties. Its value in active PsA is questionable when there are other agents, such as leflunomide and TNF-inhibitors, which are true DMARDs. This has important implications for current national and international guidance for the treatment of PsA.

Rates and Predictors of Radiographic Sacroiliitis Progression over Two Years in Patients with Axial Spondyloarthritis. Denis Poddubnyy[1], Martin Rudwaleit[1], Hildrun Haibel[1], Anja Weiss[3], Elisabeth Märker-Hermann[4], Henning Zeidler[5], Jürgen Braun[6] and Joachim Sieper[2]. [1]Charité - Campus Benjamin Franklin, Berlin, Germany, [2]Charite Campus Benjamin Frankl, Berlin, Germany, [3]Deutsches Rheumaforschungszentrum, Berlin, Germany, [4]Dr. Horst Schmidt Kliniken, Wiesbaden, Germany, [5]Medizinische Hochschule, Hannover, Germany, [6]Rheumazentrum Ruhrgebiet, Herne, Germany

Background: The current concept of axial spondyloarthritis (SpA) considers non-radiographic axial SpA and ankylosing spondylitis (AS) as two stages of one diseases suggesting progression of radiographic sacroiliitis over time. However, rates of radiographic sacroiliitis progression and predictors of such progression remain unclear until now. The objective of the study was to assess the rates of radiographic sacroiliitis progression and to explore possible progression predictors in a cohort of patients with axial SpA over a period of two years.

Methods: 210 patients with axial SpA (AS and non-radiographic axial SpA) from the German Spondyloarthritis Inception Cohort (GESPIC) have been selected for this analysis based on availability of radiographs at baseline and after 2 years of follow-up. Radiographs of pelvis at baseline were centrally digitized and the sacroiliac joints were scored independently according to the grading system of the modified New York criteria by 2 trained readers. The readers scored both time points simultaneously but were blinded for the time point and for all clinical data.

Results: In total, 115 patients (54.8%) fulfilled the modified New York criteria for AS in their radiographic part in opinion of both readers at baseline, while 95 patients (45.2%) were classified as non-radiographic axial SpA (nrSpA). After 2 years 11 patients (11.6%) from the group of nrSpA fulfilled the modified New York criteria for AS in the opinion of both readers.

Progression of sacroiliitis over two years by at least one grade at one side in opinion of both readers was found in 26 patients (12.4%). Rate of progression was higher among patients with nrSpA (16 patients or 16.8%) as compared to AS (10 patients or 8.7%), although the difference was statistically non-significant (p=0.074). At the same time, there was an improvement of sacroiliitis by at least one grade in the opinion of both readers in 11 patients (5.2%): 6 with nrSpA (6.3%) and 5 with AS (4.3%). Therefore the true radiographic sacroiliitis progression rate over two years could be estimated as 10.5% for patients with nrSpA and 4.4% for patients with AS.

The only one strong positive predictor of radiographic sacroiliitis progression was an elevated level of C-reactive protein at baseline (OR 2.61, p=0.026) - table. Interestingly, presence of definite sacroiliitis at baseline was rather negative predictor of radiographic progression (OR 0.42, p=0.038), which is also illustrated by a higher rate of progression in the group of patients with nrSpA.

Table. Odds ratios (ORs) for progression of radiographic sacroiliitis by at least one grade over 2 years in patients with axial SpA (univariate analysis).

Parameters at baseline	OR (95% CI)	p
Sex, male vs. female	0.47 (0.20–1.1)	0.080
HLA-B27, positive vs. negative	0.85 (0.32–2.3)	0.736
CRP, >6 mg/l vs. ≤6 mg/l	2.61 (1.12–6.06)	0.026
ESR, >20 mm/h vs. ≤20 mm/h	1.28 (0.54–3.06)	0.575
BASDAI, >4 vs. ≤4 points NRS	1.00 (0.44–2.28)	0.997
Disease duration, >5 years vs. ≤5 years	1.29 (0.55–3.02)	0.554
Definitive sacroiliitis* at baseline	0.42 (0.18–0.95)	0.038

* At least grade 2 unilaterally in the opinion of both readers
OR - odds ratio, CI - confidence interval, CRP - C-reactive protein, ESR - erythrocyte sedimentation rate. NRS - numeric rating scale

Conclusion: Progression of radiographic sacroiliitis by one grade after 2 years occurred in 10.5% of the patients with nrSpA and 4.4% of the patients with AS. Elevated level of CRP was found to be a strong positive predictor of sacroiliitis progression.

High Prevalence of Axial Spondyloarthritis in Patients with Familial Mediteranean Fever, and a Greater Allelic Frequency of M694V in Familial Mediteranean Fever Patients with Radiograpic Sacroiliitis. Servet Akar[2], Ozgul Soysal[2], Feride Yuksel[1], Dilek Solmaz[2], Gercek Can[2], Merih Birlik[2], Mehmet Tunca[1], Fatos Onen[2] and Nurullah Akkoc[2]. [1]Internal Medicine, Dokuz Eylul University Faculty of Medicine, Izmir, Turkey, [2]Rheumatology, Dokuz Eylul University Faculty of Medicine, Izmir, Turkey

Background: Familial Mediterranean fever (FMF) is an autoinflammatory disease characterized by recurrent attacks of fever and serositis. Limited data suggest that the prevalence of sacroiliitis, which is a hallmark of ankylosing spondylitis (AS), is increased in patients with FMF. Moreover in most recent studies we and other groups have found a significantly higher frequency of M694V in AS patients. Therefore in the present study we assessed the prevalence of axial spondyloarthritis (SpA), including AS, in FMF patients. We also studied the presence of MEFV variants in FMF patients with and without radiographic sacroiliitis.

Patients and Methods: The first 258 patients with FMF [130 female (%50,4), mean age 38,9 ± 12] who were invited to the outpatient clinic for another study were interviewed by using a structured questionnaire to capture patients with SpA. Presence of inflammatory back pain (IBP) was judged based on both Calin and Berlin criteria and the diagnosis of AS was based on the modified New York (mNY) criteria. Standard pelvic X-rays of the sacroiliac joints (SIJ) were performed in all patients. Patients with IBP were also assessed by magnetic resonance imaging (MRI) of SIJ and HLA B27 testing. MEFV variants of the patients were extracted from the patients' medical charts.

Results: Two hundred FMF patients (108 female; 54%) patients (77,5%) reported to have current and/or past back pain. IBP according to Calin and Berlin criteria were present in 53 patients (26,5%) and 42 patients (21%), respectively. One patient had inflammatory bowel disease and one had psoriasis, and 56 (21,8%) had a positive family history for SpA. A total of 15 patients (5,8%) had radiographic sacroiliitis (bilateral grade 2 or unilateral grade 3–4) and 14 of them fulfilled the mNY criteria for AS. Additionally bone marrow edema was detected by MRI of SIJ in 13 patients with IBP (5.0%). HLA-B27 positivity was found in only one of the 12 patients with sacroiliitis on MRI and in none of the 14 patients with radiographic sacroiliitis. Allele frequency of M694V in FMF patients with radiographic sacroiliitis was significantly higher in comparison to those without sacroiliitis (67,9% vs 43,7%; p=0,017) with an OR of 2,7 (95% CI= 1,2 to 6,2).

Age, years, mean ± SD	41,1 ± 11,5
Female, n (%)	9 (60)
Age at onset of FMF; years, mean ± SD	12,4 ± 5,2
Age at onset of back pain; years, mean ± SD	31,6 ± 11,6
BASDAI, mean ± SD	3,5 ± 2,3
BASFI, mean ± SD	2,0 ± 1,8
Presence of syndesmophyte, n (%)	3/14 (21)
HLA-B27 positivity, n (%)	0 (0)
M694V positivity, n (%)	12 (85)*

* Based on 14 unrelated cases.

Conclusion: Our results suggest that axial SpA in patients with FMF and SpA is more common than in the general population. Moreover, M694V may be playing a bigger role than HLA-B27 in susceptibility to AS in FMF patients.

Evidence That New Focal Fat Lesions Follow Resolution of Spinal Inflammation in AS but Existing Lesions Are More Likely To Resolve with TNF Blocking Agents. Praveena Chiowchanwisawakit[1], Robert G. W. Lambert[2] and Walter P. Maksymowych[2]. [1]Mahidol University, Bangkok, Thailand, [2]University of Alberta, Edmonton, AB, Canada

Purpose: MRI of the spine in SpA frequently shows focal fat lesions in the spine on T1W scans, especially at vertebral corners (VC) and adjacent to the vertebral endplate. Its histopathological basis and pathophysiological implications remain unclear. Adipose tissue has been shown capable of expressing proinflammatory cytokines. It is assumed that VC Fat reflects post-inflammatory change but there have been no prospective studies that have actually tested this hypothesis. We aimed to test the hypothesis that an active vertebral corner inflammatory lesion (CIL) on baseline MRI is more likely to evolve into a *de novo* VC Fat lesion on TIW scans than a VC which demonstrates no inflammation on baseline MRI.

Method: MRI scans were performed at baseline and 2 years in 61 AS patients of whom 28 received TNF blocking agents in open label follow up of clinical trials while 33 received either TNF blocking agents (n = 16) or standard therapy (n = 17) in an observational cohort. We recorded VC fat lesions, defined as increased signal in bone marrow on T1W MRI, and CIL, defined as increased signal on STIR MRI, at anterior and posterior VC on any central sagittal slice. Via televideoconference, reference images were developed in which VC fat lesions and CIL were assigned by consensus amongst an international MRI working group. VC Fat lesions and CIL were independently recorded dichotomously (present/absent) from lower C2 to the upper sacrum of the spine. Anonymized MRI scans were assessed independently by 2 readers who were blinded to treatment and time point. The primary analysis was based on concordant data (VC fat, CIL) and compared the development of new VC Fat lesions according to the presence of a CIL on baseline MRI and its persistence/resolution on follow up MRI. We also tested the effect of treatment on baseline VC fat lesions. Proportions were compared by Fisher's exact test.

Results: New VC Fat lesions developed significantly more frequently in those VC with (32/83 (38.6%)) as compared to those without (69/2647 (2.6%)) inflammation on baseline MRI in the anti-TNF group (p<0.0001). This was less evident in the standard therapy group (1/14 (7.1%) vs 8/1161 (0.7%), p = NS). New VC Fat lesions developed significantly more frequently from CIL that resolved compared to VC with persistent or no CIL in the anti-TNF therapy group (p<0.0001). These differences were again less evident in the standard therapy group. VC Fat lesions present on baseline MRI resolved significantly more frequently after TNF blocker (47/247 (16%)) compared to standard treatment (5/94 (5.1%)) (p = 0.005).

Table. Number (percentage) of new VC Fat lesions.

	Treatment	Resolved CIL	Persistent CIL	NO CIL
VC Fat+	Anti-TNF	16 (20.8)	1 (5.0)	34 (1.3)
VC Fat−	Anti-TNF	61 (79.2)	19 (95.0)	2578 (98.7)
VC Fat+	Standard	1 (11.1)	0	8 (0.7)
VC Fat−	Standard	8 (88.9)	5 (100)	1153 (99.3)

Conclusion: New VC Fat lesions occur more frequently at sites of prior inflammation, especially after inflammation has resolved following institution of anti-TNF. Existing VC Fat lesions are also more likely to resolve with anti-TNF.

New Bone Formation in the Spine of Patients with Diffuse Idiopathic Skeletal Hyperostosis (DISH) and Ankylosing Spondylitis (AS)—A Detailed Comparative Analysis of the Rates of Radiographic Progression over 6 Years. Xenofon Baraliakos[3], Joachim Listing[1], Jana Buschmann[3], Anna von der Recke[3] and Juergen Braun[2]. [1]German Rheumatism Research Center, [2]Rheumazentrum Ruhrgebiet, Herne, Germany, [3]Rheumazentrum Ruhrgebiet Herne

Background: Ankylosing spondylitis (AS) and diffuse idiopathic skeletal hyperostosis (DISH) have a similar pattern of new bone formation.

Objective: To compare the natural course of radiographic progression of AS-specific (syndesmophytes) and degenerative (spondylophytes) changes in AS and DISH.

Methods: All AS and DISH patients who had lateral radiographs of the cervical and the lumbar spine at at least 2 timepoints within 6 years were included in this retrospective study. Radiographic progression was compared on the basis of deve-lop--ment of syndesmophytes and spondylophytes and by using the mSASSS. Images were scored by 3 blinded readers. The differentiation between syndesmo-phytes and spondylophytes was made as recently proposed. Baseline characteristics and follow-up rates of radiographic progression were compared by summary statistics. Covariance and logistic regression analysis were also performed for radiographic status at baseline (BL) and development of bone formation over time.

Results: A total of 146 AS (mean age 54.2±12.3y, symptom duration 23.6±11.2y, no biologics) and 141 DISH patients (n=141, mean age 60.3±7.7y, symptom duration 21.6±12.4y) were included. At BL, the mean number of syndesmophytes/patient was 5.7±5.5 in AS and 2.7±2.8 in DISH (p=0.001), while a trend for more spondylophytes was seen in DISH (1.4±1.8) vs. AS (1.0±1.4). In the covariance analysis of all patients adjusted for baseline status of radiographic damage, more new syndesmophytes/patient were seen in AS (2.0±2.7, 95%CI: 1.7–2.4) vs. DISH (0.5±0.9, 95% CI: 0.3–1.1), (p<0.001), while a trend for more spondylophytes/patient was seen in DISH (0.54±1.0, 95% CI: 0.37–0.70) vs. AS (0.46±1.10, 95%CI: 0.30–0.62).

Syndesmophytes at BL were predictive of new syndesmophytes at follow-up in AS but not in DISH, whereas spondylophytes at BL were predictive for new spondylophytes in DISH but not in AS: 2.4±2.7 vs. 1.1±2.7 new syndesmophytes/patient (p<0.001) were seen in AS patients with vs. without baseline syndesmophytes and 0.9±1.4 vs. 0.3±0.8 new spondylophytes/patient (p<0.001) were seen in DISH patients with vs. without baseline spondylophytes.

The mean mSASSS increased from 14.3±6.7 to 17.6±7.8 (mean change: 3.2±4.2 units) and from 20.5±14.4 to 24.6±15.9 units (mean change: 4.1±9.5 units) between baseline and follow-up in DISH and AS, respectively.

Conclusions: This study shows that a radiographic differentiation between AS and DISH is possible but syndesmophytes and spondylophytes do occur in both dis-eases. In both diseases, radiographic damage at BL is predictive of further and faster progression. The finding of similar progression rates in AS and DISH is surprising.

Relationship between Active Inflammatory Lesions in the Spine and Sacroiliac Joints and New Development of Fatty Infiltration on Whole-Body MRI in Early Axial Spondyloarthritis—Results of the ESTHER Trial at Week 48. In-Ho Song[1], Kay-Geert Hermann[2], Hildrun Haibel[1], Christian Althoff[2], Joachim Listing[3], Bruce Freundlich[4], Martin Rudwaleit[1] and Joachim Sieper[1]. [1]Charite Campus Benjamin-Franklin, Medical Clinic I, Rheumatology, Berlin, Germany, [2]Charite Campus Mitte, Radiology, Berlin, Germany, [3]German Rheumatism Research Center, Berlin, Germany, [4]Wyeth/Pfizer Inc., Collegeville, PA

Purpose: To investigate the relationship between resolution of active inflammatory lesions on whole-body magnetic resonance imaging (wb-MRI) and new development of fatty infiltration in early axial spondyloarthritis (SpA) treated either with etanercept (ETA) or sulfasalazine (SSZ).

Method: Axial SpA patients enrolled in a randomized controlled trial (1) were treated with ETA (n= 40) vs. SSZ (n= 36) over 48 weeks. All patients showed active inflammatory lesions (bone marrow edema) on wb-MRI in either the sacroiliac joints (SIJ) and/or the spine at baseline (BL). Wb-MRIs were performed at weeks 0, 24 and 48 and were scored for active inflammation and fatty infiltration in the four quadrants of each SIJ and the 23 vertebral units (VUs) of the spine. Scoring was performed by two radiologists, blinded for treatment arm and MRI time point. Generalized estimation equations were used to calculate confidence intervals by taking repeated measurements within individual patients into account.

Results: There was a very low rate of new fatty infiltration of about 1% (0.8% for SIJ quadrants and 1.7% for VUs) if there was no previous inflammation in the bone (see table). There was a good relationship between disappearance of inflammation and the appearance of fatty infiltration: if inflammation resolved fatty infiltration occurred in 17.3% (SIJ quadrants) and 19.1% (VUs). If inflammation did not resolve fatty infiltration occurred much less frequently: 8.4% (SIJ quadrants) and 5.8% (VUs) (p= 0.0001 for SIJ and p= 0.1 for VUs for the difference between resolved and persistent inflammation group, see table). Interestingly, new fatty infiltration occurred more frequently in the ETA group (26 VU sites and 33 SIJ sites) compared to the SSZ group (8 VU sites and 12 SIJ quadrant sites). This was in concordance with the significantly higher increase of the mean fatty infiltration score in the ETA (mean fat infiltration score 1.86 at baseline vs. 2.56 at week 24 for the SIJ, and 3.88 vs. 4.60 for the spine) compared to the SSZ (mean fat infiltration score 1.73 at baseline vs. 1.76 at week 24 for the SIJ, and 3.34 vs. 3.51 for the spine, respectively) group (p= 0.018 and p= 0.006 for the differences).

Conclusion: These data indicate that there is a close interaction between inflammation, TNF-blockade and fatty infiltration of subchondral bone marrow. The higher amount of fatty infiltration in the ETA group is probably due to the effective suppression of active inflammation. The molecular mechanisms of these interactions have to be further investigated.

Table. Development of fatty infiltration at week 48 according in development of active inflammation

		New fatty infiltration at week 48	
Location	Active inflammation	Number	% [95% confidence intervals]
Spine-vertebral units	No active inflammation at any time	13/1555	0.8% [0.4%–1.8%]
	Active lesion at baseline and resolution at week 48	13/75	17.3% [8.5%–32.2%]
	Persistent active inflammation	8/95	8.4% [3.8%–17.5%]
SIJ-Quadrants	No active inflammation at any time	4/241	1.7% [0.4%–7.5%]
	Active lesion at baseline and resolution at week 48	29/152	19.1% [12.4%–28.1%]
	Persistent active inflammation	12/207	5.8% [2.8%–11.3%]

Growth Differentiation Factor-9 Induced by Insulin-Like Growth Factor Binding Protein-5 May Contribute to Fibrosis in Systemic Sclerosis. Yukie Yamaguchi[2] and Carol A. Feghali-Bostwick[1]. [1]University of Pittsburgh, Pittsburgh, PA, [2]University of Pittsburgh, Yokohama City University, Yokohama, Kanagawa, Japan

Background: We previously described elevated levels of insulin-like growth factor binding protein- 5 (IGFBP- 5) in fibrotic disorders such as systemic sclerosis (SSc). IGFBP- 5 is a pro-fibrotic factor that induces production of extracellular matrix (ECM) components *in vitro*, *in vivo* in lung and skin, and *ex vivo* in human skin. Using microarray analysis of IGFBP-5-expressing fibroblasts, we identified growth differentiation factor- 9 (GDF-9) as a downstream target of IGFBP-5. GDF-9 is a member of the TGF superfamily and was originally described as an oocyte-derived growth factor required for folliclogenesis. We therefore sought to examine the role of GDF-9 in mediating the fibrotic effects of IGFBP-5.

Methods: Induction of GDF-9 by IGFBP-5 was evaluated in IGFBP-5-expressing fibroblasts *in vitro* and in human skin *ex vivo*. Co-localization of IGFBP-5 and GDF-9 was assessed by immunocytostaining and immunoprecipitation in primary human lung fibroblasts. The signaling pathway mediating IGFBP-5 induction of GDF-9 was identified using chemical inhibitors. Furthermore, induction of ECM by GDF-9 was assessed by western blot, and GDF-9 expression was examined in SSc lung tissues using immunohistochemistry. Finally, the effect of overexpressing GDF-9 in human skin in an *ex vivo* organ culture model was assessed.

Results: GDF-9 was induced in IGFBP-5 expressing fibroblasts, fibroblasts stimulated with recombinant IGFBP-5, and in human skin injected with an IGFBP-5-expressing adenovirus. GDF-9 co-localized with and bound to IGFBP-5. Induction of GDF-9 was reduced in the presence of P38b-inhibitor or a BMPRII neutralizing antibody, but not following TGF-b neutralization, suggesting that GDF-9 production was mediated via P38b-dependent, BMPRII-dependent, and TGF-b-independent mechanisms. Recombinant GDF-9 triggered Smad3 phosphorylation and promoted ECM production and deposition. Interestingly, levels of GDF-9 were very high in lung tissues of patients with SSc. Finally, overexpression of GDF-9 in human skin *ex vivo* significantly increased dermal thickness.

Conclusion: GDF-9 is induced by IGFBP-5 and contributes to the development of organ fibrosis via p38b activation. Furthermore, GDF-9's pro-fibrotic effects are mediated, at least in part, via BMPRII.

Epithelial Cells Undergoing Epithelial Mesenchymal Transition (EMT) in Systemic Sclerosis Lack Caveolin-1 and Modulate WNT Signaling in the Dermis by Secreting SFRP4. Ilaria Tinazzi, Justin Gillespie, Giuseppina Abignano, Chiara Colato, Domenico Biasi, Paul Emery and Francesco Del Galdo. University of Leeds

Background: Systemic Sclerosis is a chronic fibrotic disease highly heterogeneous in clinical outcome, involving autoimmune activation, fibroproliferative vasculopathy and tissue fibrosis of skin and multiple internal organs. The mechanisms linking immune activation and tissue fibrosis are still not fully characterized. A widely accepted model of immune mediated skin fibrosis is chronic Sclerodermatous Graft versus Host Disease (SclGVHD), a form of chronic GVHD with a prevalence of approximately 3–10% in patients receiving allogenic bone marrow transplant. Recent histopathologic studies of cGVHD skin biopsies confirmed the presence of both fibroproliferative vasculopathy and tissue fibrosis in Scl-GVHD.

Purpose: To identify which of the genes differentially expressed in SSc skin biopsies are similarly expressed in the transcriptome of cGVHD skin biopsies and therefore of potential importance in linking the immune activation and the skin fibrosis.

Methods: Metanalysis of the microarray data published in the literature identified a set of 86 genes whose differential expression is highly reproduced in SSc skin biopsies that we defined the SSc signature. The mRNA expression level of these genes was measured in 8 Scl-GVHD, three cGVHD skin biopsies and compared to normal skin mRNA and to their differential expression in SSc. All the genes found to be significantly differentially expressed ($p < 0.05$) in univariate analysis were tested in multivariate analysis. Immunofluorescence studies on skin biopsies were conducted to validate the mRNA findings

Results: 46 genes were differentially expressed in cGVHD biopsies and 34 remained peculiar of Scleroderma. 78.3% of the differentially expressed genes had a similar pattern of regulation in SSc. 25% were similarly expressed in both cGVHD variants, whereas 16.6% were specific of Scl GVHD. Remarkably, this analysis allowed to identify specific chemokines (CCL5, CXCL9–10–11) involved specifically in the fibrotic versus non fibrotic response in GVHD and an increased expression of SFRP4 a potent angiogenesis inhibitor in SSc and SCL-GVHD. Double IF studies followed by confocal laser scanning microscopy allowed to identify as the source of increased SFRP4 expression, cells in the basal layer of the epidermis which lost E-cadherin expression, co-expressed Vimentin and specifically lacked caveolin-1 expression.

Conclusion: About 50% of SSc signature genes presented an altered expression in cGVHD. The further caracterization of the cells that play a role both in the fibrotic process, by undergoing EMT, and in the vasculopathy, by inhibiting angiogenesis through WNT inhibition, may pave the way to understand the link between these two processes in SSc.

The Notch Pathway Controls Fibroblast Activation and Tissue Fibrosis in Systemic Sclerosis. Clara Dees[2], Pawel Zerr[2], Michal Tomcik[2], Christian Beyer[2], Angelika Horn[2], Alfiya Akhmetshina[2], Katrin Palumbo[2], Nicole Reich[2], Jochen Zwerina[2], Mark P. Mattson[3], Oliver Distler[1], Georg Schett[2] and Joerg H. W. Distler[2]. [1]Center of Experimental Rheumatology and Zurich Center of Integrative Human Physiology, University Hospital Zurich, Switzerland, [2]Department of Internal Medicine 3, University Erlangen-Nuremberg, Germany, [3]Laboratory of Neurosciences, National Institute on Aging Intramural Research Program, Baltimore, MD

Purpose: Tissue fibrosis caused by pathological activation of fibroblasts with increased synthesis of extracellular matrix components is a major hallmark of systemic sclerosis (SSc) and other fibrotic diseases. Pathologic activation of Notch signaling has been implicated in the pathogenesis of human malignancies. The aims of the present study were to investigate whether Notch contributes to the uncontrolled activation of fibroblasts and tissue fibrosis in SSc and to evaluate the therapeutic potential of Notch inhibition for the treatment of fibrosis.

Methods: Activation of the Notch pathway was analyzed by immunohistochemistry in skin sections of SSc patients and healthy volunteers. Dermal fibroblasts were stimulated with recombinant human Jagged-1 (Jag-1) Fc Chimera and incubated with the γ-secretase inhibitor DAPT. Fibroblast activation was determined by staining for α-smooth muscle actin (αSMA) and stress fibers. Inhibition of Notch signaling for the treatment of fibrosis was evaluated in the mouse model of bleomycin-induced dermal fibrosis and in tight-skin-1 (tsk-1) mice.

Results: Notch signaling is activated in skin of SSc patients as analyzed by immunohistochemistry. Moreover, this activation persisted in cultured fibroblasts *in vitro* with significantly elevated levels of activated Notch-1, its ligand Jag-1 and its target gene hes-1. Activation of the Notch pathway by stimulation with recombinant Jag-1 potently induced differentiation of resting fibroblasts into myofibroblasts with increased levels of αSMA and formation of stress fibers. In addition, Jag-1 increased collagen synthesis to 294 ± 37 % ($p < 0.05$) which was prevented upon pre-incubation with DAPT. Consistent with the selective activation of Notch signaling in SSc fibroblasts, incubation of dermal fibroblasts with DAPT decreased the basal collagen synthesis only in SSc but not in healthy dermal fibroblasts. In the mouse model of bleomycin-induced dermal fibrosis, treatment with DAPT completely prevented dermal thickening upon bleomycin-challenge ($p < 0.05$). Inhibition of γ-secretase prevented also hypodermal thickening in tsk-1 mice with a mean reduction of hypodermal thickness by 75 ± 4 % ($p < 0.05$). Overexpression of a Notch-1 antisense construct confirmed the results obtained with the

chemical inhibitor. Bleomycin-induced dermal thickening was reduced by 85 ± 19 % ($p < 0.05$) and hypodermal thickness in tsk-1 mice decreased by 51 ± 11 % ($p < 0.05$). Of note, treatment with DAPT not only prevented fibrosis but induced significant regression of dermal thickening below pre-treatment levels in a modified model of established bleomycin-induced skin fibrosis.

Conclusion: We demonstrate that the Notch pathway is activated in fibrotic skin, induces myofibroblast differentiation and stimulates the release of collagen. Inhibition of Notch signaling exerts potent anti-fibrotic effects in preclinical models suggesting that targeting Notch signaling might be a promising molecular approach for anti-fibrotic therapy.

Myofibroblast Specific Gene Expression Signature in Systemic Sclerosis, More Than TGF-beta Induced Activation. Giuseppina Abignano[2], Heidi Hermes, Justin Gillespie, Sergio A. Jimenez, Paul Emery and Francesco Del Galdo[1]. [1]Leeds, [2]University of Leeds

The key cellular elements in the pathogenesis of tissue fibrosis are myofibroblasts. It is widely accepted that the number of myofibroblasts is increased in SSc and it correlates with the severity of tissue fibrosis. The mechanisms underlying their increased number and their heterogeneity in SSc are unknown. The heterogeneity in their frequency may explain the inconsistency of some in vitro studies published on SSc fibroblast biology, and may mirror the clinical heterogeneity of SSc patients both in natural history and severity of skin fibrosis. The purpose of this study was to unravel the specific transcriptome of myofibroblasts derived from SSc skin biopsies.

Methods: 4 patients with diffuse rapidly progressive SSc, within 18 months from skin involvement and before any immunosuppression, were enrolled in the study. Skin biopsy on forearm was performed and the fibroblasts subcultured for three passages. 250 acetone fixed alpha-SMA positive cells were isolated by laser capture microdissection (LCM) for mRNA analysis by Affymetrix Gene array and qRT-PCR validation. Pathway analysis was conducted according to David-NIH software. Immunofluorescence (IF) followed by confocal laser scanning microscopy (CLSM) was conducted as well. Normal dermal fibroblasts were utilized to evaluate the effects of TGF-beta stimulation both at mRNA and protein level.

Results: qRT-PCR for a-SMA showed in average 3.7 fold increased expression in a-SMA in the LCM captured cells. Microarray analisis identified 269 genes upregulated more than 2 fold in the myofibroblasts. Of these, 24 were clearly reconducible to profibrotic activation, including a-SMA, Collagens I, VI and XI, Fibronectin, several Integrin genes, FGF7, CD36, IGF and Rho; 16 were ribosomial genes; 14 were mitochondrial genes involved in oxidative phosphorylation, including COX1,2, 3 and 6 ND1 to 6, CYT-b and F-type ATP-ase; 28 genes were involved in cell to cell adhesion including, JAM2, ERM, and MLC and 7 in antigen processing and presentation including RAB13, B2-microgrobiulin, cathepsin, HSPs, calnexin, and calreticulin. The remaining genes were not classifiable in any specific functional pathway and comprised tropomyosin, reticulocalbin 1, caldesmon 1, and 6 members of Neuroblastome Breakpoint Family (NBPF). IF studies followed by CLSM confirmed the expression, never shown before, of NBPF in dermal fibroblasts. Functional studies on normal dermal fibroblalsts indicated that NBPF was not inducible by 24 or 48 h stimulation with 10 ng/ml TGF-beta neither at mRNA or protein level.

IF followed by CLSM of alpha-SMA positive vs negative cells showed a specific expression profile for pro-collagen-1, caveolin-1, beta-catenin and phospho-RB whereas SMAD3, SMAD1, SMAD5, and NF-kB did not differ between alpha-SMA positive or negative cells.

Conclusions: Myofibroblast secretome displayed, besides predictable genes involved in the increased ECM production and TGF-beta pathway activation, genes involved in several pathways not known to be specific of myofibroblasts or inducible by TGF-beta. The specific expression of these genes may reflect either a specific metabolic status or a specific differentiation lineage of myofibroblasts

Disclosure: G. Abignano: None; **H. Hermes:** None; **J. Gillespie:** None; **S. A. Jimenez:** None; **P. Emery:** None; **F. Del Galdo:** None.

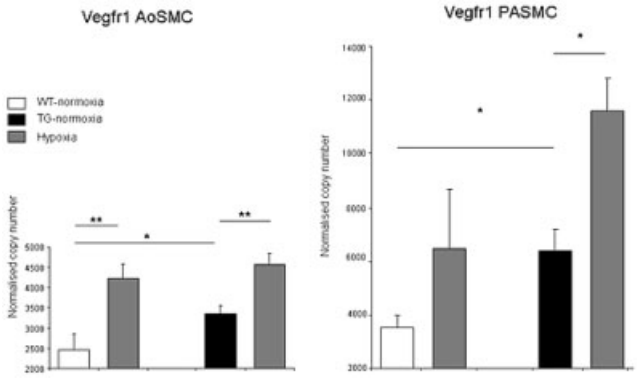
Perturbed VEGF Signalling within the Pulmonary Vasculature of a TGFβ Dependent Mouse Model of Systemic Sclerosis. Emma C. Derrett-Smith[2], Audrey Dooley[2], Reshma Baliga[1], Adrian Hobbs[1], Raymond MacAllister[1], David Abraham[4] and Christopher P. Denton[3]. [1]Centre for Clinical Pharmacology, Rayne Institute, UCL, London, Canada, [2]Centre for Rheumatology and Connective Tissue Diseases, Royal Free Campus, UCL Medical School, London, [3]Royal Free Hospital, London, United Kingdom, [4]University College London, London, United Kingdom

Purpose: Vascular complications of systemic sclerosis (SSc) are a major cause of mortality and morbidity. A role for altered VEGF signaling in PAH-SSc is supported by data that correlate circulating VEGF with mPAP at diagnosis. There is also a trend for VEGF levels to fall after initiation of PAH-specific therapy. High circulating VEGF levels may be a marker of repair in response to vascular injury. We have therefore examined VEGF signaling in a TGFβ-dependent mouse model of SSc with evidence of a constitutive pulmonary vasculopathy.

Methods: The transgenic mouse strain TβRIIΔk-fib expresses a kinase-deficient type II TGFβ receptor driven by a fibroblast-specific promoter leading to balanced ligand-dependent upregulation of TGFβ signalling. Pulmonary vasculopathy was confirmed by histological assessment of vessel architecture, isolated organ bath and *in vivo* haemodynamic studies performed on adult male transgenic and littermate wildtype animals (n=8 in each group). Biochemical analysis of the VEGF and endothelin axes were performed assessing RNA by quantitative PCR and protein by Western blotting using cultured aortic and pulmonary artery smooth muscle cells, and by immunostaining of tissue sections. Results were compared to the same cells cultured under hypoxic conditions.

Results: Within the pulmonary arterial circulation, transgenic vessel wall thickness was increased, particularly in smaller vessels (30–60μm diameter) due to hypertrophy of the smooth muscle layer (mean wildtype vessel thickness:circumference ratio 0.66±0.02, mean transgenic 0.88±0.04, $p<0.05$). Pulmonary arterial ring responses to direct and receptor-mediated contractile stimuli were reduced in the transgenic animals (in response to endothelin contraction at 10^{-5}M wildtype 1.10mN±0.02, transgenic 0.62±0.12, $p<0.05$) and right ventricular pressures were elevated in transgenic animals (wildtype mean 29mmHg±4, transgenic mean 37mmHg±3). Explanted transgenic vascular smooth muscle cells showed upregulation of TGFβ responsive genes including Vegf and Vegfr1 which were further upregulated in the pulmonary arterial circulation (PASMC) when compared to aortic smooth muscle cells (AoSMC) from the same animals.



Endothelin receptor A gene expression was also reduced in transgenic animals. Hypoxic culture resulted in upregulation of Vegf and Vegfr1 in cells from both wildtype and transgenic animals, again more marked in the pulmonary arterial cells.

Conclusions: The pulmonary vascular phenotype of this transgenic mouse model appears to replicate key histological and pathophysiological features of human SSc, and supports a potential role for perturbed TGFβ, endothelin and VEGF activity in the pulmonary circulation in this model.

The IL13/IL4RA/CCL2 Pathway Drives Sclerodermatous Graft Versus Host Disease in Mice and Correlates with Disease Activity in Scleroderma Patients. Antonios O. Aliprantis[4], Matthew Greenblatt[3], Jennifer Sargent[2], Giuseppina Farina[6], Kelly Tsang[3], Robert A. Lafyatis[1], Michael Whitfield[2] and Laurie Glimcher[5]. [1]Boston University School of Medicine, Arlington, MA, [2]Department of Genetics, Dartmouth Medical School, [3]Department of Immunology and Infectious Diseases, Harvard School of Public Health, [4]Department of Medicine, Division of Rheumatology, Allergy and Immunology, Brigham and Women's Hospital and Harvard Medical School and Department of Immunology and Infectious Diseases, Harvard School of Public Health, Boston, MA, [5]Department of Medicine, Division of Rheumatology, Allergy and Immunology, Brigham and Women's Hospital and Harvard Medical School and Department of Immunology and Infectious Diseases, Harvard School of Public Health, [6]Rheumatology Section, Boston University School of Medicine

Background: Scleroderma (SSc) is an irreversible autoimmune disease characterized by tissue fibrosis. Agents to treat SSc remain elusive since mechanisms underlying the initiation and propagation of fibrosis are not well understood. We have shown that the gene expression profile of murine sclerodermatous graft-versus-host disease (sclGVHD) approximates an "inflammatory" subset of human SSc patients and that both diseases display activation of the IL13 cytokine pathway. Here, the function of the IL13 pathway and downstream CCL2 expression is defined in the mouse model and SSc patients.

Methods: SclGVHD was induced by injection of splenocytes from allogeneic B10.D2 mice into MHC-matched BALB/c Rag2−/−, BALB/c Rag2−/−IL13−/− or BALB/c Rag2−/−IL4Ra−/− hosts. Control hosts received syngeneic BALB/c splenocytes. Recipient mice were scored biweekly for development of clinical sclGVHD. At 6 weeks, a blinded SSc expert scored back skin histopathology. Explant cultures and experiments on FACS sorted cells isolated from back skin were performed 2 or 3 weeks after cell transfer. Human SSc skin RNA was purified from a cohort of patients with a mean disease duration of 24 months. ELISA or quantitative RT-PCR was used to detect gene expression. Centocor, Inc provided previously published blocking antibodies to CCL2 and CCL12.

Results: Compared to syngeneic controls, explant cultures of back skin from sclGVHD mice displayed robust IL13 production confirming expression of this cytokine at the major site of pathology. Consistent with this, Rag2−/−IL13−/− hosts were partially protected from the development of sclGVHD. Partial protection suggested redundant expression of IL13 by both host and graft sources. Accordingly, both host macrophage and graft T-cell populations were found to produce IL13 in lesional skin. In contrast to Rag2−/−IL13−/− hosts, those lacking the ability to respond to IL13 (Rag2−/−IL4Ra−/−) were nearly completely protected from sclGVHD. Protection was associated with increased production of the anti-inflammatory cytokine IL-10 by graft T-cells isolated from Rag2−/−IL4Ra−/− hosts. Comparative expression profiling of Rag2−/− and Rag2−/−IL4Ra−/− sclGVHD mice also revealed that the latter displayed reduced CCL2 expression in whole skin, as well as in purified macrophage and CD45- stromal cell populations. Parallel exploration of additional datasets, including IL13 stimulated human dermal fibroblasts and IL13 transgenic mice, also suggested CCL2 as a common target of IL13 pathway activation. Confirming the functional significance of this finding, co-treatment with blocking antibodies to CCL2 and its murine homolog CCL12 prevented sclGVHD. Lastly, we show that expression of receptor subunits for IL13 signaling (IL13RA1 and IL4RA) and CCL2 are significantly increased in the skin of SSc patients and correlate with modified Rodnan skin scores, a clinical measure of cutaneous disease.

Conclusions: These data provide evidence that the IL13/IL4Ra/CCL2 axis is important to SSc pathogenesis. Inhibition of this pathway may be a viable therapeutic option for SSc patients exhibiting the inflammatory gene signature.

Two Year Follow-Up Results from a Randomised Trial of Rituximab Versus Cyclophosphamide for 'Generalized' ANCA-Associated Vasculitis: RITUXVAS. Rachel B. Jones[1], Jan Willem Cohen Tervaert[5], Thomas Hauser[4], Raashid Luqmani[7], Matthew D. Morgan[11], Chen Au Peh[8], Caroline O. Savage[11], Mårten Segelmark[9], Vladimir Tesar[3], Pieter van Paassen[6], Dorothy Walsh[2], Michael Walsh[2], Kerstin Westman[10] and David R. W. Jayne[1]. [1]Addenbrooke's Hospital, Cambridge, United Kingdom, [2]Addenbrooke's Hospital, [3]Charles University, [4]Immunologie-Zentrum Zürich, Zurich, Switzerland, [5]Maastricht University Medical Center, Maastricht, The Netherlands, [6]Maastricht University Medical Center, [7]Nuffield Orthopaedic Centre, Oxford, United Kingdom, [8]Royal Adelaide Hospital, Adelaide, Australia, [9]University Hospital of Skane and Lund University, Lund, [10]University Hospital of Skane and Lund University, [11]University of Birmingham, Birmingham, United Kingdom

Cyclophosphamide based induction regimens are standard therapy for ANCA-associated vasculitis with major organ involvement; however, associated mortality and adverse event rates are high and safer regimens are required. Rituximab based regimens are a potential alternative to cyclophosphamide induction.

We report the two year results of a randomised trial comparing a rituximab based induction regimen with a standard intravenous cyclophosphamide regimen for new ANCA-associated renal vasculitis. All patients had newly diagnosed ANCA-associated vasculitis with active renal disease and ANCA positivity. 44 patients were randomised; 33 to rituximab 4×375mg/m^2 & 2×15mg/kg intravenous cyclophosphamide; and 11 to intravenous cyclophosphamide 6–10×15mg/kg. Both groups received the same intravenous and oral prednisolone regimen.

At entry: median age was 68 years, Wegener's granulomatosis 50%, microscopic polyangiitis 50%; CRP 28; BVAS 18; PR3-ANCA 57%, MPO-ANCA 43%, glomerular filtration rate 18ml/min, 20% required dialysis. At two years, the primary composite outcome of relapse, death or end stage renal failure occurred in 14/33 (42%) Rituximab versus 4/11 (36%) cyclophosphamide (p=1.00). Relapse occurred in 7/33 (21%) rituximab versus 2/11 (18%) cyclophosphamide (p=1.00), death in 6/33 (18%) rituximab versus 3/11 (27%) cyclophosphamide (p=0.67) and end stage renal failure in 2/33 (6%) rituximab versus 0/11 cyclophosphamide (p=0.57). Median estimated glomerular filtration rate was 20 & 44ml/min/m^2 in rituximab patients at 0 and 24 months respectively compared to 12 & 31ml/min/m^2 in cyclophosphamide patients. Serious adverse events occurred in 61% rituximab (50 events, 20/33 patients) versus 36% cyclophosphamide (15 events, 4/11 patients) (incidence rate ratio 1.16; 95% confidence interval 0.64–2.22) (p=0.64).

Rituximab based induction therapy is efficacious but is not superior to intravenous cyclophosphamide at two years in terms of combined relapse, mortality and end stage renal failure outcome. Further strategies to reduce mortality and serious adverse events and prevent relapse should be considered.

Increased Circulating Osteoclast Precursors and Lesional Osteoclast-Like Multinucleated Giant Cells in the Lung of Patients with Wegener's Granulomatosis. Jin Kyun Park[1], Frederic Askin[2], Antony Rosen[3] and Stuart M. Levine[1]. [1]Johns Hopkins University, Baltimore, MD, [2]Johns Hopkins University, [3]The Johns Hopkins University, Baltimore, MD

Background: Tissue-infiltrating multinucleated giant cells (MNGCs) surrounding areas of geographic necrosis are the pathologic hallmarks of Wegener's granulomatosis (WG). However, the origin, phenotype, and function of these cells in WG remain undefined.

Methods: MNGC phenotype was examined by immunohistochemistry in serial paraffin sections of WG lung tissue (N=12) using antibodies recognizing the osteoclast (OC)-lineage markers CD68, cathepsin K and tartrate-resistant-acid-phophatase (TRAP). To examine whether WG patients had an increased propensity toward MNGC formation over healthy control subjects, peripheral blood mononuclear cells (PBMC) obtained from 11 patients (5 with limited and 6 with systemic disease) and 7 healthy controls were cultured in 96- well plates in the presence of RANKL and M-CSF to induce MNGC formation. After 9 days in culture, MNGC morphology and TRAP expression were examined. OC-like giant cells were defined as TRAP (+) cells containing 3 or more nuclei. Mean MNGC values were compared between groups using the Mann-Whitney U test or Student's t-test where appropriate. P-values of < 0.05 were considered statistically significant.

Results: WG lung tissue granulomata contained numerous MNGCs. All tissue-infiltrating MNGCs expressed CD68, indicative of monocytic lineage, and exhibited robust TRAP and cathepsin K staining, a phenotype thought to be unique to bone-resident osteoclasts. After co-incubation with the osteoclastogenic cytokines RANKL and M-CSF, patients with WG formed significantly more MNGCs at Day 9 than healthy controls (109 +/− 112 MNGC/well vs. 18 +/− 16 MNGC/well, p=0.03). Patients with systemic disease produced significantly more MNGC than both controls (167 +/− 114 MNGC/well vs. 18 +/− 16 MNGC/well, p=0.01) and those with a limited disease phenotype (167 +/− 114 MNGC/well vs. 39 +/− 62 MNGC/well, p=0.03). No significant difference in MNGC formation was noted between patients with limited WG and controls (p=0.87).

Conclusion: We demonstrate for the first time that MNGCs in Wegener's granulomata in the lung have osteoclast-like features. We further show that WG patients have a higher propensity to from OC-like MNGC from the peripheral blood than do healthy controls, a feature that might be more pronounced in patients with a systemic disease phenotype. Inhibition of the pathways leading to the enhanced formation and migration of these cells to target tissues in WG might provide a novel therapeutic opportunity in this disease.

Protocolised Versus Non-Protocolised Rituximab Treatment for Refractory ANCA-Associated Vasculitis. Rachel B. Jones[1], Rona Smith[2], Mary-Jane Guerry[2], Simona Laurino[2], Fausta Catapano[2], Afzal Chaudhry[2] and David R. W. Jayne[1]. [1]Addenbrooke's Hospital, Cambridge, United Kingdom, [2]Addenbrooke's Hospital

Rituximab is effective new therapy for refractory ANCA-associated vasculitis. However, the majority of patients relapse after rituximab, needing further treatment courses. Relapses occur from six months onwards and are associated with organ damage and high corticosteroid exposure. Relapse avoidance is desirable; however biomarkers that accurately predict relapse are not available.

We performed a single centre cohort study comparing six monthly, protocolised rituximab re-treatment and non-protocolised rituximab re-treatment according to clinical need for refractory ANCA-associated vasculitis.

72 patients received a protocolised rituximab regimen; 1g ×2 followed by 1g ×1 every 6 months for 2 years (5g total) with early immunosuppression and corticosteroid withdrawal. 34 received non-protocolised rituximab; either 1g ×2 or 375mg/m^2 ×4 only repeated if relapse occurred.

Overall 75% patients had Wegener's granulomatosis. At first rituximab median disease duration was 55 months: prior cyclophosphamide exposure was 14g. Rituximab indication was relapsing disease in 82% of protocol and 83% of non-protocol patients; the remainder had grumbling disease whilst receiving continuous high dose corticosteroids or immunosuppression.

Median follow-up was 31 (4–56) months, protocol patients versus 22 (6–84) months, non-protocol patients. Response to rituximab occurred in 70/72 (97%) protocol patients (93% full remission, 4% partial), and 33/34 (97%) non-protocol patients (82% full remission, 15% partial). In protocol patients only 4/72 (6%) were still receiving immunosuppression at 6 months and by 24 months 26% had withdrawn from prednisolone (4.75mg/day median). At 2 years relapse had occurred in 16/72 (22%) protocol patients versus 24/34 (71%) non-protocol patients and by the end of follow-up 21/72 (29%) protocol patients, 26/34 (76%) non-protocol patients (p<0.01). Serious infections occurred in 10/72 (31%) protocol patients and 6/34 (26%) non-protocol patients.

Six monthly protocolised rituximab re-treatment is effective for relapse prevention, allows immunosuppression withdrawal and appears safe in refractory ANCA-associated vasculitis.

Xenografted Nasal Mucosa from Wegener's Granulomatosis Patients Induces Destruction of Human Cartilage in Immunodeficient Mice. Nina Kesel[2], Dorothee Köhler[2], Martin Laudien[5], Konstanze Holl-Ulrich[3], Astrid Jüngel[1], Michel Neidhart[1], Steffen Gay[1], Renate E. Gay[1], Elena Csernok[6], Wolfgang L. Gross[6], Udo Schumacher[4] and Sebastian Ullrich[4]. [1]Center of Experimental Rheumatology, University Hospital Zurich, Switzerland, [2]Dept. of Anatomy II: Experimental Morphology, University Medical Center Hamburg, Hamburg, Germany, [3]Dept. of Pathology, University Hospital of Schleswig-Holstein, Campus Lübeck, Lübeck, Germany, [4]University Medical Center Hamburg, [5]University of Kiel, Dept. of Otorhinolaryngology, Head and Neck Surgery, Kiel, Germany, [6]University of Lübeck, Dept. For Rheumatology, Vasculitis Center UKSH & Clinical Center Bad Bramstedt, Lübeck, Germany

Background: One of the hallmarks of Wegener's Granulomatosis (WG) is a destructive chronic granulomatous inflammation of the respiratory tract whose pathogenic mechanisms remain enigmatic.

Aims: The aim was to establish a xenograft model of nasal cartilage destruction in WG, to analyze the mechanisms of tissue damage and to evaluate the effect of systemic steroid treatment upon the inflammatory process.

Methods: Nasal mucosa biopsies from active and destructive WG (n=10) and active sinusitis patients were subcutaneously co-implanted in collagen sponges with healthy human nasal cartilage as aggregates (overall 36 WG vs. 48 controls), into 25 (WG) and 24 (controls) immunodeficient pfp/rag2 −/− mice. Three mice with WG transplants were treated with systemic steroids. Transplants were removed after 21 days and examined histologically. In addition, nasal fibroblasts isolated from tissue specimens from WG patients (n=8) and healthy controls were cultured and cells proliferation and apoptosis were quantified. Furthermore, mRNA and protein levels of MMP's and cytokines were evaluated at baseline and after stimulation with TNF-alpha and IL1-beta.

Results: All untreated WG aggregates showed areas of human fibroblasts invading the human cartilage 21 days after transplantation, whereas cartilage destruction was only marginal in control samples. The destructed nasal cartilage in WG samples was replaced by proliferating human fibroblasts. Systemic steroid treatment suppressed this tissue destruction completely. The human origin of the cells was confirmed by anti-human vimentin and anti-human mitochondrial antibody staining. The tissue organization of transplanted tissues (fibroblasts, T- and B- lymphocytes, follicular dendritic cells (FDC), monocytes) remained almost identical to the tissue at the time of sampling as demonstrated by immunohistochemistry. An up-regulated production of MMP 1, 3 and 13 was found in areas of tissue destruction. Stimulation of fibroblasts in cell culture with TNF-alpha and IL-1 beta resulted in a significant up-regulation of MMPs 1, 3, 13. While proliferation of isolated fibroblasts was comparable between WG and controls, WG samples showed a significant delay of apoptosis.

Discussion: These findings show for the first time that nasal tissue destruction in WG results from local mucosal inflammation and strongly relates to the local activation of fibroblasts and locally residing inflammatory cells. As in WG patients, systemic steroid treatment of the mice impaired cartilage destruction. The delay of apoptosis may explain the invasive character of granulomatous tissue. Because of its similarity with the clinical situation, this model offers new possibilities to study novel treatments in WG in a clinically relevant xenograft model.

Rituximab for Remission Induction and Maintenance in ANCA-Associated Vasculitis: A Single-Center Ten-Year Experience in 108 Patients. Rodrigo Cartin-Ceba[3], Jason Golbin[1], Karina A. Keogh[3], Tobias Peikert[3], Fernando C. Fervenza[3], Steven R. Ytterberg[2] and Ulrich Specks[3]. [1]Long Island Lung Center, [2]Mayo Clinic, Rochester, MN, [3]Mayo Clinic

Rationale: B-cell depletion with Rituximab (RTX) and glucocorticoids has been used successfully to induce sustained remission in patients with severe refractory ANCA-associated vasculitis (AAV). The need for repeated treatments as well as the efficacy and safety of repeated and prolonged B-cell depletion for long-term remission maintenance is less clear.

Objectives: To evaluate the efficacy and safety of rituximab for remission induction and long-term maintenance in patients with chronically relapsing AAV.

Methods: Single-center observational study of all patients with AAV treated with RTX between January 2000 and May 2010. Four weekly infusions at 375 mg/m^2 were used for remission induction and maintenance. More recently, 2 weekly infusions of 1000 mg were used for remission maintenance in some patients. Patients were identified from a cohort of 637 patients with AAV followed at our institution. Participants in the RAVE trial were excluded from this analysis. Treatment response, indications for retreatment, frequency and type of clinical relapse, duration of peripheral blood B cell depletion, ANCA levels, infusion-related adverse events, and infections were abstracted from electronic medical records. Disease activity was measured using the BVAS/WG score. Data are expressed as median (interquartile range, IQR) and percentages.

Results: 108 patients with refractory AAV received glucocorticoids and at least one course of RTX therapy for remission induction; all achieved remission as measured by a BVAS/WG = 0. Fifty three patients (median age 46, IQR 28–61; 53% women) received subsequent courses of RTX for relapses or to maintain remission. All but one patient were PR3/ANCA positive. These 53 patients received a median of 4 (IQR 3–5) courses of RTX (a total of 200 courses of four weekly infusions at 375 mg/m^2, and 10 courses of two weekly infusions of 1000 mg). All patients had depletion of B cells and the median time to return of B cells was 7 months (IQR 6–11 months). All observed relapses occurred after reconstitution of B cells and were accompanied or preceded by an increase in ANCA levels except in one patient. A total of 72 (34%) courses of RTX were given due to relapse (achieving remission in all individuals) and 138 (66%) courses were given preemptively due to either B cell reconstitution or following the increase of both B cells and ANCA levels. Infusion related adverse events occurred in 7 patients and none precluded completion of treatment. During the period of B cell depletion, 8 infectious complications were observed (5 upper respiratory tract infections, 2 pneumonias, and 1 skin infection; only one patient with pneumonia required hospitalization).

Conclusion: RTX is effective and safe for induction and maintenance of remission in patients with relapsing AAV. Prolonged B cell depletion seems to be associated with a low risk of infections. Timing of retreatment can be individualized based on B cell counts and ANCA levels in these patients and the use of this treatment modality for long-term remission maintenance merits further formal investigation.

Hsp60 Proteolysis by Proteinase 3 Induces Neutrophil Degranulation: Implications for Amplification of Injury in Wegener's Granulomatosis. Shinji Sato[4], Jin Kyun Park[1], Frederic Askin[3], Antony Rosen[2] and Stuart M. Levine[1]. [1]Johns Hopkins University, Baltimore, MD, [2]The Johns Hopkins University, Baltimore, MD, [3]The Johns Hopkins University, [4]Tokai University, Kamakura, Japan

Background: Extracellular proteolytic processing by proteinase 3 (PR3) released from activated neutrophils has recently been implicated in several important biological processes. Heat shock proteins are induced in response to a variety of inflammatory stimuli, and some, such as Hsp60, can be released into the extracellular environment, where they can exert pro-inflammatory functions. Whether PR3-mediated proteolysis of Hsp60 released in the WG microenvironment contributes to the inflammatory response is unknown.

Methods: Human recombinant Hsp60 was incubated for varying times with increasing concentrations of PR3, and cleaved products were detected by SDS-PAGE and immunoblotting. Polymorphonuclear cells (PMNs) were isolated from heparinized peripheral venous blood by density gradient centrifugation. Following co-incubation with intact or PR3-cleaved Hsp60, PMN degranulation was quantified using the β-glucuronidase release assay at baseline and after 90 minutes. Activity units (U) were calculated for each experiment from the observed fluorescent intensities using a standard curve obtained from serial concentrations of a dye standard. The supernatants of TNF-primed PMNs were similarly assessed for Hsp60 proteolytic activity, and the effects of PR3 inhibition using α1-antitrypsin were examined. Hsp60 expression in WG tissue was examined by immunohistochemistry.

Results: Hsp60 was efficiently cleaved by purified PR3 *in vitro* with a k_{cat}/K_m of 7.5×10^4 M $^{-1}$ S $^{-1}$. PR3-cleaved HSP60 caused significant β-glucuronidase release from PMNs at 90 minutes compared to intact Hsp60 (73.7 U +/− 22.7 vs. 30.3 U +/− 19.1, p=0.01). Upon PMN priming with TNF-α, small amounts of PR3 released in the supernatants were detected by immunoblotting. Co-incubation of these TNF-primed supernatants with Hsp60 led to Hsp60 processing that was inhibited by the PR3 inhibitor α1-antitrypsin. Subsequent incubation of fresh, non-primed PMNs with this PR3-processed Hsp60 caused significant degranulation compared to those incubated with supernatants from non-TNF-primed PMNs (51.7 U +/− 9.9 vs. 23.5 U +/− 16.7, p=0.005), demonstrating that the PR3 released by primed PMNs can cleave exogenous Hsp60 to further amplify fresh PMN degranulation. Finally, an analysis of WG lung tissues reveals that Hsp60 is highly expressed in the giant cells of WG granulomata.

Conclusions: These studies identify multinucleated giant cells in the WG granuloma as a rich source of Hsp60. TNF-primed PMNs release PR3, and PR3-cleaved Hsp60 induces further degranulation of fresh PMNs, suggesting a novel mechanism whereby PR3 participates in amplification of the local inflammatory response in WG. This reinforcing interaction of target tissue and inflammatory cells in the local WG microenvironment may be useful for disease monitoring and therapy.

Unpredictability of Intermittent Knee OA Pain – Impact on Pain, Function and Mood. Gillian A. Hawker[2], Melissa R. French[3], Joy G. Elkayam[3] and Aileen M. Davis[1]. [1]Toronto Western Research Insti, Toronto, ON, Canada, [2]Women's College Hospital, Toronto, ON, Canada, [3]Women's College Hospital, Toronto, Canada

Purpose: In people with painful knee osteoarthritis (OA), focus groups identified the predictability of the pain as a key determinant of the pain impact. This study evaluated the effects of unpredictable knee pain (without warning) and pain after a trigger on the pain experience, physical functioning and mood in people with knee OA. We hypothesized that unpredictable knee pain would be associated with greater pain, worse physical functioning and more depressed mood than would predictable knee pain.

Methods: In a cohort with hip and knee OA, participants completed the OARSI-OMERACT Intermittent and Constant Osteoarthritis Pain (ICOAP) measure, WOMAC, and a measure of depressed mood (CES-D). For *each* symptomatic knee, those with intermittent knee pain were asked how often their pain occurs 'without warning' (*unpredictable* pain) or 'after a specific trigger', e.g. an activity (*predictable* pain) (0, never, to 4, very often). For those without hip complaints, the proportions with each type of intermittent pain were calculated (at least sometimes versus never/rarely). The relationships between type of intermittent pain and ICOAP and WOMAC scores were evaluated using linear regression. For each type of intermittent pain, we examined the relationship between the number of knees affected (0, 1 or 2) and ICOAP and WOMAC scores using Wilcoxon Rank Sum tests. We examined the relationship between each type of intermittent pain and depressed mood (CES-D scores), controlling for age, sex and arthritis severity (WOMAC summary score).

Results: The mean age of the 116 knee OA participants was 79.7 years (64.0 to 93.2); 74.1% were female and 23.4% had < high school education. 103 subjects (88.8%) reported intermittent knee pain in at least one knee; of these, 18.1% (n=21) had pain only after a trigger, 12.9% (n=15) had only unpredictable pain, while 44.0% (n=51) had both types of intermittent pain. Controlling for age and sex, unpredictable knee pain in one or both knees was independently associated with higher ICOAP and WOMAC scores ($p<0.05$ for all). Controlling for unpredictable knee pain, knee pain after a trigger was independently associated only with higher scores on the ICOAP intermittent scale (p=0.01). A greater number of knees with unpredictable pain was associated with higher ICOAP intermittent ($p<0.0001$) and WOMAC summary (p=0.01) scores. For pain after a trigger, this relationship was found

only with ICOAP intermittent scores ($p<0.0001$). Controlling for age, sex and arthritis severity, unpredictable knee pain, but not knee pain after a trigger, was independently associated with higher scores for depressed mood ($p=0.005$).

Conclusions: Both unpredictable pain and pain following a trigger occur commonly in people with chronic symptomatic knee OA. Compared with pain following a trigger, unpredictable knee pain is associated with greater pain and functional disability, and more depressed mood. Studies are needed to identify potentially modifiable risk factors for unpredictable knee OA pain in order to develop and test interventions to relieve this complaint.

Low Positive Affect Predicts the Development of Disability over 30-Months: The MOST Study. Julie J. Keysor[1], Lisa Fredman[4], Bin Zhang[2], Daniel K. White[3], James C. Torner[8], Cora E. Lewis[6], Irina Tolstykh[7] and David T. Felson[5]. [1]Boston Univ Sargent College, Boston, MA, [2]Boston Univ Schl of Medicine, Boston, MA, [3]Boston Univ School of Med, Boston, MA, [4]Boston University, [5]Boston University School of Medicine, Boston, MA, [6]University of Alabama-Birmingham, Birmingham, AL, [7]University of California and San Francisco, San Francisco, CA, [8]University of Iowa, Iowa City, IA

Low positive affect above and beyond high depressive symptoms is linked to incident frailty among older adults. The impact positive affect has on functional outcomes is not known. Cross sectional studies have the potential flaw that good functional outcomes may make people happy, making cause and effect impossible to disentangle. We propose a longitudinal study to examine whether low positive affect predicted incident disability among adults at risk of developing disabilities.

Methods: Baseline and 30-month longitudinal data from the Multicenter Osteoarthritis (MOST) Study, a prospective cohort study of progressive and incident symptomatic knee osteoarthritis, were used for these analyses. A three-category variable representing "high positive affect", "low positive affect" and "high depressive symptoms (depressed)" was computed from the Center of Epidemiological Study-Depression Scale (CES-D). Respondents who scored less than 16 on the CES-D and who scored "most of the time" on 4 positive affect questions of the CES-D were categorized as high positive affect; whereas, those reporting anything less than most of the time on the 4 items were classified as low positive affect. Respondents whose overall CES-D score was 16 or greater were classified as depressed. Disability was ascertained using the of the Late Life Disability Instrument-Instrumental Limitation subscale (LLDI-IL). The LLDI-IL was dichotomized into no/mild disability (no disability) and moderate/severe disability (disability) based on previously established cutpoints. Age, sex, education, race, body mass index (BMI), knee pain (max score of right or left knee visual analog scale), and gait speed (m/sec) were taken from baseline data and were used as covariates. Among persons with no disability at baseline, we examined the associations between baseline positive affect and depression and the development of disability at 30-follow-up using logistic regression.

Results: 2054 subjects had no disability at baseline. The mean age of the sample was 63 years. 58% were female and 89% were white. 1381 (67%) had high positive affect; 531 (26%) had low positive affect; 141 (7%) were depressed at baseline. 260 (13%) developed disability at 30-months. Subjects who reported low positive affect and those who were depressed were more likely to report disability at 30-months compared to persons with high positive affect after adjusting for covariates. As expected, high depressive symptoms was also associated with incident disability. (Table 1)

Discussion: Compared with high positive, low positive affect increased people's risk of developing disability over a 30-month time period, even above and beyond the risk associated with depressive symptoms. Further research is needed to elicit the role positive psychological factors play in disablement.

Table 1. Unadjusted and adjusted odds ratio of low positive affect and "depressed" status compared to high positive affect.

	Event/Subjects (%)	Crude OR (95% CI)	Adjusted OR (95% CI)
High Positive Affect	140/1381 (10%)	1.0	1.0
Low Positive Affect	79/531 (15 %)	1.5 (1.2–2.1)	1.5 (1.1–2.1)
Depressed (High Depressive Symptoms)	41/141 (29 %)	3.6 (2.4–5.4)	2.7 (1.7, 4.1)

Potential Gender Effect on the Association between Knee Osteoarthritis and Risk of Indoor and Outdoor Falls in Elderly Men and Women. Uyen-Sa D. T. Nguyen[4], Marian T. Hannan[5], Robert H. Shmerling[2], Douglas P. Kiel[7], Suzanne G. Leveille[8], Carol A. Oatis[1], Lien Quach[6] and Yuqing Zhang[3]. [1]Arcadia University, Glenside, PA, [2]Beth Israel Deaconess Med Ctr., Boston, MA, [3]Boston Univ School of Medicine, Boston, MA, [4]Boston University School of Medicine, Boston, MA, [5]Hebrew SL & Harvard Med Sch, Boston, MA, [6]Institute for Aging Research, Hebrew SeniorLife, [7]Institute for Aging Research, Hebrew SeniorLife and Harvard Medical School, Boston, MA, [8]University of Massachusetts-Boston

Purpose: Knee osteoarthritis (OA) and falls are common in older adults and limit mobility. A few studies have linked knee OA and risk of falls. Recent research, however, suggests that some factors increased risk for indoor falls while decreased risk for outdoor falls; thus, grouping falls together may mask the true effect of a particular risk factor. Also, older men and women may differ in factors related to falls such as gait, balance, and physical activity that may modify the association between knee OA and risk of falls. To date, no study has examined the relation of knee OA with the risk of indoor vs. outdoor falls and explored whether such association differs by sex.

Methods: This analysis included 764 participants from the MOBILIZE Boston Study, a population-based cohort of elderly men and women. Knee OA was assessed at baseline using the ACR criteria. Falls data were prospectively collected using monthly calendars, with phone follow-up assessment of location of falls, and were adjudicated. Fall rate was calculated separately for indoor and outdoor falls (falls/follow-up year). We used negative binomial regression to estimate the effect of knee OA on rate of indoor and outdoor falls separately, adjusting for age, sex, BMI, medications, number of comorbidities, and history of falls. We repeated the analyses for men and women separately, and tested whether the effect of knee OA on outdoor and on indoor falls was modified by sex by adding an interaction term (i.e., knee OA*sex) in the model.

Results: Of 486 women and 278 men (mean age: 78 years, mean BMI: 27.3), 25% had ACR-defined clinical knee OA. Over an average of 2.2 years of follow-up, 60% of participants had at least 1 fall. Rates of *outdoor* falls were 49 and 34 per 100 person-years for participants with and without knee OA, respectively. The corresponding *indoor* falls rates were 53 and 39 per 100 person-years. Compared with those without knee OA, the adjusted rate ratio (RR) for outdoor falls among participants with knee OA was 1.35 (95% CI: 1.04–1.77); the corresponding RR for indoor falls was 1.21 (95% CI: 0.94–1.57). However, the effect of knee OA on risk of indoor and outdoor falls was modified by sex. In women, knee OA was strongly associated with an increased risk of outdoor falls; no such effect was observed in men (p-value for interaction=0.04). Although the interaction term was not statistically significant for indoor falls, the association of knee OA with the risk of indoor falls was stronger in men, albeit at borderline significance, than that in women (Table).

Table. The Association between Knee Osteoarthritis and Rate of Outdoor and Indoor Falls in Men and Women

	Knee OA Rate of Falls (per 100 P-Y[1])	No Knee OA Rate of Falls (per 100 P-Y)	RR (95% CI)[2]	P-Value for Interaction
Outdoor Falls				
Men	47	45	0.91 (0.60, 1.38)	0.04
Women	50	27	1.70 (1.21, 2.40)	
Indoor Falls				
Men	60	35	1.58 (0.99, 2.32)	0.22
Women	49	41	1.11 (0.82. 1.50)	

[1]Person-Years.
[2]Adjusted for age, BMI, fall-inducing medications (anti-depressants, anti-psychotics, anti-hypertensives, and sedatives), no. of co-morbidities (high blood pressure, stroke, heart disease, diabetes, ulcer/stomach disease, kidney disease, anemia, cancer/skin cancer, rheumatoid arthritis), and history of falls.

Conclusions: Knee OA was associated with an increased risk of outdoor falls, and such an association was limited to women. Knee OA also appeared to be more strongly associated with indoor falls in men. Future studies should examine specific mechanisms such as balance, gait speed, and physical activity that may explain why knee OA on the risk of outdoor vs. indoor fall are different in women from that in men.

Increasing Prevalence of Knee Pain and Symptomatic Knee Osteoarthritis. Uyen-Sa D. T. Nguyen[5], Yuqing Zhang[2], Jingbo Niu[3], Bin Zhang[1] and David T. Felson[4]. [1]Boston Univ Schl of Medicine, Boston, MA, [2]Boston Univ School of Medicine, Boston, MA, [3]Boston University Schol of Medicine, Boston, MA, [4]Boston University School of Medicine, Boston, MA, [5]Boston University School of Medicine, Boston, MA

Purpose: Knee pain, a common complaint in older adults, limits function and mobility and is a major reason for knee replacement among those with knee osteoarthritis (OA). Obesity is a strong risk factor for knee pain and knee OA. Given the recent epidemic of obesity in the U.S., the prevalence of knee pain is projected to rise. We examined the secular trend of knee pain and knee OA prevalence and determined whether any increase in prevalence is accounted by changes in body mass index (BMI).

Methods: Data were from the Framingham OA Study (FOA) and NHANES, a nationwide population based study. Knee pain was assessed in the FOA at three exams roughly 10 years apart, in subject groups that varied from exam to exam but which were all population based, using a questionnaire that asked about pain in or around the knee lasting at least 1 month in the past 12 months. Knee pain data were also collected in the NHANES I, II, III in addition to three later surveys. In NHANES, subjects were asked about pain in or around the knee on most days for at least 1 month or 6 weeks. Starting in 1999, NHANES also specified knee pain in the past 12 months. Weight bearing anteroposterior x-rays were obtained in the FOA to define radiographic knee OA (ROA)--Kellgren Lawrence grade $\geq$ 2, and knees with both ROA and knee pain were considered as having symptomatic OA (SxOA). We estimated race- and sex-specific prevalence for each outcome by 5-year age groups, and standardized to the sex-specific, age-appropriate, 2000-census US White population distribution. We estimated prevalence ratios (PR) and 95% confidence intervals (CI) adjusting for age (years) and BMI (Kg/M^2) using Poisson regression.

Results: Included in the analyses were 3,306 participants from FOA (57% women, mean age $\pm$ SD: 70.2 $\pm$ 7.1 years) and 10,383 from NHANES (51% women, mean age $\pm$ SD: 66.6 $\pm$ 4.3). The age-adjusted prevalence of knee pain in the FOA almost tripled in a 20-year period in women, and more than tripled in men (Figure 1a). The age-adjusted prevalence of knee pain more than doubled in NHANES from 1974–1994 among White people, and continued to increase from 1999 to 2004 (Figures 1b). Similar results were found in a smaller sample of African Americans in NHANES. In FOA, there were no substantial changes in the prevalence of ROA over the period studied: 31.7%, 30.3%, and 29.0% in men; 32.7%, 34.6%, and 32.9% in women. The age-adjusted prevalence of SxOA did increase substantially over time: 5.3%, 8.2%, and 17.9% in men; 8.8%, 12.7%, and 22.6% in women. BMI adjustment explained about 25% of the increasing age adjusted prevalence of knee pain for men and women (Table).

Figure 1a. **Sex-Specific Prevalence of Knee Pain in Framingham Osteoarthritis Study**

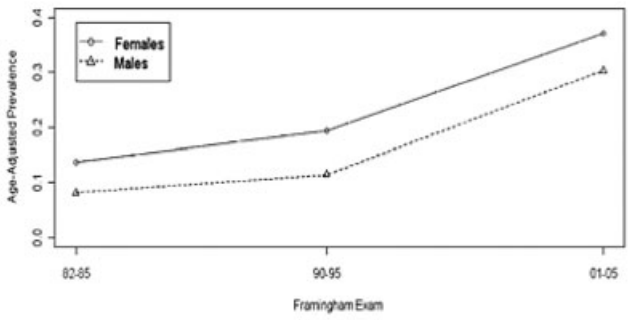

Figure 1b. **Sex-Specific Prevalence of Knee Pain in NHANES**

Community Mobility Barriers Predict the Development of 30-Month Disability: The MOST Study. Julie J. Keysor[1], Bin Zhang[2], James C. Torner[6], Cora E. Lewis[4], Irina Tolstykh[5] and David T. Felson[3]. [1]Boston Univ Sargent College, Boston, MA, [2]Boston Univ Schl of Medicine, Boston, MA, [3]Boston University School of Medicine, Boston, MA, [4]University of Alabama-Birmingham, Birmingham, AL, [5]University of California at San Francisco, San Francisco, CA, [6]University of Iowa, Iowa City, IA

Longitudinal studies linking the physical environment to incident disability are scarce. The purpose of this study is to examine whether mobility-related factors in the community environment are associated with the development of 30-month disability among older adults with functional limitations.

Methods: Data from the Multicenter Osteoarthritis (MOST) Study, a cohort study of persons with or at high risk of developing symptomatic knee OA, and the MOST-Knee Pain and Disability (MOST-KPAD), a MOST sub-cohort study of older adults with functional limitations were used. Community mobility barriers (BAR) (e.g., uneven sidewalks or other walking areas, parks and walking areas that are easy to get to and easy to use, places to sit and rest) and transportation facilitators (FAC) (e.g., public transportation close to home, public transportation with adaptations for people with disabilities, handicap parking, and car available) were ascertained at baseline using the Home and Community Environment scale. Disability was ascertained at baseline and 30-months using the Late Life Disability Instrument-Instrumental Limitation subscale and was dichotomized into no/mild disability and moderate/severe disability (disability) based on previously established cut-points. Among persons with no/mild disability at baseline, we examined the associations between baseline BAR and FAC dichotomized scores and development of disability at follow-up using logistic regression and adjusting for age, sex, race, education, body mass index, pain, walking speed, and site.

Results: Among 302 subjects who had baseline scores of no/mild disability and 30-month follow-up disability data, 50 (17%) developed disability at follow-up. The mean age of the sample at baseline was 70.3 (SD=3.9) years. 69% were women; 94% were white; 67% completed at least some college education. Overall the sample had mild pain (mean=28, SD=20, range 0–98) and functional limitation (gait speed: mean =1.2m/sec, SD=0.2, range 0.6–1.6). Subjects who reported high BAR at baseline were twice as likely to develop moderate/severe disability at 30-month follow-up compared to persons who reported low community barriers after adjusting for covariates. Report of high FAC was modestly protective of incident disability though this did not reach statistical significance. (Table 1)

Table 1. Odds of Developing Moderate/Severe Disability Over 30-Months by Features of the Community Environment

	Number of Subjects (%) Developing Moderate/ Severe LLDI-IL	Crude OR (95% CI)	Adjusted OR* (95% CI)
Community Mobility Barriers (BAR)			
Low BAR	27/219 (12)	1.0	1.0
High BAR	23/83 (28)	2.7 (1.5–5.1)	2.4 (1.2, 4.6)
Transportation Facilitators (FAC)			
Low FAC	23/112 (21)	1.0	1.0
High FAC	27/190 (14)	0.6 (0.3–1.2)	0.7 (0.3–1.3)

* Adjusted for age, sex, race, education, body mass, index, pain, walking speed, and site

Discussion: Mobility-related features of the environment may have an impact on development of disability over a 30-month time period.

When 1st Is Worst: Musculoskeletal Conditions Maintain 15 Year Reign as the Most Common Cause of Disability in US Adults. Kristina Theis[4], Jennifer M. Hootman[3], Charles G. Helmick[2] and Matthew Brault[1]. [1]Bureau of the Census, [2]CDC, Atlanta, GA, [3]Centers for Disease Control, Kennesaw, GA, [4]Centers for Disease Control and Prevention

Background: As the population ages and arthritis and related disability become more prevalent, the documented rheumatology workforce shortage and need to expand evidence-based public health interventions will be even more important. We describe the prevalence, causes of, and trends in disability among US adults.

Methods: The Survey of Income and Program Participation (SIPP) is a longitudinal panel survey fielded by the US Census Bureau representing the civilian, non-institutionalized US population. Panel members undergo in-person interviews at 4-month intervals for a period of 2.5–4 years. In 1991/1992 (T1), 1996 (T2), and, most-recently, 2005 (T3) a cross-sectional disability topic module was administered to panel adults to identify the prevalence and causes of self-reported disability (difficulty with ≥1 specified functional activities, activities of daily living, instrumental activities of daily living, selected impairments, use of an assistive aid, or limitation in ability to work around the house or at a job or business (1996 and 2005 only)). Analyses weighted to population controls and incorporating sampling weights produced estimates of disability prevalence and cause, from each disability module.

Results: The number of US adults reporting disability has increased from 42 million (T1) to 44.1 (T2) to 47.5 million (T3). Overall, the most common causes of disability at all 3 time-points were arthritis/rheumatism, back or spine problems, and heart trouble. Women report twice the prevalence of disability due to arthritis/rheumatism (26.9% T1; 22% T2; 24% T3) compared with men (13.7% T1; 11% T2; 11.5% T3) making it the most common cause of disability among women. Although women and men have similar prevalence of disability due to back/spine problems at all time points (15.3% T1; 16.6% T2; 16.3%T3 vs. 16.0% T1; 16.8% T2; 16.9% T3), back/spine problems are the most common cause of disability among men and the 2nd most common cause of disability among women. The number and percent of adults reporting disability due to musculoskeletal conditions (MSK) (arthritis/rheumatism and back or spine problems) has risen consistently from T1 to T3, while heart trouble, the next most common cause of disability, has decreased in absolute number and % prevalence. In fact, six of the 10 most common causes of disability have either declined or remained level from T1 to T3, while MSK have increased.

Conclusion: Medical and public health providers must prepare for greater demands on the healthcare and public health systems with the aging population, including training more providers in the diagnosis and management of MSK and increasing reach of evidence-based programs that address modifiable lifestyle characteristics (e.g., physical inactivity and obesity) that contribute to disability, particularly among those with MSK.

Does Physical Activity Dose Predict Physical and Mental Health-Related Quality of Life in People with Arthritis? Dina L. Jones, Ruoxin Zhang, Melissa Himes and Jennifer L. Eicher. Morgantown, WV

Background: Little is known about the relationship between health-related quality of life (HRQOL) and physical activity (PA) dose in people with arthritis (PWA). A prior survey indicated that PWA who met national PA recommendations had fewer unhealthy days per month due to physical or mental health. To further explore this relationship, we analyzed baseline data in PWA in an exercise intervention to determine if HRQOL improved over increasing increments of PA dose.

Methods: Sedentary adults with self-reported physician-diagnosed arthritis were enrolled in a 12-week, community-based, exercise intervention using the EnhanceFitness® program. Baseline data were collected on demographics, comorbidities, arthritis symptoms, performance-based physical function (Senior Fitness Test), body mass index (BMI), self-efficacy, outcome expectations, self-reported PA, and HRQOL. The CHAMPS Activities Questionnaire for Older Adults assessed the typical weekly frequency and duration of participation in 41 leisure/daily activities. Dose was the number of hours spent per week in moderate- or vigorous-intensity leisure activity: 1) inactive (0 mins), 2) insufficiently active (1–149 mins), and 3) meeting recommendations (≥ 150 mins). The SF-12 Physical Component Summary (PCS) and Mental Component Summary (MCS) scores were used to measure HRQOL. Two stepwise multiple linear regression procedures, with dose forced into each model, were performed to determine if dose predicted the PCS or MCS after adjusting for other covariates.

Results: The study included 173 participants (83% female) with a mean age of 69 ± 10.4 years. Univariate predictors of the PCS included dose ($p = 0.01$) and comorbidities ($r = -.36$), pain ($r = -.38$), stiffness ($r = -.47$), fatigue ($r = -.33$), BMI ($r = -.36$), number of chair stands in 30 secs ($r = .43$), number of seconds to walk 8 feet ($r = -.37$), number of steps marched in 2 mins ($r = .36$), self-efficacy ($r = .38$), outcome expectations ($r = .35$), and arthritis limitations (all $p < 0.001$). The best set of predictors in the PCS model were dose ($\beta = 2.7–2.9$, $p = 0.1$), stiffness ($\beta = -.68$, $p = 0.03$), chair stands ($\beta = .70$, $p = 0.003$), BMI ($\beta = -.24$, $p = 0.01$); pain ($\beta = -.83$, $p = 0.02$), and number of steps ($\beta = .08$, $p = 0.04$) ($R^2 = .47$). Univariate predictors of the MCS included dose ($p = 0.04$); employment ($p = 0.001$); outcome expectations ($r = .19$, $p = 0.02$); and age ($r = .36$), pain ($r = -.29$), stiffness ($r = -.23$), fatigue ($r = -.42$), comorbidities ($r = -.42$), and self-efficacy ($r = .34$) (all $p < 0.001$). The best set of predictors in the MCS model were dose ($\beta = 2.3–2.6$, $p = 0.25$), comorbidities ($\beta = -.26$, $p = 0.01$), age ($\beta = .38$, $p < 0.001$), and fatigue ($\beta = -1.37$, $p < 0.001$) ($R^2 = .36$).

Conclusion: Although PA dose predicted mental and physical HRQOL when considered alone, the relationship did not remain after adjusting for other factors. After controlling for dose, physical HRQOL was better in PWA with less pain and stiffness, a lower BMI, and better performance on physical

function tests. Mental HRQOL was better in PWA with fewer comorbid conditions, lower fatigue, and older age, after adjusting for dose. Future research could further investigate this relationship longitudinally by examining changes in dose and HRQOL over time.

Ready and Waiting: Adults with Arthritis Are Interested in Population-Based Physical Activity Programs. Louise Murphy[2], Teresa J. Brady[2], Kristina A. Theis[2], Julie Bolen[2] and Patience White[1]. [1]Arthritis Foundation, [2]Centers for Disease Control and Prevention

Background: Dissemination of population-based packaged physical activity (PA) programs among people with arthritis has been limited. Our study objective was to identify characteristics of adults with arthritis who are most likely to attend two types of evidence-based PA programs.

Method: We analyzed data from a national U.S. phone survey of white and black adults (n=1,002), ages 40–70 years old, who have doctor diagnosed arthritis ("Have you EVER been told by a doctor or other health professional that you have some form of arthritis, rheumatoid arthritis, gout, lupus, or fibromyalgia?), and "some" or "many" arthritis attributable activity limitations (AAAL). Participants rated how likely (i.e., very or somewhat likely, or not very or not at all likely) they would be to attend each of a generic and an arthritis-specific PA program. We estimated the percent who reported that they were very likely to attend each type of program and examined correlates (e.g., demographics, symptoms, number of comorbidities) of interest for each using multivariable adjusted logistic regression with odds ratios (ORs) and 95% confidence intervals (CI); CIs that did not overlap OR=1 were statistically significant.

Results: 30% reported being very likely to attend at least one type of PA program; among those who were very likely, 42% were interested in both, 32% in a generic program only, and 26% in arthritis-specific only. In the multivariable analysis, four groups were significantly more likely to have high interest in generic programs: women (OR=1.6), blacks (OR=2.5; ref=whites) and those with ≥3 comorbidities (OR=3.0; ref=no comorbidities) or who were very likely to attend a generic or arthritis-specific self-management education program (SME) (OR=16.5; ref=not very likely to attend either SME). For the arthritis-specific PA program, interest was significantly higher among women (OR=1.7) and respondents with less than a high school education (OR=3.3; ref=completed high school), some AAALs (OR=1.8; ref=many AAALs), who disagreed that there was nothing they could do to manage their arthritis (OR=1.6; ref=agreed), or who were very likely to attend an SME (OR=16.4 respectively; ref=no interest in either SME).

Conclusion: Approximately a third of respondents were very likely to attend at least one type of PA program. Interest was consistently higher among women and those who were very likely to attend an SME. Specific target groups for the two types of programs emerged: whereas blacks and people with multiple comorbidities had a greater interest in generic programs, those with some AAALs or less than a high school education had greater interest in arthritis-specific programs. Our findings indicate a demand for population based PA programs among a select but substantial group of adults with arthritis. The shared interest in SME and PA programs suggest that this group is eager for opportunities to learn self-management strategies. Clinical and public health practitioners can be encouraged that their efforts in program delivery are important. These study findings may help practitioners identify specific subgroups who are most ready for referral to community based PA programs.

Evaluation of Tai Chi Course Effectiveness for People with Arthritis. Leigh F. Callahan[1], Jack H. Shreffler[3], Betsy S. Hackney[3], Kathryn Remmes Martin[2] and Brian Charnock[3]. [1]Univ of North Carolina, Chapel Hill, NC, [2]University of North Carolina, Chapel Hill, Chapel Hill, NC, [3]University of North Carolina, Chapel Hill

Purpose: To evaluate the effectiveness of the Arthritis Foundation's 6-week Tai Chi course in reducing symptoms, increasing function, and improving psychosocial status in participants with arthritis using a community based randomized control trial (RCT).

Methods: At baseline, 332 participants were registered at 20 sites in North Carolina or New Jersey and randomly assigned to treatment (172) or delayed control (160). All participants received baseline and 6-week follow-up evaluations, after which the control group received the course. No adverse events were noted during the course. Self-report Instruments included pain, fatigue and stiffness visual analog scales (VAS), Health Assessment Questionnaire (HAQ), general health, Rheumatology Attitudes Index (RAI, helplessness), and Arthritis self-efficacy (ASE) for pain and symptoms. Participants also completed the PROMIS™ (PR) Short Form instruments for sleep disturbance and satisfaction with social roles. Physical performance measures were time to complete 3 chair stands, normal and fast gait speed, single leg stance, and reaching ability. The follow-up rate was 75% (120 control; 128 treatment). Regression analyses related the change in score from baseline to 6-week follow-up to the intervention status, with adjustment for baseline value, age, gender, and BMI.

Results: There are no significant differences between treatment and control groups at baseline. The participants were 85% female, with average age of 65 (19–89) and BMI of 28.5. The group was highly educated, 15% with high school diploma and 82% continuing beyond high school. The racial breakdown was 85% Caucasian and 11% African American. Results of the regression analyses showed significant ($p<0.05$) modest improvements in the treatment group for reported pain, fatigue and stiffness VAS (effect sizes ES=0.27, 0.23, 0.29, respectively). Moderate significant improvements were also seen in helplessness (RAI, ES=0.35), self-efficacy (ASE) for pain (ES=0.26) and symptoms (ES=0.35) of arthritis, PR sleep disturbance (ES=0.43), and PR satisfaction with social roles (0.31). Total of four reaching spans (left, right, forward, backward) showed significant improvement after treatment (ES=0.31).

Conclusions: Participants in the AF Tai Chi program showed improvements in pain, fatigue, and stiffness and sense of well-being related to psychosocial variables. The HAQ measure of physical function did not indicate significant change, and the physical performance measures involving chair stands, gait speed and single leg stance were not improved convincingly. The ability to reach while maintaining balance improved, perhaps reflecting the nature of the Tai Chi training and movements.

Walk with Ease Program: One-Year Follow-Up. Leigh F. Callahan[2], Jack H. Shreffler[4], Mary Altpeter[4], Laura O. Houenou[4], Britta Schoster[4], Kathryn Remmes Martin[3], Jennifer M. Hootman[1] and Todd Schwartz[4]. [1]Centers for Disease Control, Kennesaw, GA, [2]Univ of North Carolina, Chapel Hill, NC, [3]University of North Carolina at Chapel Hill, Chapel Hill, NC, [4]University of North Carolina, Chapel Hill

Purpose: One year after completing the Arthritis Foundation's 6-week Walk with Ease (WWE) group or self-directed mode of intervention, participants were evaluated to determine their adherence to the WWE program and to see what improvements in physical function, symptoms and psychosocial variables were noted

Methods: 403 individuals who completed the 6 week follow-up assessment (178 group, 225 self-directed) were mailed a self-report questionnaire designed to assess physical function, arthritis symptoms, psychosocial variables, and continuation of the WWE program at one year after the intervention completion. Repeated measures regression models were used to fit the data from baseline, 6-weeks, and 1-year. Responses were required at all time points for inclusion in the model. An indicator was included for mode of intervention (self-directed or group). Results were adjusted for age, education, gender, race, and BMI.

Results: 158 (89%) group and 204 (91%) self-directed participants completed the 1 year follow-up questionnaire. At 6-weeks, there were significant improvements in nearly all self-report measures and physical performance measures (not included in 1 year follow-up) regardless of the mode of intervention (presented previously). For both the group and self directed intervention modes, 2 measures show significant improvements at one year from baseline: PROMIS satisfaction with social roles (effect sizes ES=0.33/0.27); arthritis self-efficacy (ASE) for handling pain (ES=0.17/0.17). There were 7 outcomes where self-directed participants showed significant improvement from baseline, while the group participants did not: Health Assessment Questionnaire (HAQ) (ES =0.21); pain (ES=0.38) and stiffness (ES=0.31) Visual Analog Scales (VAS); general health (ES=0.17);

Rheumatology Attitudes Index (RAI, helplessness) (ES=0.28); PROMIS depression (ES=0.17); and ASE for dealing with symptoms (ES=0.22). The follow-up rate at 1-yr was similar for both modes, but 60% of group participants continued walking versus 70% of the self-directed participants. The most frequently cited reason for stopping walking for both modes was "pain, stiffness, or fatigue" (42%/36%). The group participants also cited "other health problems" more frequently (33%) than the self-directed (17%).

Conclusions: Both group and self-directed participants maintained some benefits 1 year after the WWE intervention. However, self-directed participants were more likely to continue walking and retained improvement in more self-reported physical function, symptoms, and psychosocial outcomes. Two factors could influence this finding. First, the self-directed participants were on average about 5.7 years younger than those in the group sessions. Second, the self-directed have chosen a mode of intervention that suited their proclivity to act alone, while the group participants may be stimulated by group instruction but have less inclination to continue after the course ended.

Fit and Strong!: Bolstering Maintenance of Physical Activity among Older Adults with Lower-Extremity Osteoarthritis. Susan L. Hughes[4], Rachel B. Seymour[4], Richard T. Campbell[3], Pankaja Desai[3], Gail Huber[2] and Justina Chang[1]. [1]JAMA, [2]Northwestern University, [3]University of Illinois Chicago, [4]University of Illinois Chicago, Chicago, IL

Osteoarthritis (OA) is the most common condition affecting older people today. Lower extremity joint impairment caused by osteoarthritis has been shown to be a risk factor for future disability. Physical activity (PA) has been shown to play a critical role in the amelioration of symptoms and progress of the disease. However, little is known about effective ways of motivating older adults to maintain PA after a formal training program ends. Fit and Strong! is an award winning, evidence-based multiple-component PA/behavior change program for older adults with lower-extremity (LE) OA. This study used a multi-site comparative effectiveness trial (N=486) with repeated measures to compare the impact of negotiated vs. mainstreamed follow-up with and without telephone reinforcement (TR) on maintenance of PA after the 8-week Fit and Strong! program ends. Random effects analyses for the total sample showed significant pre-post improvements at 2,6,12, and 18 months on PA maintenance that were accompanied by significant improvements in LE pain and stiffness, LE function, sit-stand, and 6-minute distance walk and anxiety and anxiety/depression. Analyses by treatment condition showed that persons in the negotiated group who received TR maintained a 21% increase in caloric expenditures over baseline, with lesser benefits seen in the negotiated only, mainstreamed with TR, and mainstreamed only groups. Significant benefits of telephone dose were also seen on lower-extremity joint stiffness, pain, and function as well as anxiety and anxiety/depression. The negotiated follow-up contract that Fit and Strong! uses, bolstered by TR, is associated with enhanced long-term PA maintenance and associated health outcomes. While TR was effective, it is not inexpensive, which may impede its translation and dissemination into community-based settings. Other forms of reinforcement, like participant and instructor videos will also be important to test if we are to maximize the successful translation of evidence-based programs in the future.

Characteristics of Persons with or at High Risk of Knee OA Achieving Recommended Physical Activity Levels: The MOST Study. Daniel K. White[1], Tuhina Neogi[2], Jingbo Niu[2], Michael Nevitt[3], C. Elizabeth Lewis[4], James Torner[5] and Doug Gross[2]. [1]Boston University, Boston, MA, [2]Boston University, [3]University California San Francisco, [4]University of Alabama, [5]University of Iowa

The CDC recommends physical activity for multiple health benefits with walking being the most common means of obtaining physical activity. However, as few as 24% for persons with self reported arthritis meet these guidelines. Among persons with radiographic knee osteoarthritis (ROA), it is not known how many satisfy these guidelines, nor which factors are associated with meeting them. Hence, we examined the characteristics of persons with or at high risk of ROA that meet activity guidelines as measured by an accelerometer-enabled monitor.

The Multicenter Osteoarthritis Study (MOST) is a NIH funded longitudinal study of people who have or are at high risk for knee OA. Subjects at the 60 month visit wore an accelerometer-enabled monitor to record walking activity over 7 days. Using a disablement model framework, we evaluated pathology, impairment, functional limitation, and psychosocial characteristics associated with meeting CDC guidelines. Specifically, we examined ROA and total knee replacement (TKR) (pathology), knee pain (impairment), self reported difficulty walking and walking at a pedestrian speed (>1.2 m/s) in the clinic (functional limitation), and depressive symptoms (psychosocial). We defined meeting CDC guidelines as walking at least 80 steps per minute for 150 minutes over 7 days. We compared disablement characteristics among persons meeting and not meeting activity guidelines using prevalence ratios adjusted for age, sex, BMI, race, number of comorbidities, and presence of widespread pain.

Of 806 subjects (Age 62 ± 8 yrs, BMI 31 ± 6 kg/m2, female 69%), 174 (22%) met CDC guidelines for physical activity. These persons were more often male with a lower mean age and BMI, and did not have widespread pain. In adjusted models pathology was not associated with meeting CDC guidelines, however persons with bilateral knee pain, self reported difficulty walking, and those who could not walk at a pedestrian speed were 40% to 80% less likely to meet CDC guidelines than their counterparts (see table).

Pathology-related characteristics (ROA and TKR) were not associated with meeting CDC guidelines, whereas pain and functional limitation characteristics were associated. These findings may be encouraging to providers given that these latter factors are potentially modifiable.

		% meeting CDC Guidelines (number meeting guidelines/all subjects)

Parvovirus B19 Non-Structural Protein NS1 Forms Adducts with Cellular DNA, Induces Apoptosis, and Is Condensed in Apoptotic Bodies: A Model for Viral Induction of Autoantibodies and Systemic Lupus Erythematosus. Leona Gilbert[3], Pavan K. Dhanyamraju[3], Eoin Wallace[3], Elina Dadu[3], Liping Wang[3], Harry J. Whitlow[3], Violetta Kivovich[1] and Stanley J. Naides[2]. [1]Pennsylvania State University, Milton S. Hershey Medical Center, [2]Quest Diagnostics Nichols Institute, San Juan Capistrano, CA, [3]University of Jyväskylä, Finland

Background: Human parvovirus B19 causes acute illness with many features of systemic lupus erythematosus (SLE) including transient antinuclear, anti-dsDNA and antiphospholipid antibodies. B19 may persist in various tissues, e.g. in liver, where it may cause a "restricted" infection with expression of the viral non-structural protein NS1, but little or no capsid protein. NS1 is a superfamily 3 (SF3) helicase typical of DNA viruses. Our group previously reported that expression of enhanced green fluorescent protein-NS1 (eGFP-NS1) fusion protein induced NS1 bulky adduct formation and single strand nicks in hepatocyte DNA leading to caspase 9 mediated apoptosis. Excess nucleosomes and apoptotic bodies are seen in the blood in SLE patients.

Objective: In order to construct a model for B19 induced abrogation of tolerance to self-DNA, we determined whether NS1-DNA adducts survived apoptosis by examining surface blebs and extruded apoptotic bodies for B19 NS1, DNA and proteins known to be autoantigens in SLE.

Methods: The liver-derived cell line, HepG2, was transduced with recombinant baculovirus hosting eGFP, eGFP-NS1 or eGFP-NS1 with a mutation in the NS1 putative metal coordination site. At 48 hours post-transduction, apoptotic cells and bodies were evaluated by scanning electron microscopy (SEM), comet assay, flow cytometry and confocal microscopy.

Results: eGFP-NS1, but not eGFP, transduced cells showed increased surface blebs post-transduction. An eGFP-NS1 mutant with a deletion in the putative metal coordination site, dMetal, showed decreased blebbing. eGFP-NS1, but not eGFP, induced DNA damage as demonstrated by comet formation, while a site directed mutant, Metal 1, and dMetal constructs where intermediate. Of purified apoptotic bodies, 87% induced by eGFP-NS1 fluoresced compared to only 28% in eGFP transduced cultures. Confocal imaging of apoptotic cells showed surface blebs containing NS1, dsDNA, and histone H4. Purified apoptotic bodies showed surface phosphotidylserine by Annexin V staining, internal DNA by DAPI staining, eGFP-NS1, histone 4, proliferating cell nuclear antigen, and lysosomal antigen Lamp2, but not histone H2B.

Conclusions: B19 NS1 expression damages host cell DNA and induces apoptosis. NS1 bulky adduct modified self-DNA is condensed into apoptotic bodies in the presence of nuclear and cytoplasmic self-proteins. Antigen presenting cells could ingest these apoptotic bodies, present NS1 peptides, and activate NS1 specific T cells. The last could provide costimulatory signals to anergized anti-DNA B cells presenting NS1 peptides processed after surface Ig mediated uptake of NS1-modified nucleosomal DNA. Epitope spreading would allow expansion of autoantibody specificities. The presence of similar SF3 helicases in other DNA viruses, e.g. Epstein Barr nuclear antigen 1, EBNA1, suggests that this model may more broadly explain viral induction of DNA autoantibodies and SLE disease.

Occurrence of Rheumatoid Arthritis-Associated Autoantibodies in Leishmania Donovani Infection. Erik Åhlin[1], Amir Elshafie[2], Musa A. M. Nur[4], Sayda Hassan El Safi[3] and Johan Rönnelid[1]. [1]Clinical Immunology Unit, Uppsala University, Uppsala, Sweden, [2]Clinical Immunology Unit, Uppsala University, Uppsala, Sweden. Department of Pathology and Microbiology, Alribat University Hospital, Khartoum, Sudan, [3]Department of Microbiology and Parasitology, Faculty of Medicine, University of Khartoum, Sudan, [4]Unit of Rheumatology, Alribat University Hospital, Khartoum, Sudan

Background: The presence of antibodies against citrullinated peptides (anti-CCP) and rheumatoid factors (RF) are closely associated with rheumatic diseases but are also seen in a number of infectious diseases. Our aim with this investigation was to evaluate the occurrence of anti-CCP, RF and circulating immune complexes (CIC) in Sudanese patients infected with the Leishmania donovani parasite. The infection causes an internal disease called visceral leishmaniasis (VL) with an immunopathology characterised by a strong humoral immune response with high production of antileishmanial antibodies, CIC, and polyclonal activation of B-lymphocytes, all factors that could give rise to rheumatic-like manifestations.

Methods: Serum samples were collected from 136 Leishmania infected patients and 85 healthy Sudanese controls. Twenty-one Sudanese anti-CCP positive RA patients diagnosed following the 1987 ACR criteria were also included in the study. Levels of CIC were measured by a solid-phase C1q assay. Anti-CCP was measured using a commercial ELISA-test kit. A control plate with cyclic peptides containing arginine instead of citrulline as the antigen was used to evaluate citrulline specific reactivity. Rheumatoid factor was measured by nephelometry.

Results: Among both Leishmania-infected patients and anti-CCP positive RA patients the majority (86% in both groups) were RF positive while the frequency of CIC positivity was higher among VL patients (VL: 38%, CCP pos. RA: 24%). When anti-CCP reactivity was analysed, 11% of VL patients were found to be positive. The levels of anti-CCP among VL patients correlated well to the CIC levels found (rho: 0.59, $p<0.001$). In the RA group no association was found between CIC and anti-CCP. To rule out the possibility that anti-CCP positivity was due to cross reactions with CIC, we adsorbed C1q binding CIC from sera and evaluated CCP reactivity afterwards. This procedure did not diminish the anti-CCP reactivity in either the VL group or among anti-CCP positive RA patients. We then went on to analyse the citrulline specificity among anti-CCP positive patients. All anti-CCP-positive VL patients showed equivalent reactivity towards CCP and the non citrullinated control peptide. This was in strict contrast to the anti-CCP positive Sudanese RA patients among whom anti-CCP was restricted to CCP ($p<0.0001$).

Conclusions: In this study we found that sera from Leishmania infected patients were often RF positive, had elevated CIC levels and that a substantial amount showed reactivity towards CCP. However, contrary to what was seen in RA sera, the CCP reactivity was not restricted to citrulline. This argues that this is an effect of extensive inflammation and immune activation more than a sign of shared pathogenic characteristics with anti-CCP positive arthritis. Furthermore, our findings stress the importance to interpret a positive CCP test carefully.

IL-12p70 Alteration in Antibiotic Treatment of *Chlamydia*-Induced Reactive Arthritis (ReA). Robert D. Inman[1], Basil Chiu, Alan P. Hudson[3] and John D. Carter[2]. [1]Toronto Western Hospital, Toronto, ON, Canada, [2]Univ of South Florida, Tampa, FL, [3]Wayne State Univ Schl of Med, Detroit, MI

Background: A recent study of combination antibiotics has proved to be effective for the treatment of *Chlamydia*-induced ReA, but the immune events underlying clinical response with this treatment have not been defined. In the present study we examine the cytokine signatures of patients enrolled in that randomized controlled trial.

Methods: Patients with chronic *Chlamydia*-induced ReA were randomized to a 6-month course of Rifampin + Azithromycin (AR), Rifampin + Doxycycline (DR), or placebo (PCB). Serum samples were obtained at baseline, 6 months, and 9 months after the start of treatment. The assay system was a multi-analyte ELISA, which quantitatively assays serum levels of 42 cytokines.

Results: Analysis of covariance (ANCOVA) was used to test whether treatment has an effect on cytokine values at second time point after removing the variance account of the cytokine values at the first time point. P-values were utilized to determine if the difference in means were significant for [DR vs. Placebo], [AR vs. Placebo], [global p-values for previous two tests] and [DR or AR vs. Placebo] respectively. Using a univariate analysis, the following cytokines showed significant ($p<0.05$) treatment effects: EGF (AR *vs* PCB), GM.CSF (DR *vs* PCB), IFN-γ (DR *vs* PCB), IL-1ra (AR *vs* PCB), TGF-α (AR *vs* PCB) and VEGF (AR *vs* PCB) and IL-12p70 (DR *vs* PCB and AR *vs* PCB). IL-12p70 demonstrated the most significant treatment effect ($p<0.001$ for both AR and DR). After Bonferroni adjustment for multiple test

correction, treatment effect only remains significant for IL-12p70 (at both 6 months and 9 months).

Conclusion: IL-12p70 is required for optimal host IFN-γ T cell response against intracellular pathogens and endocervical IL-12 expression has previously been shown to decline with clearance of *Chlamydia*. The distinctive changes in serum levels of IL-12p70 following antibiotic treatment of *Chlamydia*-induced ReA point toward changing host cytokine responses concurrent with clinical improvement, and highlight the importance of IFN-γ in this process.

The Efficacy and Safety of Vaccination Against H1N1 in Patients with Rheumatoid Arthritis, Systemic Lupus Erythematosus, Psoriatic Arthritis and Ankylosing Spondylitis. Ori Elkayam[2], Sharon Amir[2], Michal Mandelboim[1], Ella Mendelson[1], Jonathan Wollman[2], Uri Arad[2], Daphna Paran[2], David Levartovsky[2], Irena Wigler[2] and Dan Caspi[2]. [1]Center of Virology, Sheba Medical Center, [2]Department of Rheumatology, Tel Aviv Medical Center

Background: In spring 2009, a new swine-origin influenza virus A (H1N1) quickly spread worldwide prompting the development of pandemic H1N1 influenza vaccine launched by the end of 2009.

Purpose: To assess the efficacy and clinical safety of vaccination against H1N1 in patients suffering from Rheumatoid Arthritis (RA), Systemic Lupus Erythematosus (SLE), Psoriatic Arthritis (PsA) and Ankylosing Spondylitis (AS) in comparison with healthy controls.

Patients and Methods: The study population comprised 4 groups of patients and healthy controls: 41RA patients: 56% female, age: 52.6±14.5, disease duration: 9 years;21SLE patients: 66% female, age: 41.7±11.5, disease duration: 11 years;17 PsA: 35% female, age: 48.5±11.8, disease duration: 12 years; 15 AS: 20% female, age: 47.2±13.3, disease duration: 14 years; 17 healthy controls: 60% female, age: 47.3±11.3. All the subjects were vaccinated against H1N1 using the Novartis MF59-adjuvanted H1N1v monovalent influenza vaccine, Focetria®. Each 0.5 ml dose contained 7.5 μg H1N1 HA antigen and the full dose of the oil-in water emulsion adjuvant, MF59®, containing 9.75 mg squalene. The immunogenicity of the vaccine was assessed on day 1 and 4 weeks after by hemagglutination inhibition (HI) assay. Geometric mean titers (GMT) and seroconversion rates were calculated for each group. Seroconversion rates were calculated as the percentages of each group that displayed seroconversion in initially seronegative subjects or a significant increase in titer in initially seropositive subjects (a four-fold increase in titer in those < 40 prevaccination).The safety of the vaccine was evaluated using Disease activity score (DAS) for RA and PsA, Systemic Lupus Index disease activity (SLEDAI) for SLE and BASDAI for AS.

Results: The proportion of baseline protective levels of antibodies against H1N1 was similar in most groups, except for AS patients: RA: 23%, SLE: 24%, PsA: 29%, AS: 7% and healthy controls: 29%.A significant increase in GMT was observed in the 5 groups. A substantial proportion of patients and controls responded to the vaccine, Healthy controls demonstrating a better response (Table 1). Multivariate logistic regression analysis identified RA and PsA as parameters of significant lower response. Treatment with Infliximab and Leflunomide was associated with a lower response.DAS, BASDAI and SLEDAI remained unchanged after vaccination.

Table 1

	Healthy controls (n = 17)	RA (n = 41)	SLE (n = 21)	PsA (n = 17)	AS (n = 15)
GMT0	4.38	5.72	6.91	5.6	2.33
GMT1	85.67	64.29	70.93	55.5	57.04
Proportion of responders	82%	56%	67%	59%	53%
%seroprotection 0	29%	23%	24%	29%	7%
%seroprotection 1	88%	71%	76%	76%	60%

0 - Baseline 1–4 weeks after vaccination.

Conclusions: Vaccination against H1N1 using an adjuvanted H1N1v monovalent influenza induced an appropriate response in patients with RA, SLE, PsA and AS. The vaccine was found to be safe in this cohort of patients.

Serious Infection in Rheumatoid Arthritis Patients Switching Anti-Tumor Necrosis Factor Drugs. Bao-Anh Nguyen-Khoa[2], Earl L. Goehring, Jr[2], Kimberly Alexander[1], Wei Dong[1], Pavel Napalkov[1] and Judith K. Jones[2]. [1]Genentech, South San Francisco, CA, [2]The Degge Group Ltd, Arlington, VA

Purpose: Rheumatoid arthritis (RA) patients commonly change drug therapy for reasons of safety or effectiveness. This study describes rates of first serious infection among RA patients who switch from one anti-Tumor Necrosis Factor (aTNF) drug to another aTNF compared to those who do not switch.

Methods: Subjects with RA who received only an aTNF drug (infliximab, etanercept, or adalimumab) were observed in a large health claims database from 1/1/2001 to 12/31/2007. Non-switchers (NS) remained on one aTNF during the study period, Switchers (S) had at least one change to another aTNF. Index dates were defined as the day of the first aTNF claim for NS, and the day of the treatment switch for S. Baseline data were collected for the 365 days of enrollment prior to the index date. Serious infections included those which required IV antibiotics or hospitalization; only the first event was included in incidence rate estimates. Two attributable risk periods were used: 1) infection occurring ≤ 90 days from a prior claim for an aTNF (90-Day) and 2) any infection occurring after the index date (Ever-Treated). Data were stratified by 1-year and ≥ 2 years post-index. Cox regression was used to compare serious infection rates, adjusting for age, gender, selected comorbidities, Charlson comorbidity score, hospitalizations, and other RA treatments.

Results: There were 13,752 RA patients in the NS cohort, and 2,293 in the S cohort. In the 90-Day model, unadjusted rates of first serious infection was nonsignificantly lower for NS vs S (6.31/100 PY, 95% CI: 6.01–6.62 vs. 6.78/100 PY, 95% CI: 5.95–7.67). Rates of first serious infections declined from 8.59/100 PY and 8.72/100 PY in the first year post-index for NS and S, to 2.66/100 PY and 2.64/100 PY ≥ 2 years post-index.

In the Ever-Treated model, NS also had nonsignificantly lower unadjusted first infection rates than S (8.45/100 PY 95% CI: 8.10–8.80 vs. 9.10/100 PY, 95% CI: 8.15–10.12). Rates of first serious infection declined from 10.15/100 PY and 10.11/100 PY in the first year post-index for NS and S, to 4.18/100 PY and 4.44/100 PY ≥ 2 years post-index.

Regression analysis showed no significant difference between NS and S cohorts in the risk of serious infection for either attribution model (90-Day HR=0.93, 95CI: 0.74–1.17; Ever Treated HR=0.94, 95CI: 0.78–1.15). First and second year rates were not different between NS and S. Significant predictors for increased risk of serious infection included: age ≥ 50 years; positive history of serious or opportunistic infection, diabetes, respiratory disease; baseline Charlson score ≥ 2, or increasing number of hospitalizations. The effect of methotrexate on infection was conditionally related to several other risk factors.

Conclusions The risk of a serious infection was not different between RA patients that switched aTNF drugs and those who did not. Indications for switching an aTNF drug could not be captured in this study. Rates in the Ever-Treated model were generally higher than the 90-Day model for overall, 1-year, and ≥ 2 years post-index. Regardless of switching status, the rate of first infection 1-year post-index was up to 3 times greater than 2+ years post-index.

Defining Latent and/or Disseminated Active Tuberculous Infection with TST, Quantiferon Gold and Multisite Cultures in TNFi Exposed Individuals. Dilrukshie Cooray[2], James S. Louie[4], Rosalinda C. Moran[1] and George A. Karpouzas[3]. [1]Harbor- UCLA Medical Center, Carson, CA, [2]Harbor-UCLA Medical Center, Torrance, CA, [3]Harbor-UCLA Medical Center, Long Beach, CA, [4]University of California Los Angeles, Los Angeles, CA

Background: Patients (pts) receiving Tumor Necrosis Factor-α inhibitors (TNFi) are at increased risk for developing granulomatous infections with Mycobacterium tuberculosis (MTB) or non-tuberculous mycobacteria (NTM). Prior to starting TNFi, baseline screening for latent MTB includes tuberculin skin testing (TST) and/or ex vivo cellular responses to mycobacterial antigens [Quantiferon (QFN)] in addition to chest x-ray (CXR).

Clinically asymptomatic pts who have mycobacterial reactivity [TST or QFN positive (+)] and a negative (-) CXR are treated with Isoniazid (INH) for 9 mos. High risk pts on continued TNFi are still prone to subsequent infection and seroconversion and thus should be regularly monitored; however, the frequency and/or sequence of these screening schedules have not yet been standardized. The use of QFN assays in pts receiving TNFi has not yet been proven and more data is needed in this area. We found that the combination of TST and QFN testing may be a prudent strategy in monitoring pts on TNFi.

Methods: We report on 483 pts treated with TNFi between 11/1/2000 and 6/1/2010 in a single institution. Pts received at least one month (mo) of adalimumab (ADA), etanercept (ETN), Golimumab (GO), or loading dose of infliximab (IFX) 3mg/kg at 0,2, and 6 weeks. Screening TST and/or QFN assay plus CXR were obtained at baseline and (-) pts were serially re-screened yearly while on TNFi. Induration of > 5mm was considered a (+) TST. Those who were asymptomatic with a new (+) TST and/or QFN were tested for disseminated active disease with cultures and polymerase chain reaction (PCR) of sputum, urine, and stool (for MTB and NTM), along with CXR and chest CT.

Results: Of 481 pts exposed to TNFi, 447 pts received baseline TST; 127 (28%) had baseline (+) TST and 35/127 (28%) had old granulomatous disease (OGD) on CXR but were clinically asymptomatic. All 127 pts were treated as LTBI with INH for 9 mos. One pt developed active TB while on TNFi despite completion of LTBI treatment. The remaining 320 TST (-) pts had sequential annual TST re-screens, and 56 also underwent QFN testing. Thirty-seven of 320 (11%) pts developed a (+) TST (15.28±5.74 mm) while on TNFi. Of 56 QFN tested pts, 9 were (+) overall: 2 at baseline prior toTNFi and 7 after TNFi exposure. Two pts were QFN and TST (+); 5 had (+) QFN and (-) TST. Although clinically asymptomatic, all 41 pts with (+) TST and/or (+) QFN were assessed for dissemination as above; 9/41 (22%) pts had (+) cultures (2 with MTB, 7 with NTM). 3 of these pts were treated with multidrug anti-TB therapy and the rest were treated with INH. All patients continued TNFi without adverse outcomes to date (1589 PT-Years).

Conclusion: In high risk populations with rheumatic conditions, there is a high prevalence of LTBI both at baseline and upon subsequent rescreens while on TNFi. Our expanded cohort has combined yearly testing of TST with QFN assay. We propose conducting combined annual TST and QNF testing in all high risk individuals on TNFi and consider (+) pts for Chest CT, multisite cultures and PCR to evaluate for active disseminated disease.

Progressive Multifocal Leukoencephalopathy Associated with Biologic and Synthetic DMARD Therapy in Rheumatic Diseases: An Analysis of the FDA Adverse Event Reporting System Database. Eamonn S. Molloy[2] and Leonard H. Calabrese[1]. [1]Cleveland Clinic Foundation, Cleveland, OH, [2]St Vincent's University Hospital, Dublin, Ireland

Background: PML is a rare and often fatal opportunistic infection recently associated with several biologic therapies. Unfortunately the general understanding of PML is poor and ascribing risk to individual therapies has been problematic. This study examined the aggregate experience of PML reported in association with autoimmune disorders and biologic DMARD exposure in the FDA Adverse Event Reporting System (AERS) database through review of MedWatch forms.

Method: A Freedom of Information Act request was submitted for all cases of PML and/or JC virus infection within the FDA AERS database from November 1, 1997 to March 31, 2009. All MedWatch forms received at the time of this analysis were reviewed; those with identified autoimmune diseases and/or exposure to rituximab, anti-TNF antagonists, anakinra, or abatacept were selected for further analysis. PML was classified as confirmed, possible or unconfirmed. Other data collected from the forms included demographics, critical clinical and lab features and disease association cofactors of PML.

Results: A total of 473 cases were received and analyzed. Among all cases, 114 (24%) were found to have one or more autoimmune diseases, 40 of which were categorized as autoimmune rheumatic diseases (15 RA, 15 SLE, 6 vasculitis, 4 other).Of these 40 cases, 18 were considered 'confirmed' cases of PML based on the available information. Of these, 6 were treated with biologic agents (5 rituximab, 2 infliximab – 1 patient received both). Neither case associated with infliximab could clearly be attributed to the use of this agent – 1 subsequently received rituximab for dermatomyositis and the other was treated with cyclophosphamide for rheumatoid vasculitis. No confirmed cases were reported in association with the use of other biologic DMARDs such as other anti-TNF agents, anakinra or abatacept. The remaining 12 non-confounded, confirmed cases of PML among autoimmune rheumatic disease patients were treated with synthetic DMARDs only (7 cyclophosphamide (5 of whom subsequently received mycophenolate mofetil) and 5 others). Of 12 autoimmune rheumatic disease cases of 'possible' PML, 7 were associated with biologic therapies (5 anti-TNF therapy, 2 rituximab, 2 abatacept – 1 patient received adalimumab prior to rituximab, 1 received anti-TNF therapy prior to abatacept).

Conclusion: PML is a reported complication of a variety of disease states and associated with both synthetic and biologic immunosuppressive therapies. While the small numbers of cases involved precludes attribution of causality, two points deserve emphasis. The relative paucity of confirmed cases in patients treated with anti-TNF therapy, despite their widespread use, suggests that a causal relationship is unlikely. In contrast, there is a concerning, albeit rare, signal emerging regarding use of rituximab, especially considering that 5 cases of PML among rituximab-treated RA patients, in addition to those reported in this analysis, have been reported to Genentech. Nevertheless, until greater clarity can be achieved, all patients treated with immunosuppressive therapies for autoimmune disease should be considered at risk for PML.

Tocilizumab in Refractory Adult Still's Disease: A Cohort Study. Xavier Puéchal, Michel de Bandt, Jean-Marie Berthelot, Maxime Breban, Jean-Jacques Dubost, Olivier Fain, Jean-Emmanuel Kahn, Laurence Lequen, Maïté Longy-Boursier, Aleth Perdriger, Thierry Schaeverbeke, Eric Toussirot, Jean Sibilia and The CRI. Center for Rare Systemic and Auto-immune Diseases, Department of Rheumatology, Le Mans, France

Background: Interleukin-6 (IL-6) is thought to play a role in the pathogenesis of Still's disease. We report the first series of patients with adult Still's disease (ASD) treated with tocilizumab (TCZ), a humanized anti-IL-6 receptor antibody.

Objectives: To assess the efficacy and tolerance of TCZ in adult patients with refractory ASD.

Methods: Cohort study of all patients with ASD treated in France with off-label TCZ between July 2006 and July 2009 and enrolled in a specific French Agency for the Safety of Health Products (AFSSAPS) protocol.

Main Outcome Measures: European League of Associations for Rheumatology (EULAR) improvement criteria and resolution of systemic symptoms at 3 and 6-month follow-up.

Results: Fourteen patients were included in this study. At the start of TCZ treatment, despite a mean prednisone dose of 23.3 mg/day, mean tender joint count was 10.5/28, swollen joint count was 7.9/28 and mean DAS28 was 5.61. Recurrent systemic involvement, including fever and rash, was present in seven patients. TCZ was administered at 5 to 8 mg/kg every two or four weeks (8 mg/kg/month, n=9). Eleven patients successfully completed the six-month study; one withdrew due to necrotizing angiodermatitis, another due to thoracic oppression at each TCZ infusion and a third due to systemic flare. A good EULAR arthritis response was observed in 64% (9/14) of patients at three months and EULAR arthritis remission in 57% (8/14) at six months. Systemic symptoms were resolved in 86% (6/7) of patients. Moreover, corticosteroid dose was reduced by 56%. No other severe adverse effects occurred.

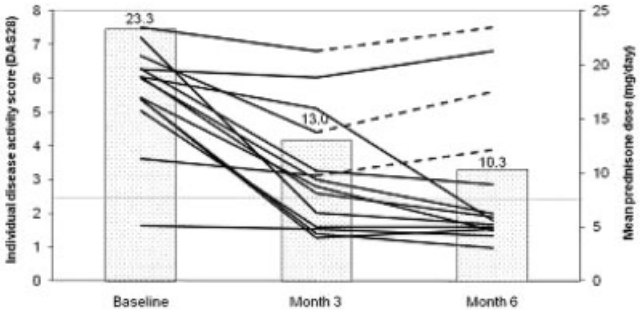

Figure. Individual disease activity score and mean prednisone dose before and after tocilizumab therapy in adult Still's disease.

Conclusions: In this cohort of patients with intractable refractory ASD, TCZ was effective against systemic involvement of the disease in almost all patients and led to arthritis remission in half the patients, showing a marked corticosteroid-sparing effect and an acceptable tolerance profile. TCZ is a promising new treatment for ASD.

Clinical Implications of the NMO-IgG Antibody and Overlapping Neuromyelitis Optica Spectrum Disorder in Patients with Connective Tissue Disease and Myelitis. Jason R. Kolfenbach[1], Brian J. Horner[3] and Sterling G. West[2]. [1]Division of Rheumatology, University of Colorado at Denver, Aurora, CO, [2]University of Colorado at Denver, Aurora, CO, [3]University of Colorado Denver School of Medicine

Objective: To identify the presence of neuromyelitis optica spectrum disorders (NMOSD) in patients with acute myelitis and suspected connective tissue disease (CTD), and to determine if the presence of NMOSD or the NMO-IgG antibody is associated with poor clinical outcomes

Methods: Seventeen patients with myelitis were identified from a university-based rheumatology clinic and prospectively followed. Clinical follow-up extended from July 1998 to February 2010. The diagnosis of myelitis was based on fulfillment of criteria established by the Transverse Myelitis Consortium Working Group, and/or diagnosis by a board-certified neurologist. Longitudinal myelitis (LM) was defined as T2 enhancement on spinal MRI of $\geq$ 3 contiguous vertebral segments. Inflammatory myelitis not meeting the criteria for LM was classified as transverse myelitis (TM). Optic neuritis (ON) was diagnosed by a board-certified neurologist or neuro-ophthalmologist. Clinical data and serologic profile were used to determine the presence of neuromyelitis optica (NMO) or NMOSD according to established criteria. Disease course and response to treatment were recorded. Statistical comparisons were calculated using Fishers exact testing.

Results: Eight of 15 (53%) patients diagnosed with a CTD and acute myelitis met criteria for NMOSD. Additionally, two patients had full-spectrum NMO without evidence of co-existent CTD. Optic neuritis was more commonly seen in Sjogren's syndrome (SS) than in systemic lupus erythematosus (SLE) (83% vs. 0%; p = 0.02), as was the serum NMO-IgG antibody (67% vs. 0%; p = 0.06). Full-spectrum NMO was diagnosed in four of six patients with primary SS, one of four with Sjogren's-associated overlap syndrome, and none of the five with SLE alone [Table]. Among patients with follow-up data (N= 15), all six with NMO-IgG positivity suffered relapse compared to 3/9 patients that were NMO-IgG negative (p = 0.03). Furthermore, patients who were positive for the NMO-IgG antibody suffered a total of 20 relapses (51 patient-years of follow-up) compared to four total relapses among 3/9 patients that were negative for the NMO-IgG antibody (114.5 patient-years of follow-up). Five of six patients with the NMO-IgG antibody were treated with rituximab in our series; evidence of clinical benefit included relapse cessation in some patients as well as prevention of LM and ON in a patient with transverse myelitis and the NMO-IgG antibody.

Table. Serologic profile & clinical characteristics of patients with CTD and myelitis

	SS (N = 6)	SLE (N = 5)	SS/SLE (N = 2)	MS/SS (N = 2)
Autoantibodies				
NMO-IgG	4/6 (67%)	0/5 (0%)	1/2 (50%)	0/2 (0%)
ANA	5/6 (83%)	5/5 (100%)	2/2 (100%)	2/2 (100%)
SS-A	5/6 (83%)	1/5 (20%)	0/2 (0%)	2/2 (100%)
SS-B	1/6 (17%)	0/5 (0%)	0/2 (0%)	1/2 (50%)
RF^+	3/5 (60%)	0/4 (0%)	0/1 (0%)	1/2 (50%)
Clinical features:				
LM	3/6 (50%)	2/5 (40%)	1/2 (50%)	0/2 (0%)
ON	5/6 (83%)	0/5 (0%)	1/2 (50%)	0/2 (0%)
Presence of NMO				
NMO	4/6 (67%)	0/5 (0%)	1/2 (50%)	0/2 (0%)
NMOSD	5/6 (83%)	2/5 (40%)	1/2 (50%)	0/2 (0%)

+: Some patients did not have RF testing performed; denominator represents patients with available results.
Abbreviations: NMO: Neuromyelitis optica; NMOSD: Neuromyelitis optica spectrum disorder; LM: longitudinal myelitis; ON: optic neuritis; MS/SS: overlap multiple sclerosis & Sjogren's syndrome.

Conclusion: NMOSD was common in our patients with CTD and autoimmune myelitis. Full-spectrum NMO and presence of the NMO-IgG antibody was more common among patients with SS than SLE. The presence of the NMO-IgG antibody was associated with disease relapse and may suggest the need for prolonged immunosuppressive therapy, supporting current recommendations for the treatment of NMO.

Diagnostic Significance of Serum Interleukin-18 Level in Adult-Onset Still's Disease. Junko Maruyama[3], Shigeko Inokuma[1] and Noboru Hagino[2]. [1]Japanese Red Cross Medical Center, [2]The University of Tokyo Hospital, [3]Tokyo Metropolitan Komagome Hospital, Tokyo, Japan

Purpose: To investigate the diagnostic significance and a cut-off value of serum interleukin-18 (IL-18) in adult-onset Still's disease (AOSD) patients.

Methods: We retrospectively analyzed serum IL-18 levels in 41 febrile patients with ferritin level elevation (>1,000 ng/mL) in our hospital from 2000 to 2008. They were compared between 16 patients who were finally diagnosed with AOSD and 25 patients with other diseases. Serum IL-18 levels were also compared between 16 AOSD patients and 5 hemophagocytic syndrome (HPS) patients associated with other diseases among the 25.

Results: The median levels of serum IL-18 were 99,106 pg/mL (interquartile range [IQR] 145,484) in patients with AOSD, 1,365 pg/mL (IQR 1,899) in other febrile patients ($p<0.000005$, vs. AOSD), and 2,709 pg/mL (IQR 4,408) in HPS patients with other diseases ($p=0.0017$, vs. AOSD). According to the receiver operating characteristic curve analysis, a cut-off IL-18 level of >20,000 pg/mL had a sensitivity of 93.8% and a specificity of 96.0% for diagnosing AOSD. There was no difference in serum ferritin levels among the groups.

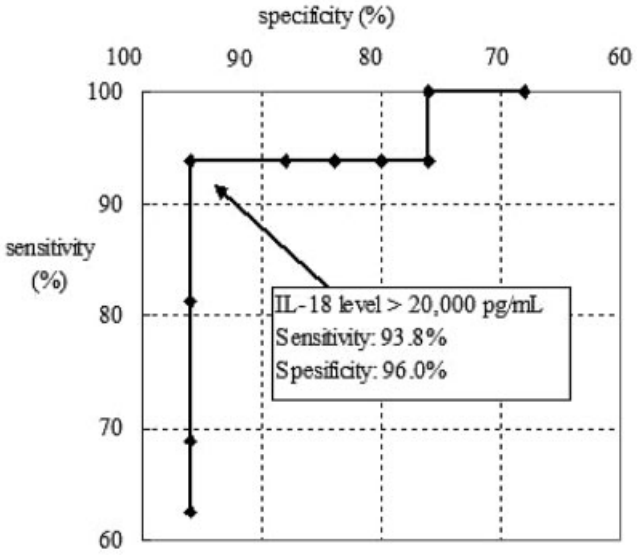

Figure. ROC curve analysis of serum IL-18 level for diagnosing AOSD.

Conclusions: Serum IL-18 level is a powerful diagnostic test for AOSD.

Disclosure: J. Maruyama: None; **S. Inokuma:** None; **N. Hagino:** None.

Extrapulmonary Course of Connective Tissue Disease and Survival after Lung Transplant. Troy K. Takagishi, Iffat Ahmed and Rodney Tehrani. Loyola University Medical Center

Purpose: Interstitial lung disease (ILD) is a common cause of morbidity and mortality in patients with connective tissue diseases (CTD). Lung transplants (LT) are becoming an increasingly viable option for the management of these patients. A review of the literature revealed no studies evaluating for extrapulmonary flares of the primary CTD following LT. Very few studies have documented the survival outcomes of this group of patients. We hypothesize that extrapulmonary disease flares rarely occur following LT and also that survival (%) is similar in patients with LT for CTD as compared to LT for COPD.

Methods: We performed an observational and retrospective chart review of all patients in a large tertiary care medical center that had a LT for CTD (LT/CTD) between 1999 and 2010 and evaluated for any extrapulmonary flares of the primary CTD following LT. Also, we compared their survival outcomes to those who underwent LT for COPD (LT/COPD). COPD was chosen as the control group because it comprises the largest group of patients undergoing LT nationally. From 1995–2008 there had been 8,417 LT due to COPD documented in the UNOS national registry which is compared to 181 for CTD during the same time period.

Results: From 1999–2010 at a large tertiary care medical center, 15 patients underwent LT for ILD secondary to their CTD: 5 with dermatomyositis or polymyositis (33%), 5 with rheumatoid arthritis (33%), 3 with lupus (20%), and 2 with mixed connective tissue disease (13%). 4/15 (27%) of the patients had an extrapulmonary flare of their primary CTD following LT. All episodes were arthritic flares (3 monoarticular and 1 polyarticular) and each occurred in a different patient (3 with RA and 1 with SLE). This data equates to 1 flare/15.71 patient years. The Kaplan-Meier survival curves for LT/CTD and LT/COPD respectively at 3 mo was 93% and 93%; at 1 yr was 92% and 93%; at 5 yrs was 75% and 77%.

Conclusion: There is no published literature on the extrapulmonary manifesations of CTD following LT. There is only scarce data on the survival outcome of this patient population. We found that extrapulmonary flares of the primary CTD are extremely rare following LT likely due to the use of immunosuppressants for LT. In addition, survival following LT for CTD was found to be equivalent to that for LT for COPD. LT appears to be a viable option in a select group of patients with end stage ILD secondary to CTD.

Idiopathic Retroperitoneal Fibrosis: Treatment-Related Outcomes and Predictors of Clinical Response. Tanaz A. Kermani[1], Cynthia S. Crowson[2], Sara Achenbach[2] and Harvinder S. Luthra[1]. [1]Mayo Clinic, Rochester, MN, [2]Mayo Clinic

Purpose: 1) To compare outcomes by treatment type, and 2) to determine baseline variables associated with treatment response, in 151 patients with retroperitoneal fibrosis (RF) followed at a single tertiary-care center.

Methods: In this retrospective study, incident cases of RF diagnosed between 1/1/1996 and 12/31/2006 were included. RF was defined by compatible imaging findings. Medical records were reviewed and treatment and outcomes were abstracted.

We defined 4 response types: partial response (stabilization/improvement in imaging findings on stable medical regimen for 1 year), complete response (stabilization/improvement in imaging findings on a stable medical regimen with discontinuation of prednisone for 1 year), remission (stabilization/improvement in imaging findings off all therapy for 1 year), and relapse (worsening imaging findings 1 year after an initial response). Patients were followed until last contact, death or December 31, 2009. Kaplan-Meier methods were used to compare outcomes by treatment group. Cox proportional hazard models were used to evaluate the association between baseline variables and treatment response.

Results: We identified 185 patients with RF, mean age at diagnosis 57.6 (±11.8) years. Follow-up was available in 151 patients which included 87 men (58%) and 64 women (42%); median length of follow-up 4.0 years (total 671 person-years).

Forty-seven patients (31%) were treated with medications only (Group 1), 67 patients (44%) received medications and ureteral stenting (Group 2) and 20 patients (13%) were treated with medications and ureterolysis (Group 3). Commonly prescribed medications were prednisone (96 patients), tamoxifen (107 patients) and methotrexate (46 patients). Five patients (3%) who received no treatment and 12 patients (8%) treated only with stenting or ureterolysis were not analyzed due to small numbers.

At baseline, all 3 treatment groups were similar in age at diagnosis, ethnicity, sex, smoking status, anemia, ESR and CRP ($p>0.05$). However, baseline creatinine (Cr) was elevated in 2 patients (4.4%) in Group 1 compared to 39 patients (62%) in Group 2 and 11 patients (55%) in Group 3 ($p<0.001$). Also, more patients in Groups 2 and 3 had hydronephrosis compared to Group 1 ($p<0.001$).

Kaplan-Meier curves for the 3 groups were similar for all response types ($p>0.05$). At 2 years from diagnosis, 59% of all patients achieved at least partial response. Relapses occurred in 18 patients. There were no differences in relapse rates by treatment group ($p=0.198$). Age at diagnosis, ethnicity, sex, smoking status, anemia, ESR, CRP, elevated Cr, or hydronephrosis did not predict any response type.

Conclusions: This is the largest series to systematically evaluate treatment outcomes and predictors of response in RF. We defined 4 response types. While patients with baseline renal insufficiency or hydronephrosis were more likely to undergo a urologic procedure, the outcomes for all treatment groups analyzed were similar. No baseline variables were associated any response type. Our findings suggest that regardless of baseline Cr, with close follow-up and appropriate treatment (medical and surgical), the overall outcomes were good.

Disclosure: T. A. Kermani: None; **C. S. Crowson:** None; **S. Achenbach:** None; **H. S. Luthra:** None.

Osteoarthritis - Clinical Aspects: Genetics, Novel approaches, and Therapy

Monday, November 8, 2010, 4:30 PM–6:00 PM

706

Clinical Trial of Vitamin D To Reduce Pain and Structural Progression of Knee Osteoarthritis (OA). Timothy E. McAlindon[3], Bess Dawson-Hughes[5], Jeffrey Driban[4], Michael LaValley[2], Ji Yeon Lee[4], Grace H. Lo[1], Melynn Nuite[4] and Lori Lyn Price[4]. [1]Baylor College of Medicine, [2]Boston University School of Public Health, [3]Tufts Medical Center, Boston, MA, [4]Tufts Medical Center, [5]USDA HNRC; Tufts University

Background: Observational epidemiologic studies suggest that vitamin D may reduce the structural progression of knee OA, an effect that could be mediated through bone or chondrocyte mechanisms. The aim of this study was to test for disease-modifying effects of a vitamin D intervention strategy for knee OA.

Methods: This was a 2-year, NIH-funded, double–blind, placebo-controlled clinical trial among individuals with symptomatic knee OA (ACR criteria). Randomization was blocked and stratified by disease severity (Kellgren Lawrence (KL) grade). The intervention consisted of vitamin D3 2000 IU daily (Tishcon Corp, NY), which was escalated in increments of 2000 IU as needed at 3,6, and 9 months, for a target serum vitamin D level of >30 ng/ml. Blinding was maintained by the use of a dummy escalation protocol in the placebo group. Assessments included the WOMAC questionnaire at each visit, physical function tests; annual MRI (Siemens Avanto 1.5T; sagittal and coronal IW FS and DESS sequences); and standardized semi-flexed knee radiography at the beginning and end of study. Cartilage volume and thickness, and bone marrow lesion (BML) volume, in the index tibial and femoral compartments, were determined by manual segmentation of registered images using Analyze©. Intra-tester reliability ICCs were .96 & .90 for cartilage volume and volume loss, and.87-.98 for BML volume. Minimal radiographic joint space width was measured using a semi-automated computer program. Primary outcomes were WOMAC pain and cartilage volume loss. To test for differences we used mixed effects regression for repeated measures with linear, or linear and quadratic time trends, with adjustment for KL grade, knee alignment, and body mass index (BMI).

Results: Out of 282 screened, 146 subjects were randomized (mean age 62.4 [s.d. 8.5]; 57% female; 79% Caucasian; mean BMI 30.7 kgm-2 [5.7]; 56% taking supplements; mean vitamin D level 22.3 ngml-1 [10.0]; femoral neck BMD 0.95 gcm-2 [0.14]). 50% had KL grade 2, 29% grade 3 and 21% grade 4. The groups were evenly balanced for these characteristics and outcome measures (Table). 124 (85%) completed the study. Mean serum vit D level increased by 15.0 ng/ml in vitamin D compared to 1.8 in the placebo group ($p<0.0001$). There were no substantial or significant between-group

differences in any the outcome measures (Table). In the repeated measures analyses, neither treatment assignment nor increase in serum vitamin D level had any influence on the outcomes. There were 28 serious adverse events in the vitamin D and 23 in the placebo group, all classified as unrelated except one 'possibly related' (hip fracture).

	Vitamin D Group		Placebo Group	
	Baseline	Δ*	Baseline	Δ*
WOMAC Pain	6.86 (3.78)	−2.14 (3.79)	5.81 (3.41)	−1.20 (4.00)
Chair Stand Time (s)	19.8 (7.2)	−1.06 (5.56)	18.6 (5.8)	−1.30 (6.67)
Tibia				
cartilage volume (mm^3)	1010 (437)	−39.2 (36.5)	1148 (473)	−42.5 (32.5)
cartilage thickness (mm)	1.17 (0.39)	−0.06 (0.06)	1.21 (0.36)	−0.05 (0.04)
BML volume (cm^3)	15.8 (28.0)	0.17 (14.5)	13.6 (19.4)	−1.71 (18.2)
Femur				
cartilage volume	4212 (1349)	−167 (118)	4740 (1273)	−182 (131)
cartilage thickness	1.77 (0.36)	−0.06 (0.04)	1.84 (0.30)	−0.06 (0.05)
BML volume	8.5 (15.0)	0.34 (14.37)	9.4 (14.2)	−3.52 (9.88)
Minimum JSW (mm)	3.25 (1.64)	−0.20 (0.73)	3.39 (1.67)	−0.16 (0.72)

All between-group p-values >0.05.

Conclusions: Vitamin D supplementation at a dose sufficient to elevate serum levels above 30 ng/ml does not appear to have any symptom or structure-modifying benefits for knee OA.

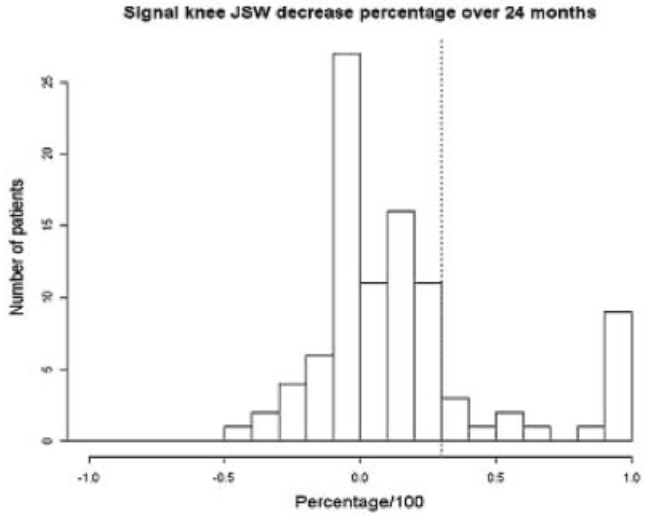
Interleukin-1 Receptor Antagonist (IL-1RN) Gene Variations Predict the Severity and Progression of Knee Osteoarthritis. Mukundan Attur[8], Cheongun Oh[7], Svetlana Krasnokutsky[6], Jonathan Samuels[5], Leon Rybak[9], Jenny Bencardino[9], Jeffrey D. Greenberg[1], Virginia Kraus[2], Kenneth Kornman[4] and Steven B. Abramson[3]. [1]Millburn, NJ, [2]Duke University Medical Center, Durham, NC, [3]Hospital for Joint Dis/NYU, New York, NY, [4]Interleukin Genetics, [5]New York University Hospital for Joint Disease, New York, NY, [6]NYU Hospital for Joint Disease, New York, NY, [7]NYU-Hospital for Joint Diseases, [8]NYU-Hospital for Joint Diseases, New York, NY, [9]NYU-Hospital for Joint Diseases Radiology Dept.

Purpose: We have previously shown that carriage of an IL1RN haplotype (CTA) was associated with substantially lower odds of radiographic severity (KL score, joint space width [JSW]) (Ann Rheum Dis. 2010). In this 24 month prospective study we assessed whether IL1-RN haplotypes predicted disease progression in patients with symptomatic knee OA.

Methods: Ninety-seven (N=97) patients from NYUHJD who met ACR criteria for symptomatic knee OA were genotyped for single nucleotide polymorphisms (SNPs) in the IL-1b and IL-1RN genes. Standardized fixed-flexion radiographs were taken on all patients at baseline and 24 months. Radiographic progression of signal (more painful) knee OA was determined by change in JSW over 24 months. To account for variations in baseline JSW, we defined progression as greater than 30% joint space narrowing (JSN) of the diseased compartment over 24 months, rather than in change in absolute JSW in millimeters.

Results: Decreases in JSW ranged from zero to 3.7 mm over the 24 months; 19 of 97 patients exhibited > 30% JSN.



Patients with the IL-1RN (rs419598/rs315952/9005) TTG haplotype exhibited increased radiographic knee OA severity at baseline compared to those without TTG ($p<0.08$). These TTG patients exhibited increased risk for radiographic progression at 24 months that approached significance based on ≥30% JSN [OR = 2.85; 95%CI=0.68–11.67; $p<0.15$]. In contrast, OA patients with IL-1RN CTA haplotype showed decreased risk for JSN over 24 months in the signal knee [OR= 0.33; 95%CI=0.170–1.014; $p<0.05$]. Differences in reported VAS pain between the CTA and TTG group were significant at 24 months ($p< 0.01$), indicating that while these patients were not distinguishable by radiograph or symptoms at onset, IL1RN haplotype predicted symptomatic differences at two years. Finally, the TTG haplotype group of patients expressed relatively increased IL-1b gene expression [15.683 ± 9.407 ($p<0.0001$)] as assessed by TaqMan QPCR in peripheral blood leukocytes. The TTG patients also exhibited decreased sIL-1Ra [283.64 ± 36.4 pg/ml ($p<0.001$) in plasma samples compared to IL-1RN CTA haplotype protective groups [IL-1b (fold change), 5.444 ± 10.083; sIL-1Ra, 370.35 ± 43.3pg/ml] of patients respectively.

Conclusion: IL-1RN gene family polymorphisms, which appear to affect host production of IL-1Ra, merit evaluation as biomarkers that predict the risk of progression in patients with symptomatic knee OA.

Hand Osteoarthritis (OA) a Predictor of Accelerated Progression in Knee OA? Jonathan Samuels[3], Catherine Petchprapa[6], Elizabeth L. Carpenter[6], Svetlana Krasnokutsky[4], Mukundan Attur[2], Leon Rybak[5], Jenny Bencardino[5], Cheongeun Oh[6] and Steven B. Abramson[1]. [1]Hospital for Joint Dis/NYU, New York, NY, [2]Hospital for Joint Dis/NYU Langone Medical Center, [3]New York University Hospital for Joint Disease, New York, NY, [4]NYU Hospital for Joint Disease, New York, NY, [5]NYU Hospital for Joint Diseases, [6]NYU Langone Medical Center

Purpose: There is insufficient understanding regarding how generalized OA involving the hand and knee differs from isolated knee OA, which may result from other factors such as obesity or trauma. The purpose of these studies is to determine whether the presence of hand OA involving interphalangeal (IP) and first carpometacarpal (CMC) joints, alone or in combination, predicts progression of patients with symptomatic knee OA.

Methods: Hand radiographs were obtained on 94 patients at NYUHJD who met ACR criteria for symptomatic knee OA, and who were enrolled in a two-year NIH-sponsored prospective study. The patients completed standardized fixed-flexion knee radiographs at baseline and 24 months, with progression the signal (more painful) knee OA determined by change in joint space width (JSW) and KL score. For these analyses, the patients were separated into two groups by results on their signal knee: 17 progressors, defined by at least 30% decreased JSW over 24 months, and 77 non-progressors. For each set of hand x-rays, 2 radiologists evaluated 18 IP joints and 2 CMC joints for joint space narrowing and/or osteophytes, and whether or not there was erosive change at the IP joints; we averaged the scores from the two readers.

Results: Kappa scores between the two scoring radiologists for the IP and CMC joints, and for the presence of erosive IP disease, were 0.79, 0.87 and 0.96, respectively. The overall mean IP score was 5.6 and 1st CMC score was 0.9, while medians were 5 and 1.0, respectively. The 17 progressors had a higher average IP (but not CMC) score than the non-progressors, 7.2± 5.4 vs. 5.0±4.6, p=0.13. Since the IP scores were not normally distributed, we further analyzed data by dichotomizing the study populations into two groups using the median IP total (5) as the cutoff point. When so analyzed, the presence of "hand OA" increased the odds ratio of knee OA progression to 2.8 (p=0.096). Of interest, the severity of knee OA correlated with hand OA scores: the average total hand OA scores (out of 20 joints) increased with baseline KL score, with mean scores of 3.8±5.5, 6.1±6.1 and 7.2±5.6 for KL 1 to 3 (p=0.06). There is also an increasing trend of total hand OA joint scores by KL score (p=0.042) when dichotomized around the median (5 joints), and with IP scores alone (p=0.026). The 8 patients with radiographic evidence of erosive IP disease, as compared with the 31 non-erosive IP OA patients (>5 IP joints) and the 54 without IP OA, demonstrated faster knee OA progression over 2 years by average KL increases (1.00, 0.35, 0.30) and decreases in joint space width (0.65, 0.56, 0.36), although perhaps given small numbers, this was not statistically significant (p=0.839).

Conclusions: In cross-sectional analysis, the quantitative "burden" of hand OA correlates with the radiographic severity of knee OA (KL).

Moreover, radiographic hand OA at the IP joints, but not at the 1st CMC joint, predicts more rapid progression of knee OA. Erosive IP disease may be an even stronger predictor than non-erosive IP disease of accelerated progression of knee OA.

Funding: This study is funded by NIAMS (R01- AR052873).

Bone Marrow Lesions (BMLs) Are Strongly Associated with Increased Bone Volume Fraction; "Virtual Bone Biopsy" Using MRI. Anna M. Tassinari[3], Grace H. Lo[1], Jeffrey Driban[3], Lori Lyn Price[3], Erika Schneider[2] and Timothy E. McAlindon[3]. [1]Baylor College of Medicine, Houston, TX, [2]The Cleveland Clinic, Cleveland, OH, [3]Tufts Medical Center, Boston, MA

Introduction: BMLs are a common MRI feature of knee osteoarthritis (KOA) that associate with symptoms and predict structural progression. In a recent study, we have observed that worse radiographic KOA is associated with higher periarticular bone volume fraction (aBVF).

While BMLs are probably associated with trabecular damage, their pathological basis remains poorly understood and has not been evaluated in-vivo. Our aim was to evaluate trabecular structure changes within KOA BMLs using MR trabecular morphometry.

Methods: The sample comprised 158 participants in the Osteoarthritis Initiative (OAI) who had 3T MRIs (Trio, Siemens) that included coronal 3D FISP trabecular sequences for morphometry and sagittal intermediate-weighted TSE, fat-suppressed images for BML scoring.

We used a trabecular morphometry program with a modified algorithm (*calcDCN, UCSF*) to evaluate aBVF and explore additional trabecular features, such as number, spacing and thickness. The four measures were calculated for 20 consecutive central slices, within a 15 mm × 3.75 mm ROI placed periarticular in the medial tibia, and then averaged. Intra-rater reproducibility was high (*ICC* = 0.99). We validated the modified *calcDCN* algorithm for aBVF against aBVF values from images segmented manually in Analyze® (*ICC* = 0.99).

We defined BMLs as areas of increased signal intensity visible on ≥ 2 consecutive sagittal slices, and situated adjacent to the articular cartilage. Based on estimated volume of the BML within the medial tibia, we classified knees as having *none*, *small* or *large* BMLs.

We performed Analyses of Variance (ANOVA) to evaluate whether mean aBVF, trabecular number, spacing or thickness differed by BML score. We also assessed their associations using linear regression, adjusting for age, gender, ethnicity, body mass index (BMI) and hip bone mineral density (BMD).

Results: One hundred fifty eight subjects were included; 52% were female; 13.3% were Black, 3.2% Hispanic; mean age was 69.0 ± 8.9 yrs, BMI = 29.22 ± 5.0 kg/m2, hip BMD = 0.944 ± 0.16 gm/cm2; 79% with no BMLs, 15% with small BML and 6% with large BML.

BMLs were significantly associated with higher aBVF, trabecular number and thickness and lower trabecular spacing (Table). After adjusting for confounders, BML score remained significantly and independently associated with all four measures.

Table. Trabecular bone changes in BMLs

BML score	Mean aBVF ± SD	Mean Trabecular Number ± SD (mm^{-1})	Mean Trabecular Spacing ± SD (mm)	Mean Trabecular Thickness ± SD (mm)
none (n = 124)	0.122 ± 0.077	0.87 ± 0.39	1.51 ± 1.3	0.131 ± 0.023
small (n = 24)	0.183 ± 0.095	1.13 ± 0.39	0.93 ± 0.57	0.152 ± 0.028
large (n = 10)	0.221 ± 0.094	1.35 ± 0.33	0.73 ± 0.31	0.163 ± 0.032
Overall (n = 158)	0.138 ± 0.09	0.94 ± 0.4	1.37 ± 1.2	0.14 ± 0.03
Overall model p-value	**p < 0.0001**	**p < 0.0001**	**p = 0.02**	**p < 0.0001**

Conclusion: Bone volume appears increased in BMLs. The exploratory trabecular measures suggest that as BMLs are associated with higher trabecular number and thickness, but lower separation. These findings could represent locally increased bone turnover or compression and suggest that treatments targeting bone that could influence these pathologies should be explored.

REGN475/SAR164877, a Nerve Growth Factor Inhibitor, in Osteoarthritis Patients with Moderate to Severe Knee Pain: Results of a Phase 2, Randomized, Double-Blind, Placebo-Controlled Study. Paul Tiseo[4], Alan J. Kivitz[1], John E. Ervin[2], Scott J. Mellis[3], Haobo Ren[4], Damir Skific[4], Richard Wu[4] and Peter Powchik[4]. [1]Altoona Arthritis & Osteo Ctr, Duncansville, PA, [2]Center for Pharmaceutical Res, Kansas City, MO, [3]Regeneron Pharmaceuticals, Inc., Tarrytown, NY, [4]Regeneron Pharmaceuticals, Inc.

Purpose: To evaluate the safety and efficacy of REGN475/SAR164877 (R/S), a fully human monoclonal antibody with highly selective binding affinity for nerve growth factor (NGF), in the treatment of osteoarthritis (OA) pain.

Methods: This phase 2, double-blind, placebo-controlled, parallel-group, repeat-dose study enrolled patients aged 40–75 y with physician-confirmed diagnosis of active, moderate to severe OA (ACR criteria + subjective pain + Kellgren-Lawrence G2-G3 radiographic severity). Other eligibility requirements included walking knee pain (WKP) levels ≥ 4 at baseline [11-pt numerical rating scale (NRS)] and washout of any current pain medications prior to baseline visit (Day 1). Rescue medication with acetaminophen (up to 4g per day; no more than 4 consecutive days) was permitted. Patients (N=217) were randomized to receive intravenous (IV) R/S 0.03, 0.1, or 0.3 mg/kg or IV placebo (Pbo) on Day 1 and Day 57, with a 16-wk follow-up period after the second dose. Safety/tolerability [frequency of treatment emergent adverse events (TEAEs)] was the primary endpoint. Key efficacy variables included change from baseline on WKP and Western Ontario and McMaster Osteoarthritis (WOMAC) Index.

Results: Baseline characteristics were similar among treatment groups: mean (SD) age 59.3±8.7 yrs; 31.2% male; and 78.1% white. After 24 weeks, the incidence of TEAEs ranged from 66.1–75.0% in the R/S groups vs 63.6% for placebo. The most common TEAEs included headache (R/S range 7.1–7.7% vs Pbo 7.3%), hypoaesthesia (3.8–7.7% vs 0%), musculoskeletal pain (3.6–19.2% vs 5.5%), paraesthesia (0–5.8% vs 5.5%), peripheral edema/joint swelling (3.6–9.6% vs 0–1.8%), and respiratory infections (1.9–8.9% vs 1.8–7.3%). 5.6% of R/S patients and 3.7% of Pbo patients withdrew due to TEAEs; serious TEAEs were infrequent and the incidence was similar between active treatment groups and Pbo. Evidence of treatment effect was reported in the individual R/S dosing groups vs Pbo; results of the key efficacy evaluations are summarized in the table below. At Week 16, a consistent dose-response relationship was demonstrated in the WOMAC pain and function subscales.

Treatment Differences from Baseline at Weeks 8 and 16

Key Efficacy Variables	Placebo (n = 55)	REGN475/SAR164877 0.03 mg/kg (n = 53)	0.1 mg/kg (n = 53)	0.3 mg/kg (n = 54)
Walking Knee Pain (NRS)				
Mean Change (SD) from Baseline at Wk 8	−2.01 (2.08)	−2.8 (2.29)	−3.3 (2.61)*	−3.6 (2.48)*
Mean Change (SD) from Baseline at Wk 16	−2.5 (2.15)	−3.4 (2.24)*	−3.4 (2.58)*	−3.3 (2.55)
WOMAC Pain Score				
Mean Change (SD) from Baseline at Wk 8	−1.9 (1.74)	−2.6 (2.01)*	−3.4 (2.54)*	−3.5 (2.42)
Mean Change (SD) from Baseline at Wk 16	−2.4 (2.18)	−2.7 (1.89)	−3.4 (2.53)*	−3.2 (2.24)*
WOMAC Function Score				
Mean Change (SD) from Baseline at Wk 8	−1.8 (1.95)	−2.8 (2.07)*	−3.4 (2.32)*	−3.4 (2.57)
Mean Change (SD) from Baseline at Wk 16	−2.3 (2.30)	−2.9 (1.78)	−3.4 (2.28)*	−3.1 (2.18)*

* P ≤ 0.05 (difference vs Pbo).

Conclusions: REGN475/SAR164877 was generally well-tolerated; incidence and type of TEAEs were similar to those previously reported with NGF inhibition. Preliminary data suggest that neurosensory TEAEs were more frequent at higher doses. Efficacy assessments indicate that anti-NGF therapy may be associated with a significant reduction in OA knee pain for up to 8 weeks, with dropouts at the highest dose possibly accounting for the reduced efficacy at 16 weeks.

Novel Biomarkers of Knee Osteoarthritis Identified Using a Non-Targeted Metabolomic Approach. Guangju Zhai, Karsten Suhre, Deborah Hart, Christian Gieger, Nicole Soranzo and Tim D. Spector. King's College London, London, United Kingdom

Objectives: There is a pressing need to develop reliable molecular biomarkers that can inform on the process of joint destruction in osteoarthritis (OA). Such biomarkers could aid in drug development by identifying fast progressors and early response to therapy. Recent advance in metabolomics (the quantitative analysis of all metabolites present within a biological sample) has opened new avenues for biomarker identification. Using targeted metabolomic profiling approach, we have identified that serum branched chain amino acid to histidine ratio is associated with knee OA (Zhai G, et al Ann Rheum Dis 2010). To identify additional novel metabolic biomarkers for OA, we carried out this study using a non-targeted metabolomics approach.

Methods and Subjects: An available fasting serum sample derived from the TwinsUK cohort was utilized. 1052 Caucasian females were profiled metabolomically using non-targeted approach with LC-MS/MS. Among them, 891 individuals with mean age of 58±10.7 years had knee OA data available. 158 were knee OA cases defined as either having total knee joint replacement due to primary OA (n=22), radiographic knee OA if Kellgren-Lawrence score >=2 (n=72), or self-reported clinical diagnosed knee OA (n=64). 733 were controls with none of these three case definitions. We examined the association between knee OA and the serum metabolomic profile using robust linear regression. Their abundance in each individual's serum sample was measured by the area counts under the MS spectral peak. The area counts were then transformed by natural logarithm to approximate the normal distribution and used in the subsequent analysis after correcting for multiple testing with Bonferroni method.

Results: A total of 275 serum metabolites were identified. We examined the association between each of the 275 serum metabolites and knee OA with adjustment for age, and identified four metabolites associated with knee OA ($p < 0.00018$). γ-glutmyl valine was increased in knee OA patients ($\beta=0.42$ SD, $p=0.00017$), which is a confirmation of our previous findings. In addition, we found that α-tocopherol and bilirubin were negatively associated with knee OA ($\beta=-0.47$ SD, $p=0.00004$, and $\beta=-0.43$ SD, $p=0.0001$, respectively), and hyodeoxycholate was positively associated with knee OA ($\beta=0.46$ SD, $p=0.0001$).

Conclusion: This novel study using high-throughput metabolomics confirms our previous findings of valine as a marker of OA and identified an additional three novel serum metabolic biomarkers for knee OA, which could have potential clinical utility.

Rheumatoid Arthritis - Animal Models: Insight in Pathogenesis and Novel Therapeutic Targets

Monday, November 8, 2010, 4:30 PM–6:00 PM

712

Anti-CD20 Therapy Inhibits the Progression of Synovitis and Focal Erosion in the Knee Joints but Not in the Ankle Joints of TNF-Tg Mice. Jie Li, Igor Kuzin, Christopher Ritchlin, Ignacio Sanz, Andrea Bottaro, Lianping Xing and Edward Schwarz. University of Rochester, Rochester, NY

Purpose: B cell depletion therapy (BCDT) is effective for some RA patients. However, its mechanism of action and variable efficacy remains an enigma. Previously we utilized contrast enhanced (CE) MRI, micro-CT and near infrared-indocyanine green (NIR-ICG) lymphatic imaging to evaluate arthritis in TNF-Tg mice, and demonstrated that disease commences in the ankle, which is consistent with reports defining tenosynovitis in the foot as the initiating pathology. We also found that arthritic progression occurs following a sudden decrease in lymphatic flow from the lower limb to the popliteal lymph node (PLN). This decrease leads to a "collapsed" phenotype characterized by the translocation of CD23+/CD21hi B cells from the follicles into the sinus space, resulting in "clogging" lymphatic flow of the PLN. Thus, we hypothesize that BCDT ameliorates TNF-induced arthritis by increasing lymphatic flow through the depletion of these B cells, and tested this in our murine model.

Methods: TNF-Tg mice with collapsed PLNs and ankle synovitis were identified by CE-MRI and followed with scans every two weeks. NIR-ICG footpad clearance (T-clearance) and micro-CT scans were performed before and after treatment with anti-CD20 (n=8; 16 knees) (10mg/kg/i.v. every two weeks) or placebo (n=4; 4 knees) for 6 weeks. PLNs were harvested for flow cytometry or immunohistochemistry (IHC). Ankle and knee joints were harvested for H&E and TRAP stained histology.

Results: 1) Anti-CD20 significantly decreased knee synovial volume ($SynVol=4.55+/-2.39mm^3$, $p=0.002$) and synovitis progression ($p=0003$) vs. placebo ($SynVol=8.98+/-4.16mm^3$), and PLN B cells (80–95% depletion). 2) Anti-CD20 significantly increased T-clearance from 82.3+/−0.16% to 90.4+/−0.08% ($p=0.02$). 3) Anti-CD20 protected the knee from focal erosions, as there was no significant change in patellar bone volume ($p=0.1$). However, it failed to prevent bone erosion in the ankle joint, as the talus volume dramatically decreased from $0.64+/-0.32mm^3$ to $0.30+/-0.27mm^3$ ($p=2\times10^{-6}$) during the 6-week treatment.

Conclusion: Our results show BCDT effectively inhibits progression of arthritis in knee, but not in the ankle, suggesting distinct etiologies for large and small joint pathogenesis. The lack of efficacy observed in the foot is consistent with unabated tenosynovitis in which B cells play little if any role, as evidenced by arthritis in the ankles of TNF-TgxRAG1−/− mice. In contrast, the absence of tendon insertions proximal to synovium in large joints precludes tenosynovitis as a mechanism of inflammatory-erosive arthritis in the knee. Our observations that draining lymph function and the location of B cells in PLNs correlates with disease in the adjacent knee of TNF-Tg mice is consistent with a novel mechanism of action for BCDT in which removal of the B cells that are "clogging" the lymphatic vessels restores draining function to ameliorate synovitis. Our current clinical pilot to test this hypothesis in anti-TNF refractory RA patients receiving BCDT will be discussed.

Identifying the TLR4 Bearing Target Cell in Experimental Arthritis. Ben T. van den Brand, Shahla Abdollahi-Roodsaz, Miranda B. Bennink, Onno J. Arntz, Wim B. van den Berg and Fons A. J. van de Loo. Radboud University Nijmegen Medical Centre

Purpose: The IL-1 receptor antagonist (IL-1Ra) knockout mice spontaneously develop T-cell driven arthritis due to excessive IL-1 signalling. Joint destruction is accompanied by increased Th17 cells and elevated IL-17 levels compared to wild type (Balb/c) mice. When cross bred with TLR4 knock out (TLR4−/−) these animals showed reduced inflammation, joint destruction, and diminished IL-17 levels. To reduce adverse effects of TLR4 inhibition a cell specific targeted therapy of arthritis is desired. Therefore, we set out to identify the TLR4 bearing cells in experimental arthritis responsible for increased IL-17 production and arthritis severity.

Method: A reciprocal sex-mismatched bone marrow transplantation was performed with TLR4−/− and TLR4+/+ mice in the IL-1Ra−/− background and Balb/c bone marrow as control. Y-chromosome staining of bone marrow was performed to assess engraftment. Clinical manifestation of disease was assessed macroscopically over time. Spleen and lymph node cells were isolated and subjected to T-helper subset analysis.

Results: Engraftment of bone marrow was near 100% successful as determined by Y-chromosome staining of the bone marrow, which indicates a successful reconstitution. Lack of TLR4 on either the engrafted bone marrow cells or the radio-resistant cells in the joint did not affect disease incidence. However, animals that lacked TLR4 on the engrafted bone marrow derived cells, radio-resistant cells, or both showed reduced macroscopic arthritis scores. In mesenteric lymph nodes there were no differences observed in percentage of IFNγ and IL-17 producing cells. Neither was there a difference in Th1 cells in the spleen. However, decreased Th17 levels were observed in the spleen when radio-resistant cells lack TLR4.

Conclusion: These data suggest that TLR4 plays a role on both the bone marrow derived and local resident cells in aggravating experimental arthritis. TLR4 plays a role locally on the synovial fibroblasts by creating a more aggressive inflammatory environment in the joint cavity and thereby increas-

ing joint destruction. Conversely, TLR4 activation on the bone marrow derived cells could increase T-cell activation by antigen presenting cells and thereby promoting a more aggressive Th17 phenotype and increase joint swelling.

Local Expression of IL-27 Reduces Collagen Induced Arthritis through Reduction of Monocyte Migration and Vascularization. Sarah R. Pickens[4], Michael V. Volin[1], Arthur M. Mandelin[2] and Shiva Shahrara[3]. [1]Midwestern University, [2]Northwester University, Chicago, IL, [3]Northwestern Univ Feinberg, Chicago, IL, [4]Northwestern University

Introduction: To determine the effect and potential mechanism of IL-27 treatment in rheumatoid arthritis (RA), local expression of IL-27 was studied in ankle joints of collagen induced arthritis (CIA) mice compared to control animals.

Methods: Adenovirus containing IL-27 transcript (Ad-IL-27) was constructed and was locally delivered into the ankles of CIA mice. Clinical parameters were assessed histologically and by measuring ankle circumference. IL-17 and its downstream targets, as well as cytokines promoting TH-17 cell differentiation, were quantified by ELISA from CIA tissue homogenates locally expressing IL-27 or Ad-control. Ankles from both treatment groups were immunostained for neutrophil and monocyte abundance and vascularization was determined by quantifying ankle hemoglobin levels and PECAM expression by real-time RT-PCR.

Results: The joint circumference of Ad-IL-27 injected animals was significantly smaller than control animals throughout the study. Histological analysis of ankles from day 41 confirmed that local expression of IL-27 resulted in significantly less inflammation compared to the control group. Further histological studies demonstrated that local expression of IL-27 resulted in a significant decrease ($p<0.05$) of synovial lining thickness and bone erosion. Next, we found that the cytokines which induce TH-17 cell differentiation (IL-1β and IL-6) and the downstream targets of IL-17 (CXCL1, CXCL5 and CCL2) were significantly decreased in ankle homogenates by local expression of IL-27 compared to control treatment. CIA ankles immunostained for neutrophils and monocytes showed that the local expression of IL-27 greatly decreased the infiltration of these cells into the ankle joints compared to control group. In order to quantify the vascularization changes in the Ad-IL-27 group, ankle hemoglobin and PECAM levels were quantified and compared to control group. Ad-IL-27 treated CIA ankle joints had significantly reduced hemoglobin and PECAM levels compared to control joints.

Conclusion: Our results suggest that increased IL-27 levels relieved arthritis in CIA ankles. This amelioration of arthritis involved a reduction of IL-27-induced TH-17 cell differentiation and resulted in decreased IL-17-mediated monocyte recruitment and angiogenesis. Hence, IL-27 may be a therapeutic target in RA.

Impaired B Cell Immunity in IL-22 Knock-Out Mice in Collagen Induced Arthritis. Odilia Corneth[1], Anne-Marie Mus[2], Patrick Asmawidjaja[2], Laurens Kil[2], Wenjun Ouyang[3], Rudi Hendriks[2] and Erik Lubberts[2]. [1]Erasmus MC, University Medical Center, Rotterdam, ZH, The Netherlands, [2]Erasmus MC, University Medical Center, [3]Genentech

Background: The role of IL-22, a cytokine produced by Th17 cells, in autoimmunity is not fully understood. Previous research has shown that IL-22 is important in the development of collagen induced arthritis (CIA). However, the mechanism behind the apparent protection in IL-22 knock-out mice against CIA remains unclear.

Objective: To investigate the mechanisms by which IL-22 knock-out mice are protected against collagen induced arthritis.

Materials and Methods: For CIA, IL-22 knock-out and wild type mice were immunized with chicken collagen type II (CII) and complete Freud's adjuvant (CFA) and boosted 21 days later. Antigen specific serum IgG levels were measured by ELISA. Mice were sacrificed 50 days after immunization. Splenocytes were analyzed by flow cytometry and immunohistochemistry (IHC). Functional assays were performed with splenic Th17 cells sorted from mice ten days after immunization. For antigen induced arthritis (AIA), mice were immunized with methylated bovine serum albumin (mBSA) and CFA and triggered seven days later by intra-articular mBSA injection.

Results: In IL-22 knock-out mice, the severity of CIA was lower compared to wild type controls. No significant difference in disease incidence was observed between wild type and IL-22 knock-out mice. This prompted us to study the pathogenicity of Th17 cells from these mice. Synovial fibroblasts produced higher levels of IL-6 when co-cultured with Th17 cells from IL-22 knock-out mice compared to wild type Th17 cells. To study the pathogenicity of these cells in vivo, we made use of the Th17 mediated AIA model. IL-22 knock-out mice developed AIA similarly to wild type controls, showing that Th17 cells function normally in vivo. As CIA is strongly driven by B cells and immune complexes, we investigated whether B cell immunity is normal in IL-22 knock-out mice. Antigen specific serum IgG2a levels were significantly lower in IL-22 knock-out mice at early onset of disease. Flow cytometric analysis of splenic B cells showed no significant differences in B cell numbers or activation. However, IHC slides of spleens from IL-22 knock-out mice show no or very small germinal centers and fewer IgG2a plasma cells compared to wild type controls.

Discussion: Here we show that lack of IL-22 production affects B cell immunity in CIA. We show that Th17 cells in IL-22 knock-out mice function normally in vitro in a functional assay and in vivo in antigen induced arthritis (AIA). This indicates that the lack of IL-22 production does not affect the pathogenicity of Th17 cells. However, germinal center formation, plasma cell formation and IgG2a antibody production are lower in IL-22 knock-out mice in CIA, suggesting that IL-22 has a role in further differentiation of B cells in autoimmunity.

Repair of Bone Erosions in Inflammatory Arthritis Occurs as Inflammation Resolves, Accompanied by Alterations in the Wnt Signaling Pathway. M. M. Matzelle[4], M. A. Gallant[3], K. W. Condon[2], N. C. Walsh[5], C. A. Manning[1], J. B. Lian[1], D. B. Burr[2] and Ellen M. Gravallese[1]. [1]Worcester, MA, [2]Indianapolis, IN, [3]Department of Anatomy and Cell Biology, Indiana University School of Medicine, Indianapolis, IN, [4]Department of Medicine and Department of Cell Biology, University of Massachusetts Medical School, Worcester, MA, [5]St. Vincent's Institute, Fitzroy, VIC, Australia

Background: Rheumatoid arthritis (RA) is characterized by chronic synovial inflammation and invasive pannus that drives osteoclast-mediated articular bone erosion. While effective therapies can slow the progression of bone erosion, repair occurs in only a small percentage of RA patients and generally correlates with control of disease.

Methods: To examine the potential for erosion repair and mechanisms driving this process, inflammatory arthritis was induced by transfer of arthritogenic K/BxN serum to 12-week old C57BL/6J mice and arthritis was subsequently allowed to resolve. Clinical inflammation peaked at day 10 after initial serum injection and full resolution of clinical inflammation occurred between days 28 and 38. Forefoot bones of the hind paws were evaluated by histology, microCT, and histomorphometry, and quantitative RT-PCR (qPCR) was performed on synovial tissue.

Results: qPCR of synovial tissue confirmed resolution of inflammation, with a 20-fold induction of IL-1β mRNA, 1.5-fold induction of TNF, and 40-fold induction of MMP-13 at day 10, all of which returned to non-arthritic levels by day 28. RANKL/OPG mRNA ratios in synovium also correlated with inflammation, favoring osteoclast-mediated resorption at day 10 and protection from resorption beginning as early as day 15. Serial microCT and histologic analysis of the forefoot bones were consistent with repair of previously established erosions. To quantify bone formation occurring with the resolution of inflammation, dynamic histomorphometric analyses of fluorochrome incorporation at sites of erosion were performed on days 10, 28, 38, 48 and 58. Inflammation at the bone interface (day 10) was accompanied by a low bone formation rate (BFR), similar to rates in non-arthritic mice, as we previously reported. In this study, we found that resolution of inflammation from days 28 to 48 was accompanied by a significant increase in BFR and mineral apposition rate (MAR) in arthritic compared to non-arthritic mice, contributing to repair at sites of erosion. Reduction of inflammation was accompanied by striking changes in the expression of modulators of the Wnt/β-catenin pathway, a pathway responsible for bone formation. qPCR revealed that inflammation induced expression of the Wnt antagonist sFRP1,

whereas resolution of inflammation reversed this induction. Correlating with the increase in osteoblast-mediated bone formation, we found an increase in the expression of Wnt10b and the Wnt antagonist DKK2, which are both required for bone matrix synthesis and mineralization. In addition, inflammation induced expression of Wnt7b, which has been shown to exhibit a negative relationship with DKK2 (Li et al., Nature Genetics, 2005; 37: 945).

Conclusions: Resolution of inflammation promotes osteoblast-mediated repair of articular bone erosions in this murine RA model. These data provide further rationale for aggressive treatment of inflammation in RA, which not only inhibits bone erosion, but may also promote bone formation and repair of existing bone erosions. Finally, these data demonstrate that there is a complex relationship between inflammation and regulation of components of the Wnt signaling pathway.

SB1578, a Novel Selective JAK2 Inhibitor, Is Highly Efficacious in Rodent Models of Rheumatoid Arthritis. Kee Chuan Goh, Stefan Hart, Yung Kiang Loh, Yong Cheng Tan, Chithra Amalini, Ramesh Jayaraman, Kantharaj Ethirajulu and Jeanette Wood. S*BIO Pte Ltd

Background: JAK2, a member of the Janus kinase family, is a key component in the signaling pathways elicited by pro-inflammatory cytokines such as interferon-g, interleukin-6, interleukin-12 and interleukin-23. These cytokines, in different sequence and combinations with other factors, initiate and/or sustain the T-helper cell subsets activated during autoimmune inflammatory diseases. The JAK2 kinase may therefore serve as a useful target for pharmacological intervention in some of these diseases, including rheumatoid arthritis (RA). We report here SB1578, a novel JAK2 inhibitor which demonstrates a unique kinase spectrum, activity on cellular biomarkers, favorable pharmacokinetic and *in vitro* safety profile, and promising activity in 2 rodent models of rheumatoid arthritis.

Methods: *In vitro* potency of SB1578 against a diverse panel of kinases was evaluated using recombinant enzymes with synthetic substrates. Potency on intracellular signaling pathways was assessed by Western blot analyses of the phosphorylated substrates in cell lysates. Viability assays were performed on tumor cell lines to investigate potential anti-proliferative activity. *In vivo* efficacy was tested in a rat model of adjuvant-induced arthritis and a mouse model of collagen-induced arthritis.

Results: SB1578 was shown to be a potent inhibitor of JAK2 (IC_{50} = 46 nM) as well as two other kinases reported to be implicated in human rheumatoid arthritis, namely FLT3 and CSF-1R (IC_{50} = 62 nM and 69 nM respectively). In a panel of 25 cell lines, SB1578 selectively inhibits proliferation in cell lines with a known dependence on JAK2 or FLT3 signaling, whether wild-type or mutated. These include MV4–11, Molm13, 32D, and BaF3 cells with transfected wild-type or mutant JAK2 (IC_{50} from 39 to 500 nM). Phosphoblot analysis in these cells showed that FLT3 or JAK2 signaling pathways are blocked in a dose-dependent manner. In a Lewis rat model of adjuvant-induced arthritis, administration of SB1578 (20 and 40 mg/kg BID, *i.p.*) led to dose-related reductions toward normal for histopathologic bone resorption, paw inflammation, ankle measurements, and splenic inflammation. In a B10RIII murine model of collagen-induced arthritis, oral administration of SB1578 (100, 200 and 300 mg/kg BID) led to dose-dependent reductions of clinical arthritis scores and hallmarks of mouse CIA model, including pannus formation and histological joint damage. The highest dose of 300 mg/kg BID led to zero disease incidence in terms of paw inflammation and histological parameters. Analyses of terminal serum samples showed that two cytokines, IL-6 and the chemokine KC, were significantly elevated in diseased compared with normal mice, and levels of these two cytokines were normalized by treatment with SB1578. Studies on primary PBMCs to illustrate the effects of SB1578 on Th1 and Th17 pathways will also be reported.

Conclusions: SB1578, a novel and selective JAK2 inhibitor, has demonstrated promising on-target activities in JAK2-dependent cell lines and is highly efficacious in two rodent models of rheumatoid arthritis. It is currently undergoing final preclinical development activities to prepare it for clinical studies.

Certolizumab Pegol Use in Pregnancy: Low Levels Detected in Cord Blood. Douglas Wolf[1] and Uma Mahadevan[2]. [1]Atlanta Gastroenterology Associates, Atlanta, GA, [2]UCSF Center for Colitis and Crohn's Disease, San Francisco, CA

Introduction: Infliximab is an IgG1 antibody against TNF alpha. Although its pregnancy classification is B, infliximab is detected in cord blood and newborns. Because IgG1 is actively transferred across the placenta during the third trimester, newborn serum infliximab levels are higher than maternal serum levels at birth.[1] Adalimumab is also an IgG1 antibody and is assumed to have similar transfer characteristics but commercial assays for measurement are not available. Certolizumab pegol (CZP), a Fab' fragment against TNF-alpha, has been shown to have low placental transfer levels in a rat model.[2] The transfer in humans is not known.

Methods: CZP levels were measured in women with IBD receiving therapy during pregnancy. Serum levels were measured by ELISA; 0.41 μg/ml is the lowest limit of detection. On the day of birth, levels were measured in the mother, the infant and in the cord blood.

Results: Ten mothers were enrolled. There were 2 sets of twins for a total of 12 infants. The table lists the time of last dose prior to delivery and the levels of CZP in mother, infant and cord blood on the day of birth. For patient 2, levels were again checked 1 month after birth and mother was 22.93 μg/ml, infant was 0.84 μg/ml and 5 samples of breast milk at varying times from CZP dose had levels <0.41 μg/ml.

Conclusions: CZP does not appear to be actively transferred across the placenta in the third trimester of pregnancy, unlike infliximab. These results are consistent with animal studies and may impact the choice of anti-TNF agent in the pregnant patient.

Table.

		Birth (μg/ml)

Anti-TNF Therapy Reduces Adipocytokine Levels and Improves the Lipid Profile in Patients with Rheumatoid Arthritis: A Possible Mechanism Contributing to Lowered Cardiovascular Risk. Marieke Herenius[2], Ruth Klaasen[2], Wilco de Jager[4], Berent Prakken[4], Daniëlle Gerlag[3] and Paul P. Tak[1]. [1]Academic Med Ctr/Univ of Amsterdam, Amsterdam, The Netherlands, [2]Department of Clinical Immunology and Rheumatology, Academic Medical Center, University of Amsterdam, Amsterdam, The Netherlands, [3]Department of Clinical Immunology and Rheumatology, Academic Medical Center, University of Amsterdam, The Netherlands, [4]Department of Pediatric Immunology, University Medical Center Utrecht, Wilhelmina Children's Hospital, Utrecht, The Netherlands

Background: The atherosclerotic process is accelerated in patients with rheumatoid arthritis (RA), contributing to higher mortality rates than those found in the general population. Recently, treatment with TNF-blockers has been associated with a lower risk of first-ever CVD events. However the mechanisms by which TNF-blockers exert this effect is unclear. Adipocytokines have been linked to obesity, insulin resistance, inflammation, and coronary heart disease in the general population and their serum levels are elevated in RA. To explore the relationship between inflammation and atherogenesis, we investigated the effects of anti-TNF therapy on serum adipocytokine levels (adiponectin, resistin, leptin and visfatin) and known risk factors such as C-reactive protein levels and lipid profile in RA patients.

Methods: 49 patients with active disease (disease activity score evaluated in 28 joints (DAS28)) ≥3.2) were started on adalimumab therapy (40 mg subcutaneously every other week). Blood was drawn from patients while fasting at baseline and 16 weeks after the initiation of therapy. Lipid profiles (total cholesterol (TC), high density lipoprotein (HDL), low density lipoprotein (LDL), triglycerides (TG), lipoprotein (a) (Lp(a)), ApoA- I and Apo B levels), CRP and ESR were determined. Adiponectin, resistin and leptin levels were measured using multiplex analysis and visfatin levels were measured by ELISA.

Results: After 16 weeks of treatment, there was a significant reduction in DAS28 ($p<0.001$), ESR ($p<0.001$), and CRP ($p<0.001$) levels. Of interest, we found a decrease in serum concentrations of resistin (19,2%, $p=0.02$) and visfatin (17.2%, $p=0.09$). There were not clear cut changes in serum levels of adiponectin ($p= 0.91$) and leptin ($p=0.55$). Furthermore, a significant improvement was seen of the TC/HDL ratio ($p=0.047$**),** the apoB/apo A-I ratio ($p=0.013$) and lp(a) levels ($p<0.001$). Baseline visfatin levels correlated with BMI, TC/HDL ratio and LDL/HDL ratio. In addition, the decrease in visfatin levels was related to improvements in LDL/HDL ratio ($r=0.32$, $p=0.05$) and TC/HDL ratio ($r=0.35$, $p=0.03$)

Conclusions: These data support the downregulation of visfatin as a potential new mechanism by which anti-TNF therapy might reduce vascular inflammation, and as such cardiovascular morbidity in RA patients. These data are in line with recent observations that elevated visfatin levels are related to abnormalities in lipid metabolism.

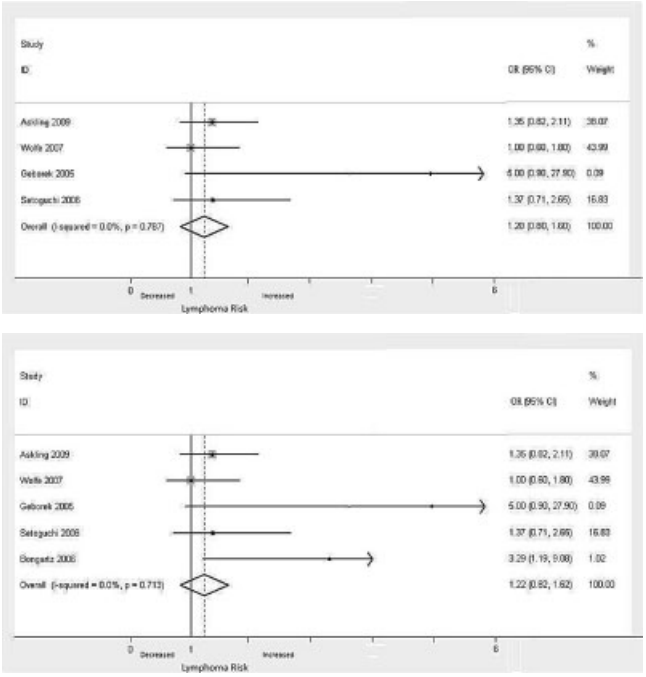
Biologics and Risk of Lymphoma in Patients with Rheumatoid Arthritis: A Systematic Review and Meta-Analysis. Lindsay C. Burns[1], Mary De Vera[1], Vidula Bhole[1], Yanyan Zhu[3], Peter Grayson[2], Devyani Misra[3] and Hyon K. Choi[4]. [1]Arthritis Research Centre of Canada, [2]Boston University, [3]Boston University School of Medicine, [4]Univ of British Columbia, Vancouver, BC, Canada

Purpose: A previous meta-analysis of biologics trials has reported a three-fold increased risk of malignancies (including lymphoma) (Bongatz et al JAMA 2006), but trials are not designed to capture long-term safety outcomes. To this end, we conducted a systematic review and meta-analysis to determine whether biologic use among RA is associated with risk of lymphoma.

Methods: We searched MEDLINE, EMBASE, and INTERNATIONAL PHARMACEUTICAL ABSTRACTS databases from Jan 1990 to May 2010 for studies that evaluated adverse effects of biologics or evaluated efficacy of biologics with reporting of adverse events. Eligibility criteria were: a) use of an RCT or observational study design (case control, cohort study), b) a study duration of ≥12 weeks, c) sample size of ≥100 for observational studies, d) RA population, or if mixed population, reporting of RA-specific results, e) evaluation of a biologic therapy as mono-therapy or in combination with other RA therapies, f) clearly defined lymphoma outcomes, and g) information on relative risk (RR), odds ratio (OR), and 95% confidence intervals (95% CI). We calculated weighted-pooled summary estimates for lymphoma risk using a random effects model. Then, we combined our results with the previous meta-analysis assuming the reported cancer risk (OR=3.3) as the lymphoma risk. We used the Q statistic to test for heterogeneity and the Egger's test the possibility of publication bias.

Results: We reviewed 11 articles that evaluated lymphoma outcomes associated with biologic use in RA, including 2 RCTs and 9 cohort studies. Of these, 7 articles were excluded from subsequent pooling because they failed to report risk estimates for lymphoma (n=5) or were earlier studies on the same study sample (n=2). The remaining 4 articles were large cohort studies that reported risks of lymphomas associated with infliximab, etanercept, adalimumab, and anakinra, with sample sizes ranging from 757 to 7815 and average RA duration ranging from 127 to 158 months. A total of 19,323 patients contributed 119,433 person years of follow up, and 129 lymphomas were identified. Using adjusted values, the pooled risk estimate for lymphoma was 1.20 (95% CI, 0.80–1.60) (Figure). Heterogeneity was small (I2-statistic $p=0.79$) and we did not detect publication bias (Egger test $p=0.26$). Combining results with recent meta-analysis did not change the pooled risk estimate (1.22; 95% CI, 082–1.62) materially.



Conclusions: Our meta-analysis of the current literature does not support an increased risk of lymphoma with biologic use in RA. The differences between the previous meta-analysis of trials and the current study include study type (trial vs. observational study), durations, and sample sizes.

The Comparative Incidence of Serious Infections among Rheumatoid Arthritis Patients Who Switch Biologic Agents. Jeffrey R. Curtis[3], Fenglong Xie[2], Lang Chen[2], John Baddley[2], Timothy Beukelman[4], Kenneth G. Saag[5], Kevin Winthrop[1] and Elizabeth Delzell[2]. [1]OHSU, [2]Univ of Alabama at Birmingham, Birmingham, [3]University of Alabama– Birmingham, Birmingham, AL, [4]University of Alabama-Birmingham, Birmingham, AL, [5]University of Alabama-Birmingham, Birmingham, AL

Background: The safety profile of the anti-TNF agents has been well characterized. However, it is unclear whether the comparative safety of newer biologics with different mechanisms of action is similar to the anti-TNF agents. Our objective was to evaluate the incidence of hospitalized infections among rheumatoid arthritis (RA) patients switching to a new biologic.

Methods: Using the administrative databases of a large U.S. healthcare organization from 1/2005-8/2009, we identified enrollees with RA based on having at least 1 physician visit for RA (ICD9 714.X). To control for confounding related to characteristics that cause patients to switch from one biologic to another, eligible patients were those switching to a new biologic who had been treated with a different biologic in the preceding 6 months, defined as the baseline period. Observation time began on the switch date. To further control for confounding, we created pair-wise propensity scores (PS) for each drug contrast using covariates measured at baseline. PS were categorized into quintiles; non-overlapping regions of the PS distributions were trimmed. Exposure was defined as current use of the biologic, allowing for an extension of 90 days. Outcomes of interest were hospitalized infections identified using previously-validated algorithms. Cox proportional hazards models evaluated the incidence rate of hospitalized infections, comparing each biologic to infliximab, selected as a convenient reference standard for

uniform comparison. Observation time was censored at the first hospitalized infection, end of study, or lack of current exposure.

Results: Among a total of 101,906 unique RA patients enrolled in the health plan, 1923 switched to a new biologic and contributed 1915 person-years (py) of observation. Characteristics of these eligible patients were mean ± SD age 49.3 ± 11.2 years, 78% women. A total of 82 first hospitalized infections were identified; the rate of hospitalized infections ranged from a low of 1.8 (switch to etanercept) to a high of 6.2 (switch to rituximab) per 100py. There was insufficient use of golimumab or certolizumab to evaluate these agents. Referent to infliximab, there were no significant differences between the rates of infection for any biologic after adjusting for age, sex, and PS quintile (Table). There were no cases of active tuberculosis or of hospitalized progressive multifocal leukoencephalocathy (PML).

Conclusion: The rate of all hospitalized infections among RA patients switching to a new biologic varies across a relatively small range and was not significantly different between agents.

Hazard Ratio Comparing the Rate of Serious Infections for Persons Switching to Various Biologies

Drug Switching To	Incidence Rate (per 100 pt-years)	Crude Hazard Ratio	Adjusted for age, sex, propensity score
Abatacept	5.8	1.08 (0.57, 2.04)	0.87 (0.45, 1.70)
Adalimumab	3.8	0.73 (0.40, 1.34)	0.68 (0.36, 1.29)
Etanercept	1.8	0.44 (0.19, 1.05)	0.46 (0.19, 1.12)
Infliximab	4.8	1.0 (ref)	1.0 (ref)
Rituximab	6.2	1.07 (0.56, 2.05)	0.89 (0.43, 1.82)

722

Characteristics of Cases of PML among Patients with Selected Rheumatic and Autoimmune Diseases. Timothy Beukelman[5], Fenglong Xie[3], Lang Chen[3], John Baddley[3], Elizabeth Delzell[3], Carlos G. Grijalva[7], Nivedita M. Patkar[2], Kenneth G. Saag[6], Kevin Winthrop[1] and Jeffrey R. Curtis[4]. [1]OHSU, [2]Univ of AL at Birmingham, Birmingham, AL, [3]Univ of AL at Birmingham, [4]University of Alabama - Brimingham, Birmingham, AL, [5]University of Alabama-Birmingham, Birmingham, AL, [6]University of Alabama-Birmingham, Birmingham, AL, [7]Vanderbilt

Background: The incidence and antecedent risk factors for infection with progressive multifocal leukoencephalopathy (PML) infection have been minimally characterized in patients with rheumatic diseases.

Methods: Using individually-identifiable, person-level administrative data from the entire United States from the Center for Medicare and Medicaid Services (CMS) from 2000–2006, we identified both Medicaid-only and also 'dual-eligible' (Medicare + Medicaid) individuals with at least one diagnosis of rheumatoid arthritis (RA), psoriatic arthritis (PsA), psoriasis (PsA), juvenile idiopathic arthritis (JIA), inflammatory bowel disease (IBD), and anklylosing spondylitis (AS) claim at any time. PML was identified using hospital discharge diagnosis codes (ICD9 046.3), and the 'case date' was assigned as the date of hospital admission. Risk factors for PML were evaluated in the 6 months prior to the case date, and separately using all data prior to the case date. During these assessment periods, patients must also have had full insurance coverage (e.g. Medicare Part A+B, not enrolled in Medicare Advantage). 4 month mortality following the case date was described. Data Use Agreement restrictions from the Center for Medicare and Medicaid Services (CMS) required collapsing categories with individual cell sizes < 11.

Results: Among 712,708 unique individuals with RA, PsA, PsO, JIA, IBD, or AS, a total of 55 hospitalizations for PML were identified (7.7 per 100,000 individuals). Of these cases, 29 had insurance coverage for at least 6 months prior to the PML case date and had one or more physician diagnoses of a rheumatic disease that occurred before the PML case date. Characteristics of these 29 PML cases include mean ± SD age 46.8 ± 8.18 years, 41% women. There was at least 1 case of PML that occurred among patients with each rheumatic disease studied except for JIA. The most prevalent concomitant comorbidity was HIV (83% of patients). Additional comorbidities present with low prevalence among PML cases included malignancy and concomitant systemic lupus erythematosus. At least one individual with PML had none of these comorbidities nor HIV but was a current user of infliximab.

Among all PML cases, more than 1 patient had antecedent exposure to infliximab in the 6 months prior to the PML case date; the median time from the most recent exposure to infliximab to hospitalization for PML was between 1 and 2 months. No other PML patients had any prior exposure to any other biologic agent. Fewer than 10 patients were using glucocorticoids in the 6 months prior to the PML infection. More than 1/3 of patients died in the 4 months following the PML case date.

Conclusion: PML is a rare infection that has been observed to occur among patients with inflammatory and autoimmune conditions, even in the absence of recent biologic drug exposure or other risk factors such as HIV disease. A better understanding of the epidemiology of PML infections and associated risk factors may be useful to inform patients regarding this rare but serious adverse event.

Consequence of Remission Misclassification Due to Reduced Joint Counts Omitting the Forefeet. Lilian H. D. van Tuyl[8], Karin Britsemmer[3], David T. Felson[2], George A. Wells[6], Josef S. Smolen[4], Bin Zhang[1], Julia Funovits[5], Dirkjan van Schaardenburg[3] and Maarten Boers[7]. [1]Boston Univ Schl of Medicine, Boston, MA, [2]Boston University School of Medicine, Boston, MA, [3]Jan van Breemen Institute, [4]Krankenhaus Lainz, Vienna, Austria, [5]Medical University of Vienna, [6]Univ of Ottawa Faculty of Med, Ottawa, ON, Canada, [7]VU University Medical Center, Amsterdam, The Netherlands, [8]VU University Medical Center, Amsterdam

Introduction: With remission in rheumatoid arthritis (RA) a realistic outcome of treatment, the ACR, EULAR and OMERACT have joined forces to develop a new definition for remission in RA to be used in clinical trials. One of the issues on the research agenda is the consequence of using a 28- vs a more complete joint count. Several studies report residual disease activity in the feet in patients with a 28-joint count of zero, although this might not be a problem in defining remission if such patients fail to classify because of activity in other measures within the definition.

In an observational early disease cohort we studied the consequences of misclassification due to residual disease activity in the feet of patients in remission by 28-joint counts.

Methods: All patients fulfilling the '87 ACR criteria for RA at inclusion or at 1 year follow up in the early arthritis cohort of the Jan van Breemen Institute (Amsterdam, The Netherlands), not using biologicals were included.

Boolean as well as index-based candidate remission definitions were calculated using the 28- and 38 joint count that includes the 10 metatarsophalangeal joints. Disease stability was defined as stable x-ray scores over 1 year (change ≤0 in van der Heijde/Sharp scores) AND stable and low scores on the Health Assessment Questionnaire (HAQ change ≤0 AND HAQ score consistently ≤0.5), all during the 2nd year after inclusion.

Analyses comprised: 1) residual disease activity (swollen or tender joints>0) in the feet of patients that fulfilled the candidate remission criteria using a 28 joint count; 2) likelihood ratio's of remission definitions to predict disease stability.

Results: Of a total of 423 RA patients 8 to 30% reached remission at 1 year using a 28 joint count (Table 1).

Table 1. Count(%) of patients in remission with active feet

Remission definition	Total in remission	Subset with TJC or SJC > 0 in feet
TJC+SJC+CRP+		
PtGA≤1*	38 (9)	10 (2)

DAS28 < 2.6	128 (30)	56 (13)

*New ACR/EULAR preliminary remission definitions in RA

The 6-measure Boolean definition is most strict, the DAS28<2.6 most relaxed. Of these, 26 to 44% showed activity in the feet, ~70% being due to both swelling and tenderness. Misclassification due to reduced joint counts was observed in 2 to 3 % of patients measured with a Boolean definition.

A state of remission increased the likelihood of stability of both x-ray and HAQ, with slightly higher LRs for definitions using 38 joint counts vs definitions using 28 joint counts.

Table 2. Likelihood ratio's of remission definitions with 28 vs 38 joint counts to predict disease stability

Remission definition	Joint counts	Total in remission	Stable and: in remission	Stable and: not in remission	LR	P
TJC+SJC+CRP+						
PtGA ≤1	28	38	15	70	2.6	*
PtGA ≤1	38	29	12	73	2.8	*
PtGA+PhGA ≤1	28	36	15	70	2.8	**
PtGA+PhGA ≤1	38	27	12	73	3.2	**
PhGA+pain ≤1	28	38	19	66	4.0	**
PhGA+pain ≤1	38	26	14	71	4.6	**
PtGA+pain ≤1	28	34	14	71	2.8	**
PtGA+pain ≤1	38	25	11	74	3.1	*
PtGA+pain+PhGA ≤1	28	32	14	71	3.1	**
PtGA+pain+PhGA ≤1	38	23	11	74	3.7	**

*P-value <0.01; **P-value ≤0.001

Conclusion: A substantial proportion of patients in remission according to 28 joint counts show activity in the feet. Actual misclassification occurs in 2–3% of the total population studied. The ability of remission definitions with 28 vs 38 joint counts to predict long term good radiological and functional outcome is highly similar.

Use of Serum Clara Cell 16-kDa (CC16) Levels as a Potential Indicator of Active Pulmonary Fibrosis in Systemic Sclerosis. Minoru Hasegawa, Manabu Fujimoto and Kazuhiko Takehara. Kanazawa University

Background: Pulmonary fibrosis (PF) is one of the major systemic sclerosis (SSc) -related causes of death. Krebs von den Lungen-6 (KL-6) and surfactant protein-D (SP-D) are currently considered the best serum markers of PF in patients with SSc. However, these markers are not perfect and an additional serum marker may be helpful for reliable monitoring of PF. Clara cell 16-kDa (CC16, previously named CC10) is a pneumoprotein secreted from along the tracheobronchial tree, specifically in the terminal bronchioles where Clara cells are localized.

Objective: To clarify the clinical significance of serum CC16 protein levels in the diagnosis and monitoring of PF in patients with SSc, and to compare CC16 levels with levels of KL-6 and SP-D.

Methods: Serum CC16 levels were determined by competitive enzyme-linked immunosorbent assay (ELISA) and serum levels of KL-6 and SP-D were measured by sandwich ELISA in 92 SSc patients, 20 systemic lupus erythematosus (SLE) patients, and 20 healthy controls. In a retrospective longitudinal study, correlation of serum CC16 levels with the progress of PF was assessed in 16 SSc patients with elevated serum CC16 levels at their first visit.

Results: Although CC16 levels at the first visit were higher in patients with SSc than in SLE patients or healthy controls, the difference was not significant. Serum levels of CC16 were comparable in limited cutaneous SSc and diffuse cutaneous SSc patients (60.8 ± 109.5 vs. 78.3 ± 124.3 ng/ml) and significantly elevated in SSc patients with PF compared with SSc patients without PF (90.8 ± 110.7 vs. 42.1 ± 80.7 ng/ml, $p<0.05$). Furthermore, SSc patients with active PF showed significantly elevated serum CC16 levels compared to patients with inactive PF (168.8.8 ± 161.5 vs. 53.8 ± 95.0 ng/ml, $p<0.01$). Serum CC16 levels were significantly associated with SP-D ($r=0.39$, $p< 0.01$), but not with KL-6 ($r=0.19$, $p=0.15$). In a longitudinal study, reduced serum CC16 levels were associated with the stabilization of PF activity. Although the serum CC16 levels were less useful for the evaluation of PF severity, CC16 levels were likely as effective for the monitoring of PF activity as KL-6 or SP-D.

Conclusions: Our findings suggest that CC16 levels can be used as a potential serum biomarker for active PF in SSc. Use of this marker in combination with KL-6 and SP-D may be a more valuable as an indicator of PF activity in SSc patients than KL-6 and SP-D alone. Further prospective and comparative studies in larger populations will be needed to confirm these studies.

HLA DRB1*0407 and *1304 Are Predictive Biomarkers for Scleroderma Renal Crisis. Binh Y. Nguyen[1], Maureen D. Mayes[6], Frank C. Arnett[7], Deborah J. del Junco[2], Emilio B. Gonzalez[4], Hilda T. Draeger[3], Marilyn Perry[2], Amir Hendiani[2], John D. Reveille[5] and Shervin Assassi[1]. [1]Univ of Texas Health Science Center Houston, Houston, TX, [2]Univ of Texas Health Science Center Houston, [3]Univ of Texas Health Science Center San Antonio, San Antonio, TX, [4]Univ of Texas Medical Branch, Galveston, TX, [5]Univ Texas Health Sci Ctr, Houston, TX, [6]University of Texas-Houston, Houston, TX, [7]UT Medical School, Houston, TX

Background: Scleroderma Renal Crisis (SRC) is a life-threatening complication of systemic sclerosis (SSc). The Major Histocompatibility Region (MHC) showed the strongest association with SSc in a recently published large genome-wide association study, raising the possibility that this gene locus might be also important for biomarker development. The predictive significance of MHC genetic markers for SRC has not been previously investigated. The goal of the current study was to examine the predictive role of MHC genetic markers for the SRC beyond the known clinical correlates in a large population of patients with SSc.

Methods: SSc patients from the Scleroderma Family Registry and DNA Repository, Genetics versus Environment in Scleroderma Outcomes Study (GENISOS) and divisional registry at the University of Texas Health Science Center at Houston were included in the study. Patients, enrolled in more than one of the above mentioned sources, were identified and duplicate entries were omitted. ANA, anticentromere (ACA), anti-topoisomerase (ATA), and anti-RNA polymerase III (ARA) antibodies were detected utilizing commercially available kits. Furthermore, HLA Class II genotyping (DRB1, DQA1, DPB1) was performed on extracted and purified genomic DNA. Multivariate models were constructed following a purposeful variable selection method. First, we evaluated the demographic and clinical variables without genetic risk factors for their multivariable associations with SRC. Subsequently, we conducted a separate purposeful model building analysis after addition of the MHC genetic data. Ethnicities were included in all univariate and multivariable genetic analysis models.

Results: Overall, 1519 patients with SSc were included in this study, from which 90 patients (5.9%) had developed SRC. Of the 90 patients with SRC, diffuse cutaneous subtypes were found in 76%, ATA in 9%, ACA in 2%, and ARA in 50%. ARA and diffuse disease type were independent risk factors for presence of SRC, whereas ACA and ATA were protective in the multivariate model of clinical variables. In the final multivariable analysis after inclusion of HLA allotypes, we identified HLA-DRB1*0407 (OR=3.21, 95% CI 1.27–8.08; P=0.013) and *1304 (OR=4.51, 95% CI 1.30–15.68; P=0.018) as independent risk factors for SRC. Only 3 clinical characteristics, ARA, diffuse disease type and ACA remained statistically significant in the final model.

Conclusion: This study suggests that HLA DRB1*0407 and *1304 can be used as biomarkers for identification of SSc patients at risk for developing SRC beyond the information provided by known clinical predictors.

GAVE (Gastric Antral Vascular Ectasia) in Early Diffuse SSc: Updated Report from the SCOT (Scleroderma Cyclophosphamide or Transplant) Trial. Emily W. Hung[9], Maureen D. Mayes[10], Lynette Keyes-Elstein[5], Leslie J. Crofford[6], Mary Ellen Csuka[3], Daniel E. Furst[8], Ellen Goldmuntz[4], Peter McSweeney[11], Richard Nash[2], Victor Machicao[7] and Keith Sullivan[1]. [1]Duke University Medical Center, for the SCOT Trial Investigators, Durham, NC, [2]Fred Hutchinson Cancer Research Center, [3]Medical College of Wisconsin, Milwaukee, WI, [4]NIAID, [5]Rho Federal Systems Inc., [6]Univ of KY, Lexington, KY, [7]Univ of Texas Health Science Center at Houston, [8]University of California Los Angeles Medical School, Los Angeles, CA, [9]University of Texas at Houston, Houston, TX, [10]University of Texas-Houston, Houston, TX, [11]US Oncology

Objective: To identify the prevalence of, and predictors for, clinically silent GAVE in early diffuse SSc.

Introduction: Also known as watermelon stomach, GAVE is an endoscopic finding consisting of dilated sub-mucosal vessels radiating in a spoke-like fashion from pylorus to antrum. It is usually associated with chronic anemia. The prevalence of clinically silent GAVE (ie no anemia or evident GI bleeding) in SSc has not been previously reported. The SCOT (Scleroderma: Cyclophosphamide or Transplant) study is a pivotal randomized, NIH supported trial of monthly IV cyclophosphamide for 12 months versus immunoablation followed by CD34 selected autologous stem cell rescue in early, diffuse scleroderma with internal organ involvement. The presence of active GAVE, as defined by evidence of bleeding on endoscopy, is an exclusion criterion for SCOT due to the risk of gastric hemorrhage in the thrombocytopenic period for the stem cell arm. Complete inclusion/exclusion criteria and trial description are at www.sclerodermatrial.org.

Methods: 103 subjects without overt GI bleeding were screened for participation in the SCOT trial and had an upper endoscopy. All subjects had diffuse cutaneous systemic sclerosis with ≤ 5 years of disease duration from the first non-Raynaud's phenomenon symptom.

Results: Twenty three of 103 (22.3%) individuals were found to have GAVE (all inactive). Table 1 provides a comparison of demographic and disease-related features for those with GAVE and those without this characteristic. Not all subjects had results for all parameters.

Feature	GAVE = Present (n = 23)	GAVE = Absent (n = 80)
Age in years, mean ± sd	48.2 ± 7.45	45.99 ± 11.52
% Female	73.7%	75.0%
Race/ethnicity		
Caucasian	85.0%	79.7%
African-American	0	6.2%
Other/Not given	15.0%	14.1%
*BMI (kg/m^2), mean ± sd	27.44 ± 5.56	24.75 ± 4.00
Hemoglobin (g/dl), mean ± sd	11.76 ± 1.78	12.41 ± 1.50
Mean corpuscular volume, mean ± sd	85.19 ± 6.72	86.94 ± 6.09
mRSS (modified Rodnan Skin Score) Mean ± sd	30.5 ± 9.3	29.2 ± 9.4
% predicted FVC, mean ± sd	78.4 ± 13.92	75.64 ± 15.75
% predicted DLCO, Adjusted for Hb Mean ± sd	53.04 ± 7.65	58.86 ± 17.10
RVSP (right ventricle systolic pressure) Mean ± sd	31.33 ± 7.87	31.17 ± 7.43
Creatinine Clearance, mean ± sd	105.12 ± 37.60	110.55 ± 43.49

*This comparison was statistically significant (p = 0.0112)

The only clinical feature that distinguished those with versus those without GAVE was the BMI, which was marginally higher in the group with GAVE by simple t-test (uncorrected). The clinical significance of this finding is uncertain. All other demographic and clinical features were not statistically significant between groups. Other abnormal findings on upper endoscopy were common and expected, consisting of esophagitis and/or gastritis of varying degrees of severity.

Conclusion: In this study, 22.3% of subjects with early diffuse SSc, without overt GI blood loss, had characteristic findings of GAVE on screening EGD. This was a somewhat surprising finding and suggests that upper endoscopy should be performed prior to initiation of therapies that increase the risk of bleeding.

A Formula To Predict Mean Pulmonary Artery Pressures in Patients with Connective Tissue Disease Based on Echocardiography, NTproBNP and O_2 Saturation. Benjamin E. Schreiber[3], Christopher J. Valerio[3], Clive Handler[3], Greg Keir[1], Athol U. Wells[1], Christopher P. Denton[2] and J. Gerry Coghlan[3]. [1]Royal Brompton Hospital, London, [2]Royal Free Hospital, London, United Kingdom, [3]Royal Free Hospital, London, London, United Kingdom

Introduction: Pulmonary Hypertension (PH) is an important complication of connective tissue disease (CTD). Diagnosis is confirmed by right heart catheter (RHC) but no single non-invasive test accurately predicts PH. To improve selection of patients for RHC, we analysed the relationship between non-invasive tests and mean pulmonary artery pressure (mPAP) at RHC and derived a new formula to predict PAP.

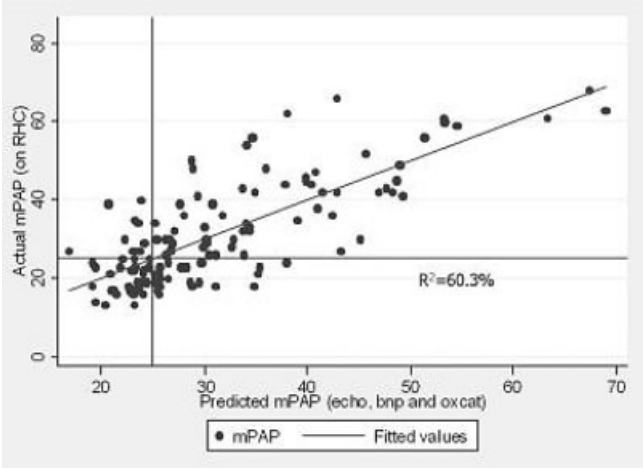
Methods: Retrospective analysis of patients with CTD undergoing a first RHC. In our database we have 968 patients (811 SSc, 53 SLE, 15 RA, 42 UCTD, 8 MCTD, 12 DM, 7 PM, 6 Sjogrens, 3 antiphospholipid syndrome, 3 vasculitis). We included for analysis NTproBNP and echocardiography if performed within 3 months of RHC and pulmonary function tests if done within 6 months. Pulse oximetry was measured at the time of the RHC.

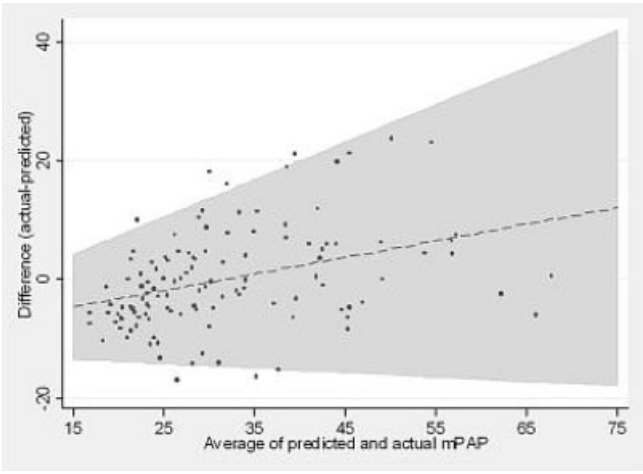
Results: Regression analysis of these variables individually against mPAP at RHC gave the following results: DL_{CO} (n=469) gave R^2=8.7, AUC=0.68; NTproBNP (capped at 300 pmol/litre to reduce the skewing effect of large values) with n=380, gave R^2=31.5, AUC=0.74 and echo derived tricuspid valve gradient (n=165) gave R^2=48.9, AUC=0.81. Capping NTproBNP gave similar results to a log transformation.

Multivariable linear regression showed significant correlation with mPAP for Echo derived TV gradient (p<0.0005), capped NTproBNP and Oxygen (p=0.004). Addition of predicted DL_{CO}, K_{CO}, FVC, weight or height did not improve the fit. To reduce heteroskedasticity, oxygen was used categorically (1 if SpO_2 >94%, 2 if 90–94%, 3 if <90%). Based on all 123 patients for whom we had NTproBNP, echo and SpO_2 data, the derived formula is:

Predicted mPAP = 8.37
+3.83 × Oxygen category
+ 0.328 × Echo derived Tricuspid Valve gradient
+ 0.032 × NTproBNP (capped)

This formula had R^2 of 60.3%.





The area under the curve was 0.84 (95% CI 0.77–0.91). Using a threshold predicted mPAP of 25 it has a sensitivity of 87.3%, specificity of 55.8%, positive LR of 2.0 and negative LR of 0.2. Using a threshold predicted mPAP of 30, it has a sensitivity of 66.2%, specificity of 90.4%, positive LR of 6.9, negative LR of 0.4.

Bland-Altman analysis showed a mean agreement of −0.6 (95% CI −16.4, 16.3) for difference between predicted and actual mPAP, although as seen in the figure, the 95% CI are tighter at lower predicted values.

This compares favourably with echocardiography done within 1 hour of the RHC (Fisher MR et al, Am J Respir Crit Care Med. 2009).

Conclusions: This formula may help identify CTD patients requiring RHC. Patients with a formula predicted mPAP under 25 are unlikely to have PH, and those patients with predicted mPAP above 30 are very likely to have PH.

Predictive Factors of Hand Radiographic Lesions in Systemic Sclerosis: A Prospective Study. Jerome Avouac[4], Giulia Mogavero[1], Henri Guérini[2], Jean-Luc Drapé[2], Alessandro Mathieu[1], Andre Kahan[3] and Yannick Allanore[3]. [1]2nd Chair of Rheumatology, University of Cagliari, Cagliari, Italy, [2]Paris Descartes University, Radiology B Department, Cochin Hospital, APHP, Paris, France, [3]Paris Descartes University, Rheumatology A Department, Cochin Hospital, APHP, Paris, France, [4]Paris Descartes University, Rheumatology A Department, Cochin Hospital, APHP, Paris, France

Background: Joint, bone and soft tissue involvement has been shown to strongly contribute to impaired hand function in systemic sclerosis (SSc). We previously showed in a cross-sectional study performed on 120 SSc patients the prominent level of hand radiographic involvement in SSc (1). However, this study had no longitudinal follow-up, precluding the identification of predictors of hand radiographic progression in SSc.

Objective: To examine the outcomes of hand radiographic X-Rays in patients with SSc and identify risk factors for the progression of hand radiographic lesions in a prospective cohort.

Patients and Methods: Subsequently to our initial cross-sectional study, dual time-point X-Rays with standard posteroanterior views of the hands and wrists were systematically performed after a median interval of 5 years (range: 4–7 years) in 103 SSc patients consecutively recruited. Univariate and multivariate Cox proportional hazards models evaluated predictors of progression of hand radiographic lesions (incident or worsened involvements) for three radiographic patterns of abnormalities of joints (erosive arthritis, defined by the presence of both erosion and joint space narrowing), bone (acro-osteolysis) and soft tissue (calcifications, flexion contracture). SSc patients (81% women) were 61±12 years old and had mean disease duration of 12±8 years.

Results: Incidences of erosive arthritis, acro-osteolysis, calcinosis and flexion contracture were 10%, 9% 14% and 8% respectively. The worsening of already known erosive arthritis, acro-osteolysis, calcinosis and flexion contracture occurred respectively in 13.5%, 12.5%, 11.5% and 10% of SSc patients. Cox regression analysis did not identify any predictor of the progression of erosive arthritis. Digital ulcers were shown to independently predict the progression of acro-osteolysis and calcinosis (Hazard Ratio, HR:12.43, 95% confidence interval, CI:1.97–88.40 and HR:3.16, 95%CI: 1.22–9.43, respectively). The diffuse cutaneous subset was shown to be an independent predictor of the progression of flexion contracture (HR:7.52, 95%CI:1.21–43.93).

Conclusion: This is the first prospective study to determine the outcomes and identify predictors of hand radiographic lesions in patients with SSc. This systematic examination highlights the striking level of incident and worsened hand radiographic lesions in SSc after a median interval of 5 years. Our data suggest a close monitoring of patients with the diffuse cutaneous subset with the need of early therapeutic intervention for prevention flexion contracture. Our results also show that severe peripheral vascular involvement predict both acro-osteolysis and calcinosis, highlighting their vascular background and suggesting that the impact of vascular treatments on these severe complications need to be addressed.

Predictive Value of Non-Invasive Tests for the Diagnosis of Scleroderma-Associated Pulmonary Hypertension: PHAROS Registry. Dinesh Khanna[4], Rajeev Saggar[4], Daniel E. Furst[4], Yannick Allanore[3], James R. Seibold[5], Philip J. Clements[4], Rajan Saggar[4], Chi-hong Tseng[4], Paul Maranian[4], Monique Hinchcliff[2], Virginia Steen[1] and PHAROS Investigators. [1]Georgetown University, [2]Northwestern Univ, [3]Paris Descartes University, [4]UCLA, [5]Univ of Connecticut

Background: Pulmonary hypertension (PH) is a major cause of death in systemic sclerosis (SSc). The Pulmonary Hypertension Assessment and Recognition of Outcomes in Scleroderma (PHAROS) is a prospective longitudinal study of patients at risk of developing PH and those who have definite PH.

Objective: Our objective was to assess the performance of non-invasive tests (echo RVSP, PFTs, serum BNP) for the diagnosis of PH (defined as mPAP≥25 mmHg on right heart catheterization [RHC]; includes WHO Groups1–3) in SSc patients.

Methods: Entry criteria for patients "at risk" for PH included a DLCO≤55% predicted, a FVC%/DLCO% ≥1.6 or a PASP on echo ≥ 40 mmHg. RHC are performed based on the clinical judgment of the physician. We performed 3 analyses: 1) assessed individual positive (PPV) and negative predictive value (NPV) for echo RVSP, FVC/DLCO, DLCO% predicted, and serum BNP compared to initial RHC mPA; 2) analyzed discriminatory power of echo RVSP, FVC%/DLCO%, DLCO% predicted, and BNP using classification and regression tree (CART) analysis; and 3) calculated what proportion of patients are captured by serum BNP and PFTs who were missed by different RVSP cut offs.

Results: We analyzed 209 SSc patients who underwent RHC after enrollment into PHAROS; 177 had the cath done at visit#1 and 32 had it done during follow-up visits. 143 (68%) had PH on RHC. PPV for RVSP (35 –50 mmHg) ranged from 0.78 to 0.91; FVC%/DLCO% (1.4 to 2.0) ranged from 0.67 to 0.78; and DLCO% cut offs (50%–70%) ranged from 0.68 to 0.73, and serum BNP (>100) was 0.94. Combination of RVSP >50 mmHg and DLCO< 50% had greatest PPV (0.95). CART analysis showed that RVSP >50 mmHg had greatest discrimination for diagnosing PH followed by serum BNP >100 units (Figure). However, 10% to 40% (Echo cutoff>50 mmHg) of patients with PH were missed with RVSP > 35 and > 50mmHg respectively (Table). In those missed, 2–5% were captured by serum BNP> 100, 5–29% by DLCO< 60% and 3–23% by FVC/DLCO ≤ 1.6. (Table).

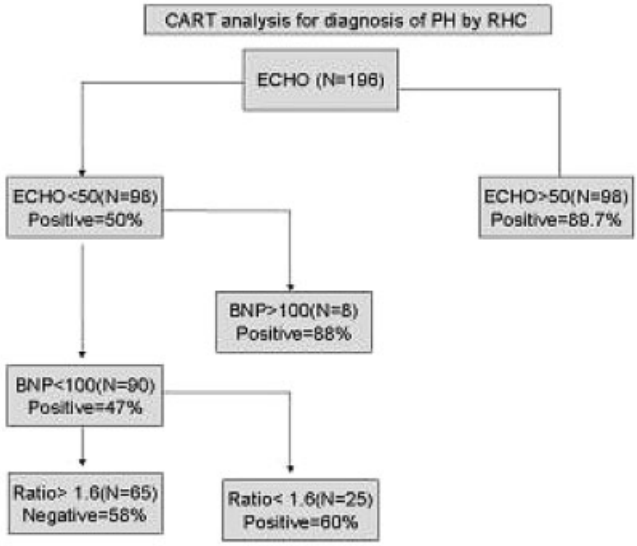

Table. Performance of various non-invasive tests

Echo cut off	PH missed by Echo RSVP	Additional patients captured with RHC-defined PH: Serum BNP >100*	DLCO <60%	FVC/DLCO ≥1.6
Echo >35 mm Hg	10%	2%	5%	3%
Echo >40 mm Hg	20%	3%	14%	10%
Echo >45 mm Hg	30%	4%	22%	16%
Echo >50 mm Hg	40%	5%	29%	22%

*only 67 patients had serum BNP reported

Conclusion: Echo RVSP > 50 mmHg has the greatest discriminatory power to detect PH in SSc in this enriched cohort. However, at this cut-off, serum BNP and PFT captures additional 27% of patients with PH. Serum BNP and PFTs complement Echo RVSP and should be included as part of work up of PH in SSc. This data needs to be confirmed in another real-life cohort.

730

Single-Nucleotide Polymorphisms Associated with Systemic Lupus Erythematosus (SLE) Skew Alternative Splicing of Human Complement Receptor 2 (CR2/CD21) towards an Isoform with Increased Ligand Binding Ability. Kara M. Lough[3], Katherine B. Douglas[3], Carissa L. Homme[3], Daniela Ulgiati[1], Betty P. Tsao[2] and Susan A. Boackle[3]. [1]School of Biomedical, Biomolecular and Chemical Sciences, University of Western Australia, [2]University of California, Los Angeles, [3]University of Colorado Denver School of Medicine

Background: Human complement receptor 2 (CR2/CD21) exists as two known isoforms consisting of 15 or 16 extracellular repeating subunits termed short consensus repeats (SCRs) that result from alternative splicing of exon 11 in the primary mRNA transcript. The major alleles of three lupus-associated single-nucleotide polymorphisms (SNPs) in the CR2 gene (rs1048971 and rs17615 in exon 10 and the rs4308977 in exon 11) and a closely linked fourth SNP in exon 11 (rs17616) increase the splicing efficiency of exon 11 in vitro and ex vivo. The differential function of the two isoforms generated by this process and the factors controlling it are not known.

Methods: The cDNA for each isoform was amplified from Raji B cell RNA, cloned into the pcDNA5-FRT-V5-His TOPO TA expression vector (Invitrogen), and transfected into Flp-In CHO cells (Invitrogen). Stable clones were incubated with recombinant C3dg (rC3dg) tetramers prepared with biotiylated rC3dg and PE-streptavidin and binding was determined by flow cytometry. To identify the specific SNP(s) influencing splicing efficiency of exon 11, an exon-trapping vector (pL53In) containing genomic DNA spanning introns 9 to 12 of CR2 was modified by site-directed mutagenesis to generate vectors containing various allelic combinations of these SNPs. After transient transfection into Raji B cell and HK FDC lines, the relative amount of vector-derived mRNA transcripts including or excluding exon 11 was measured by quantitative RT-PCR.

Results: CHO cells expressing the long CR2 isoform bound up to two-fold higher levels of tetramers than CHO cells expressing equivalent amounts of the short isoform. In the Raji cell line, the presence of the minor allele at both rs17615 and rs17616 reduced splicing efficiency of exon 11 to the same extent as when all four SNPs were minor, whereas in the HK cell line, the presence of the minor allele at only rs17616 was sufficient to reduce the splicing efficiency of exon 11 to that seen in the all minor allele construct.

Conclusions: These data demonstrate that the long isoform of human CR2 is better able to bind C3d-opsonized ligands, suggesting that the introduction of SCR11 alters the structure and function of the receptor. The data also suggest that the minor alleles at rs17615 and rs17616 modify the secondary structure of the CR2 pre-mRNA, interfering with splice site recognition by regulatory proteins. Variations in the relative amounts of these splice isoforms of CR2 on the surface of B cells or follicular dendritic cells may influence susceptibility to lupus, and the regulatory proteins that determine this process could serve as future targets for therapeutic intervention.

Purpose: Our previous collaborative effort demonstrated an association between systemic lupus (SLE) and cancer, driven primarily by lymphoma risk. We aimed to more precisely estimate cancer incidence rates in SLE, compared to the general population. We also present results stratified by age group.

Methods: We assembled an expanded multi-centre international cohort of clinically confirmed SLE patients. Patients at each center were linked to regional tumor registries to determine cancer occurrence. Standardized incidence ratios (SIRs) were calculated as the ratio of observed to expected cancers. Cancers expected were determined by multiplying person-years in the cohort by the geographically matched age, sex, and calendar year-specific cancer rates, and summing over all person-years.

Results: The 13,492 patients from 24 centers were observed for a total of 118,359 patient-years, with an average follow-up of 9 years. Within the observation interval, 632 cancers occurred. The data confirmed an increased risk of cancer among patients with SLE. For all cancers combined, the SIR estimate was 1.15 (95% confidence interval, 95% CI, 1.06–1.24), and for all hematologic malignancies combined, the SIR was 2.53 (95% CI 2.05–3.07). Regarding specific types of hematological malignancies, increased risk was demonstrated for all lymphomas (SIR 3.21, 95% CI 2.48–4.07) as well non-Hodgkin's lymphoma specifically (SIR 3.41, 95% CI 2.61–4.39), and for leukemia (1.69, 95% CI 1.00–2.67). We also demonstrated an increased risk of lung cancer (SIR 1.24; 95% CI 1.00–1.53), cervical cancer (SIR 1.65, 95% CI 1.09–2.41), vulvo-vaginal cancers (SIR 2.80, 95% CI 1.12–5.77), and hepatic cancer (SIR 2.18, 95% CI 1.16–3.73). Meanwhile, a significant decreased risk was seen for hormone-sensitive cancers, including breast cancer (SIR 0.70, 95% CI 0.58, 0.85), endometrial cancer (SIR 0.49, 95% CI 0.27, 0.83), and ovarian cancer (0.56, 95% CI 0.28, 0.97). When SIR estimates were stratified by age, SLE patients in the youngest age group (<40) appeared to have a particularly high relative cancer risk (compared to the general population), with an over-all cancer SIR of 1.70 (95% CI 1.34, 2.12)

Conclusion: These results more precisely define cancer risk in SLE, highlighting a higher risk of hematological malignancies, both lymphoma and leukemia; these are being further studied in case-cohort analyses of drugs and disease activity. One additional hypothesis for the higher risk of certain events, such as cervical and vulvo-vaginal cancers, is the possibility of altered clearance of viruses (e.g. HPV). On the other hand, the lower risk of several hormone-sensitive cancers may invoke the possibility of alterations in the metabolism of estrogen and/or other hormones. Although cancers in general are more common with age, younger SLE patients have a particularly high relative cancer risk (compared to the general population).

Table: Cancer Risk in Systemic Lupus

Cancer Type	Observed	Expected	SIR	95% CI	
Hematological	99	39.2	2.53	2.05	3.07
Non-Hodgkin Lymphoma	61	17.9	3.41	2.61	4.39
All lymphoma	67	20.9	3.21	2.48	4.07
Multiple Myeloma	8	5.6	1.41	0.61	2.79
Leukemia	18	10.6	1.69	1.00	2.67
Breast	112	159.2	0.70	0.58	0.85
Ovarian	12	21.4	0.56	0.28	0.97
Cervical	27	16.3	1.65	1.09	2.41
Vulvo - Vaginal	7	2.5	2.80	1.12	5.77
Endometrial	14	28.2	0.49	0.27	0.83
Lung	89	71.7	1.24	1.00	1.53
Hepatic	13	5.9	2.18	1.16	3.73
Pancreatic	13	12.1	1.07	0.57	1.84
Gastric	11	11.3	0.96	0.48	1.73
Colorectal	60	62.5	0.95	0.73	1.23
Thyroid	17	11.7	1.45	0.84	2.32
Bladder	21	15.3	1.37	0.84	2.09
Prostate	12	18.3	0.65	0.33	1.14
Melanoma	13	16.8	0.77	0.41	1.32

Hydroxychloroquine and Prevention of Anti-SSA/Ro Associated Cardiac Disease in Mothers with a Previous Child with Neonatal Lupus. Peter M. Izmirly[4], Cecilia Pisoni[2], Mimi Y. Kim[1], Deborah Friedman[3], Carolina Llanos[5], Nathalie Costedoat-Chalumeau[7], Munther A. Khamashta[6] and Jill P. Buyon[4]. [1]Albert Einstein College of Medicine, [2]King's College of London, [3]New York Medical College, [4]NYU School of Medicine, New York, NY, [5]Pontificia Universidad Catolica de Chile, [6]The Rayne Institute, London, United Kingdom, [7]Universite Paris VI Pierre et Marie Curie

Purpose: Despite weekly monitoring of fetuses exposed to maternal anti-SSA/Ro antibodies, immediate treatment has never permanently reversed complete heart block. This irreversibility strongly supports an emphasis on preventative strategies. A recent case-control study revealed that fetal exposure to Hydroxychloroquine (HCQ), which prevents endosomal acidification and Toll-Like Receptor ligation (proposed pathway involved in cardiac inflammation and scarring), decreases the risk of cardiac manifestations of neonatal lupus (cardiac-NL) in Systemic Lupus Erythematosus (SLE) mothers with anti-SSA/Ro antibodies. That study did not address the effect of HCQ on the recurrence rate in subsequent pregnancies which is nearly 10 fold the frequency in anti-SSA/Ro positive women who have not had an affected child. Accordingly, this study explores whether HCQ prevents the development of cardiac-NL in these highest risk pregnancies.

Methods: Twenty-four pregnancies of 22 mothers satisfied the inclusion criterion: exposure to HCQ in a pregnancy of a mother whose previous child had either cardiac or cutaneous-NL. Exposure was defined as the sustained use of HCQ throughout pregnancy with initiation prior to 6 weeks gestation. In 19 of these 22 families the previous child had cardiac-NL (1- isolated cardiomyopathy and 18- advanced congenital heart block (CHB) 8 of whom died from complications of the disease) and in 3 families the prior child had cutaneous-NL. Of these 22 previous NL pregnancies, 15 were unexposed to HCQ (13 CHB, 1 cardiomyopathy and 1 rash), 6 were exposed to HCQ (4 CHB and 2 rash) and in 1 CHB child, exposure to HCQ was unknown.

Results: Sixty-eight percent of the mothers were Caucasian. The maternal health status was SLE in 41%, Sjogren's Syndrome (SS) in 32%, SLE with secondary SS in 18%, and Undifferentiated Autoimmune Syndrome in 9%. Sixty-four percent (14/22) of the mothers were positive for both anti-SSA/Ro and anti-SSB/La antibodies. The mean daily dose of HCQ was 352.6 mg. Using prospective data from the Research Registry for Neonatal Lupus, the recurrence rate of cardiac-NL following a child with cardiac-NL is 18% (based on 161 pregnancies following a previous child with CHB) and the occurrence rate of cardiac-NL following a child with cutaneous-NL is 13% (based on 39 pregnancies following a previous child with cutaneous-NL). These data suggest that the expected rate of cardiac-NL in this cohort should be approximately 17.2%. Of the 24 subsequent pregnancies exposed to HCQ in this study only one fetus developed cardiac-NL (3rd degree) and this mother's previous child had cutaneous-NL. Thus, the recurrence/occurrence rate was 4.2% (95% CI:(0.11% - 21.1%), a reduction of 75.7%. In addition to HCQ, 25% (6/24) of the mothers received intermittent low dose IVIG, 75% (18/24) non-fluorinated steroids, 17 of whom were on $\leq$ 10 mg of Prednisone, and 8.3% (2/24) fluorinated steroids, one after the diagnosis of CHB.

Conclusion: This case series suggests that in mothers with anti-SSA/Ro antibodies and a previous child with NL, exposure to HCQ during a subsequent pregnancy may decrease the risk for fetal development of cardiac-NL.

A Systems Biology Approach to Understanding SLE Complexity. John Jung[5], Jennifer Hossler[5], Youqun Huang[5], Elise Palmer[5], Elides Marin[5], Tracy Sanford[5], Ehtisham Akhter[2], Michelle A. Petri[1], Alex Rosenberg[5], Jennifer H. Anolik[3], Chungwen Wei[5] and Ignacio Sanz[4]. [1]Timonium, MD, [2]John Hopkin University School of Medicine, Baltimore, MD, [3]University of Rochester, Rochester, NY, [4]University of Rochester Medical Center, Rochester, NY, [5]University of Rochester Medical Center, Rochester, NY

Background: B cell involvement in SLE has been demonstrated as a significant contributing determinant to disease pathogenesis. However, phenotypic heterogeneity and physiological importance of B cell subsets remain elusive and pose a challenge to understanding the complex mechanisms resulting in autoimmunity. Therefore, utilizing 3 different 12-color flow cytometry panels we have captured a comprehensive high-resolution footprint of the B cell profile in SLE in order to systematically explore the diverse human B cell repertoire and identify biomarkers of disease activity and prognosis.

Methods: B-cells from Healthy Controls (n=26) and SLE patients (n=127) were analyzed by multi-color flow cytometry for expression of anchor markers that identify larger parental B cell populations. The individual panels also included subset specific markers to further define parental populations: Memory; Transitional and Naive; and Plasma B cells. Multivariate methods were used to seek natural divisions based on the B cell profiles, and to relate them to various clinical parameters. SLE patients met ACR criteria for the classification of SLE, and were sub-categorized based on primary clinical manifestation. Disease activity and flares were measured by SELENA-SLEDAI and physician global assessment.

Results: Preliminary analyses show SLE B cell profiles exhibited a broader spread across different subsets compared to Healthy Control (HC). However, after sub-categorizing SLE patients based on primary clinical manifestations, the SLE sub-categories were revealed to have distinct B cell profiles. Overall, SLE patients had higher transitional populations and lower true naive B cells than HC ($p<0.05$). Nephritis, musculoskeletal/skin, and flaring patients exhibited a CD27- memory B cell expansion ($p<0.05$) with expression of CD95+ ($p<0.05$) and CD21- ($p<0.05$), markers of putative effector memory B cells, compared to HC. Nephritis patients had a unique memory CD27- B cell subset expressing significantly higher B220+ ($p<0.05$) and CD24- ($p<0.0005$). Musculoskeletal/skin patients exhibit CD27- memory that expressed CXCR3+ and high CD27+ memory with CD95+ ($p<0.005$) when compared to HC. Overall, Spearman correlation shows SLE DAI scores correlated with CD27- Memory with phenotypes CD95+($r=0.46$, $p<0.005$), CD21-($r=0.44$, $p<0.005$), and CD24- ($r=0.44$, $p<0.005$). SLE DAI also correlated with plasmablast counts ($r=0.35$,$p<0.05$).

Conclusions: These results indicate that unique B-cell signatures cluster with distinct clinical parameters, indicating a spectrum of disease states in SLE. Moreover, the exploration of multiple B cell subsets by a multi-colored flow-cytometry approach suggests that B cell profiles may serve as biomarkers of disease phenotype, activity, and treatment response. These profiles will be invaluable to understand disease heterogeneity and possibly its genetic basis and should prove of great help in the design of future therapeutic studies, especially with B cell targeting agents. Ongoing studies are exploring longitudinal changes in B cell phenotypes and correlation with T cell abnormalities to create an even more comprehensive picture of SLE disease pathogenesis.

Antibodies from Antibody-Secreting Cells Following Vaccination in Patients with Systemic Lupus Erythematosus Are Autoreactive and Polyspecific. Kenneth A. Smith[2], Lori Garman[3], Jennifer Morris[3], Linda Thompson[3], Patrick C. Wilson[4] and Judith A. James[1]. [1]Oklahoma Medical Research Foundation, Oklahoma City, OK, [2]Oklahoma Medical Research Foundation, Fort Wayne, IN, [3]Oklahoma Medical Research Foundation, [4]University of Chicago

Background: Immunization against *Streptococcus pneumoniae* and influenza is recommended for patients with systemic lupus erythematosus (SLE), but with vaccination comes the risk of inducing or exacerbating an autoimmune response. Several components of vaccines are well known to induce antibodies that are cross-reactive to self-antigens, including tetanus toxiod which has been reported to induce antibodies to cardiolipin (aCL) or DNA and phosphorylcholine (a component of *S. pneumoniae* C polysaccharide) which has been reported to induce antibodies to dsDNA. However, the induction of antibodies specific to other SLE autoantigens after immunization remains unclear. Most of the previous studies on vaccine-induced autoreactivity have been done using patient sera; in our study, we sought to examine the physiological autoantibody response to two implicated vaccinations, the yearly influenza vaccine and the *S. pneumoniae* vaccine (PN), by analyzing the antibody repertoire arising during the immune response through generation of human monoclonal antibodies.

Methods: Two SLE patients were vaccinated, with at least 4 weeks between vaccinations, and PBMCs were isolated seven days after each immunization. Vaccine-specific ASCs were isolated as single cells from bulk PBMCs. The VDJ regions of the heavy and light chains of individual ASCs were cloned into vectors and expressed together in mammalian cells as monoclonal antibodies (mAbs). Vaccine-specific (PN polysaccharides or influenza virion) binding and autoreactivity (Ro, La, Sm, nRNP) ELISAs were performed on each mAb. Cloning of mAbs were also performed in four healthy individuals, two receiving the flu vaccine and two receiving PN.

Results: On average, 27 mAbs were produced per individual, about 14 specific to each vaccine. PN-specific antibodies were much more likely to use VH3 genes (81%) than flu-specific antibodies (50%; $p = 0.007$, Chi-square). Overall, the SLE individuals produced more mAbs reactive against SLE antigens (33% of anti-flu and anti-PN) than control individuals (2.7%). Of the mAbs generated from SLE patients, mAbs specific to PN were more likely to be reactive against the tested SLE antigens (47%) than flu mAbs (12%; $p = 0.008$, Chi-square with Yate's correction). Remarkably, virtually all of these antibodies cross-react with at least two of the autoantigens tested and many mAbs react to all four. Notably, the polysaccharide antibodies were highly serotype specific yet still bound multiple self-antigens, albeit at affinities several orders of magnitude lower than against the immunogen. While pre-incubation with polysaccharide could inhibit mAb binding to SLE antigens, the converse was not true.

Conclusions: These results suggest that *S. pneumoniae* and influenza vaccination are both capable of inducing antibodies which are cross-reactive to both vaccine antigens and SLE antigens and can escape selection in SLE individuals. In addition, these results indicate that antibodies monospecific to SLE antigens, particularly Ro and La, are rare in the SLE memory pool.

Antibodies to CCP Versus the Unmodified Arginine-Containing Peptide (CAP) as a Serological Marker To Differentiate SLE from RA. Jason Chan[2], Rufus Burlingame[1], Angela Ceribelli[2], Eric S. Sobel[3], Yi Li[3], Westley H. Reeves[3], Edward K. L. Chan[3] and Minoru Satoh[3]. [1]INOVA Diagnostics, Inc., [2]University of Florida, [3]University of Florida, Gainesville, FL

Purpose: Anti-cyclic citrullinated peptide (CCP) ELISA has been established as a serological marker of RA and used extensively in clinical practice. Early studies on anti-CCP emphasized the selective reactivity of sera from patients with RA for CCP but not with the corresponding unmodified peptide containing arginine (CAP); however, reactivity against CAP is not generally considered in clinical practice or in most studies using commercial anti-CCP ELISA. Recent studies reported that anti-CCP reactivity in non-RA patients is often not specific for CCP but also reactive with CAP, indicating the importance of comparing reactivity with CCP vs CAP. In the present study, reactivity against CCP was compared with that to corresponding unmodified peptide containing arginine (CAP3) in RA, SLE, scleroderma (SSc), polymyositis/dermatomyositis (PM/DM), and controls.

Methods: An ELISA kit using a peptide corresponding to CCP3 but containing unmodified arginine (CAP3) was developed. Anti-CCP3 and CAP3 in sera from SLE ($n = 201$), SSc ($n = 105$), PM/DM ($n = 44$), RA ($n = 84$), and healthy individual ($n = 34$) were tested by ELISA. Reactivity of each serum was calculated as units following the manufacturer's protocol. Patients were classified into 4 groups based on their serum reactivity against CCP vs CAP. Clinical information was from a database.

Results: Anti-CCP was positive in 70% of RA (69% were specific for CCP) vs 12% in SLE (7% specific for CCP), 6% in SSc, and 4% PM/DM,

similar to previous studies. All except one anti-CCP positive RA showed CCP selective reactivity but 42% (10/24) of anti-CCP positive SLE sera also reacted strongly with CAP, indicating lack of specificity for citrullinated peptide in SLE. Surprisingly, anti-CAP reactivity without anti-CCP was frequently seen in SLE (45%) but uncommon in other systemic rheumatic diseases or NHS ($P < 0.0001$).

	RA (84)	SLE (201)	SSc (105)	PM/DM (44)	NHS (34)
CCP(+) CAP(−)	**69%**	7%	5%	4%	0%
CCP(+) CAP(+)	1%	5%	1%	0%	0%
CCP(−) CAP (+)	1%	**45%**	5%	0%	3%
CCP(−) CAP(−)	29%	43%	89%	96%	97%

Conclusions: Anti-CAP without CCP was in high prevalence and relatively specific for SLE among systemic rheumatic diseases. When patients with early undiagnosed arthritis are seen at clinic, positive anti-CAP and negative anti-CCP can serve as a useful serological marker to differentiate SLE from RA. RA sera specifically reacted with CCP but not with CAP as previously described. In contrast to CCP specific reactivity in RA, CAP positivity was common in anti-CCP positive SLE sera.

Apoptotic Cell Bodies and Blebs Stimulate Self Reactive B-Cells Via Engagement of the BCR and Endosomal Toll-Like Receptors. John McCahan[2], Nathanial Green[1] and Ann Marshak-Rothstein[3]. [1]Boston University, Boston, MA, [2]Rheumatology Section, Boston University, [3]The University of Massachusetts Medical School, Worcester MA

Purpose: Apoptosis is a genetically programmed pathway of cell death that results in the condensation of a cell into sub-cellular particles. Under normal circumstances these are removed by surrounding cells and nearby phagocytes with a non-inflammatory effect. However, disruption of pathways involved in the removal of apoptotic cells has been shown to lead to signs of autoimmunity including autoantibody formation and tissue damage. The mechanisms that lead to the induction of auto-antibodies remain unclear. B cells from AM14 transgenic mice are a model of self reactive B-cells. They express an antigen receptor specific for IgG2aa/j and make a class of auto-antibodies known as rheumatoid factor (RF). It has been shown that immune complexes composed of IgG2a-chromatin or IgG2a-RNA can stimulate AM14 B-cells by the synergistic engagement of the antigen receptor and a member of the Toll-like receptor (TLR) family. Our purpose was to determine if apoptotic cells express auto-antigens that can stimulate self-reactive B-cells.

Methods: Keratinocyte and fibroblast cell lines were induced to undergo apoptosis by several methods including ultraviolet light exposure, etoposide, and serum starvation. In some experiments, cell surface proteins were biotinylated prior to the induction of apoptosis to nonspecifically label cell-surface-derived apoptotic debris. Subcellular particles were fractionated by differential centrifugation yielding two populations defined as apoptotic cell bodies and apoptotic blebs. Each fraction was analyzed by flow cytometry for the induction of apoptosis and autoantigen expression including nucleosomes, Ro, Smith antigen, and nucleoli. Immune complexes composed of subcellular particles bound by IgG2a autoantibodies were used to stimulate AM14 B cells. The contribution of TLR7 and TLR9 in this activation process was addressed by using cells from TLR-deficient mice.

Results: A robust proliferative response was induced by immune complexes composed of apoptotic cell bodies and blebs bound by autoantibodies. This effect was enhanced with IFN-β priming and stimulation was mediated by binding of the B-cell receptor and engagement of either TLR7 or TLR9. Biotinylation experiments indicated that the autoantigens were associated with the cell membrane. By comparing the activity of immune complexes formed with the anti-biotin mAb and mAbs specific for defined autoantigens, we have been able to address the differential expression of autoantigens on apoptotic debris derived from diverse cell types.

Conclusion: Our findings suggest that self reactive B-cells can be stimulated by apoptotic cell bodies and blebs through a TLR mediated process.

B Cell-Dependent Regulation (Breg) of T-Cell Proliferation Is Deficient in Systemic Lupus Erythematosus (SLE). Jacques-Olivier Pers, Sébastien Lemoine, Ahsen Morva, Christophe Jamin and Pierre Youinou. Brest University

Background: Association of B-cell depletion with increased inflammation in murine models suggests that B cells exert regulatory function, through inhibition of T-cell proliferation. The current study was aimed at evaluating the functional aspect of regulatory B cells in humans and specifically in autoimmune disorders.

Methods: B and T lymphocytes were negatively purified from peripheral blood of 9 healthy donors (HDs), 5 primary Sjögren's syndrome (pSS) patients, 5 SLE patients, and 4 rheumatoid arthritis (RA) patients. T cells were induce to proliferate by stimulation with anti-CD3 and anti-CD28 antibodies. The results was measured by flow cytometry analyses of CFSE stained cells. CD40, TLR9 and/or BCR stimulation were evaluated for their ability to activate the B cells and to induce a regulatory effect. Activated B cells were co-cultured with stimulated T cells, and modulation of the T-cell proliferative response assessed by flow cytometry.

Summary of the Results: Resting B cells from HDs did not affect the proliferation of T cells. In contrast, activated B cells exhibited regulatory effects resulting in a decreased T-cell proliferation rate. For B cells to modulate the T-cell response, CD40 activation appeared to be required. Furthermore, TLR9 signals synergized with CD40 to trigger the most efficient down-regulation of the T-cell proliferative response. Activated Breg from pSS and RA patients were all efficient whilst those of SLE were unable to control the T-cell proliferation.

Conclusion: Human Breg are functionally effective when appropriately activated. They can alter the T-cell proliferation. Our results suggest that both population behave as those of HDs in pSS and RA patients. In contrast, Breg properties appear to be defective in SLE patients. Whether this is due to defective Breg function or to T-cell refractory response remains to be determined.

B Cells Modify Regulatory T Cells in Healthy Individuals but Not in Patients with Systemic Lupus Erythematosus. Mark N. Lazarus, Hardeep S. Kalsi, David A. Isenberg and Michael R. Ehrenstein. UCL Div of Medicine, London, United Kingdom

Background: A number of publications have demonstrated that B cells can modify regulatory T cells (Treg) number indicating that B cells could contribute to the maintenance of tolerance via effects on Treg. B cell depletion therapy is currently used to treat some patients with systemic lupus erythematosus, but conflicting results have been obtained on the effects on Treg. We therefore investigated whether Treg are affected by removal of B cells *in vitro* and *in vivo*.

Methods: Treg were enumerated in healthy individuals and patients with lupus before and after rituximab therapy and correlated with B cell numbers. Intracellular cytokine staining for IL-2 and interferon gamma was performed in some assays. Peripheral blood mononuclear cells (PBMC) from healthy controls and lupus patients were cultured whole or following depletion of B cells by MACS LD™ beads and stimulated with anti-CD3/CD28. CD4, Foxp3 and CD25 expression assayed after 3 days using FACS.

Results: In patients with SLE, Foxp3 expression was significantly increased compared to healthy controls ($p<0.001$). Both CD4+Foxp3+ and CD4Foxp3hi T cells were significantly increased compared to healthy individuals. CD4+Foxp3+ T cells did not produce any IL-2 or interferon gamma suggesting that these are not simply activated T cells. Following B cell depletion, the increased frequency of Treg compared to healthy controls remained unchanged during depletion and repopulation. There was a strong correlation between Treg numbers and the CD19:CD4 ratio in healthy individuals (r2 0.6059, $p<0.005$), but not in lupus patients. Treg numbers were significantly reduced in the PBMC of healthy individuals ($p<0.001$) but not lupus patients following removal of B cells *in vitro*.

Conclusions: B cells partly drive an increase in Treg numbers *in vitro* following activation in healthy individuals. However, this was not observed in PBMC from lupus patients suggesting that this control on Treg is defective. The notion that the increased frequency of Treg in lupus patients is driven by B cell independent mechanisms is supported by our observation that Foxp3

expression remains unchanged following B cell depletion therapy and that a strong correlation between Treg frequency and B:T cell ratio in healthy individuals is lost in patients with SLE.

BAFF Binding Receptors (BBR) Related To Relapse after Rituximab in Patients with Reumatoid Arthritis (RA). Inmaculada De la Torre[1], Lara Valor[1], Rita Moura[2], Maria J. Leandro[3], Jonathan C. W. Edwards[3] and Geraldine Cambridge[3]. [1]Hospital Gregorio Maranon, Madrid, Spain, [2]Instituto de Biologia Molecular, Lisboa, Portugal, [3]University College London, London, UK

Background: Coordinated expression of BBR (BAFF-R, TACI, BCMA) control differentiation of B cells into immunoglobulin (Ig) secreting cells. We have previously shown that i) BAFF levels increase after B cell depletion with rituximab (rtx) in patients with RA, remaining raised even after B cell return ii) BAFF-R expression in naïve (NB) and memory B (MB) cells is reduced after rtx and related to clinical relapse independently of circulating BAFF levels or time to relapse after B cell return. iii) Class-switch recombination (CSR) and autoantibody production is also related to clinical relapse after rtx. When B cells differentiate into Ig secreting cells, BAFF-R is lost and BCMA up-regulated. TACI is induced upon B cell activation. Although it can be expressed on activated NB cells (<25%) it is related to CSR and memory-plasma cell differentiation.

Aim: To investigate BBR expression in relation to B cell maturation and clinical relapse in RA patients after rtx.

Methods: Phenotypic analysis of BAFF-R, TACI and BCMA expression on PBMC were performed using combinations of CD19, CD27, CD38 and IgD (% and mean fluorescence intensity-MFI) in normal controls (NC) (n: 5) and patients pre (n: 10) and after rtx, classified as concordant ie relapsing at B cell repopulation (C-R, n: 16), or discordant relapsing > 3 months after repopulation (D-R, n: 10) or non-relapsing after B cell return (D-NR, n: 11).

Results: Mean % of NB cell BAFF-R+ was significantly lower only in patients relapsing (C-R: 65.3%, D-R: 89.7%) when compared to NC ($p=0.027$,$p=0.026$). Percentage and MFI of MB cell BAFFR+ was significantly lower in all patients when compared to both NC and pre-rtx (%: $p<0.05$, MFI: $p<0.005$). In patients relapsing, % NB cell TACI+ tended to be higher in C-R than D-R (23.4% vs 9.9%). All patients pre and after rtx had significantly lower % of MB cell TACI+ when compared to NC ($p<0.05$). However % of MB cell TACI+ was significantly higher in D-NR when compared to D-R ($p=0.001$).

	BAFFR Naïve B cells		BAFFR Memory B cells		TACI Naïve B cells		TACI Memory B cells	
	%	MFI	%	MFI	%	MFI	%	MFI
NC (n:5)	98.5	126	95.43	107.6	16.2	206.5	81.5	155.7
Pre (n:10)	93.40	82.8	83.5	79.4	13.5	62.1#	50.4#	65.3#
C-R (n:16)	65.3#/*	45.3#/*	44.6#/*	51.7#/*	23.4	60.4#	43.6#	67.6#
D-R (n:10)	89.7#/**	60.9#	63.2#/*	57.5#/*	9.9	73.2#	38.9#/*	77.2#
D-NR (n:11)	92.03	47.6#	63.8#/*	56.7#/*	18.1	71.4#	49.8#/***	83.5#/***

P < 0.05: # vs NC, *vs Pre, **vs CR, ***vs DR

BAFF-R and BCMA did not always had an inverse correlation in plasma cells population after rtx. Finally, C-R patients had higher % of plasma cells than D-R and D-NR (16.5 vs 2.06 and 1.85; $p=0.03$ and $p=0.06$).

Conclusions: Rises in autoantibody levels have been related to clinical relapse after rtx. Modulation of BBR expression permissive to plasma cell formation in C-R patients with an earlier down regulation of BAFF-R and up regulation of TACI on (presumably activated autoreactive) NB cells may explain clinical relapse closer to B cell return. Normal BAFF-R expression on NB cells from D-NR patients may reduce the chance of becoming Ig-producing cells, allowing a normal maturation process within germinal center reactions. The consequences of disturbed BBR expression on B cell selection and the advancement or inhibition of progression to autoantibody production may explain timing of relapse after rtx.

Cellular and Serological Changes Following B Cell Repopulation after Rituximab Therapy Suggest Antibody-Independent Roles for B Cells in Systemic Lupus Erythematosus. Mark N. Lazarus, Andrew Fester, Tabitha Turner-Stokes, David A. Isenberg and Michael R. Ehrenstein. UCL Div of Medicine, London, United Kingdom

Introduction: For the last ten years B cell depletion therapy (BCDT) has been used in the treatment of systemic lupus erythematosus (SLE). However, the clinical improvements that follow BCDT are not always associated with a reduction in autoantibody titres suggesting that B cells might also induce disease via antibody-independent mechanisms.

Purpose: The aim of this study was to investigate whether B cells exert an effect on other immune cells which are known to be low in the blood of patients with active disease.

Methods: We analysed changes in the titres of anti-dsDNA antibodies, C3 and lymphocyte and monocyte numbers in the blood of 55 patients with SLE during B cell depletion and over a 52 week period following repopulation. PBMCs were obtained from 53 rituximab treated patients and analysed by flow cytometry for the expression of the activation markers CD69 and HLA-DR by CD4+ T cells. Chemokines were measured in the serum of 19 rituximab treated patients using a cytometric bead assay. *In vitro* experiments were carried out using PBMCs from 5 healthy controls and 5 patients with SLE.

Results: Our results showed that in patients with high anti-dsDNA antibody titres (above 100 IU/L) pre BCDT titres only fell in patients who remained in remission at 52 weeks following B cell repopulation ($p<0.05$) but did not change in patients that relapsed, either during the B cell depletion phase or during repopulation. C3 levels rose during B cell depletion and fell again during relapse but only in patients with high anti-dsDNA antibodies pre-BCDT ($p<0.01$; $p=0.07$). Lymphocyte numbers increased during repopulation in all patients ($p<0.05$) but fell during relapse only in patients who had low titres of anti-dsDNA antibody pre-BCDT ($p<0.05$). The fall in lymphocytes was paralleled by an increase in the expression of HLA-DR by CD4+CD49d+ T cells ($p<0.05$). Expression of CD69 was increased in all lupus patients and did not change following B cell depletion. *In vitro* experiments revealed that B cell activation directly led to increased expression of HLA-DR, but not CD69, on CD4+ T cells. Finally, monocyte numbers increased during depletion and fell during relapse in all groups ($p<0.05$). These changes in monocyte numbers coincided with a reduction in the serum levels of the monocyte recruiting chemokine, MCP-1 ($p<0.05$). MCP-1 production increased *in vitro* when PBMCs were stimulated through the B cell receptor ($p<0.05$).

Conclusion: These results demonstrate that changes in anti-dsDNA antibody and C3 correlate with response to BCDT but only in patients with high titres of anti-dsDNA antibody pre-BCDT. In patients with low anti-dsDNA titres pre-BCDT changes in lymphocyte and moncyte numbers may be more important. These changes in lymphocyte and monocyte numbers correlated with changes in HLA-DR expression by CD4+ T cells and MCP-1 levels respectively, suggesting that B cells might also induce the migration of T cells and monocytes to sites of inflammation in addition to producing autoantibodies. In conclusion, these results suggest that responses to rituximab may be partly governed by antibody independent mechanisms providing an explanation for some of the heterogeneous responses to BCDT that have been observed in SLE.

Elevated Serum BAFF Correlates with Loss of Mature B Cells and Promotes B Cell Recovery in Mice after B Cell Depletion Treatment. Yue Wang[2], Sandra Gallagher[1], Isharat Yusuf[1], Bahija Jallal[1], Anthony Coyle[1] and Ronald Herbst[1]. [1]MedImmune LLC, [2]MedImmune LLC, Gaithersburg, MD

Purpose: B cell depletion therapy with anti-CD20 monoclonal antibody (MAb) is an effective treatment for rheumatoid arthritis. There are ongoing clinical trials for treating autoimmune diseases with new B cell depleting MAb therapies, which may lead to more complete B cell depletion. It is therefore important to compare the outcome of B cell depletion with different MAbs and correlate that with changes of diseases status as well as pharmacodynamic (PD) markers. Previous studies have indicated that following treatment with anti-CD20 MAb in patients, serum BAFF (B cell activating

factor belonging to the TNF family) levels significantly increase. In this study, we used animal models to investigate the relationship of serum BAFF levels with loss of B cells and the contribution of BAFF to B cell depletion and recovery.

Methods: Mice were treated with escalating doses (0.1～10 mg/kg) of B cell depleting MAb. Numbers of B cells in blood and tissues (spleen and bone marrow) were quantified by FACS and serum BAFF levels detected by ELISA. To study whether elevated BAFF levels can affect B cell depletion, mice were dosed with 2ug recombinant BAFF before and during MAb treatment. To investigate the role of BAFF during B cell recovery, mice were treated with BAFF-R-Fc starting at the time when B cell recovery was detected. The biological function of recombinant BAFF and BAFF-R-Fc were confirmed by in vitro assays.

Results: Treatment of mice with B cell depleting MAb led to dose-dependent reduction in B cell numbers. At a dose of 0.5mg/kg or above, more than 90% of B cells were depleted, spanning from pre-B cells in bone marrow to mature B cells in spleens. The duration of B cell depletion is also dose-dependent and followed by reconstitution of B cells in blood and spleens. Changes in serum BAFF levels and B cell numbers were coupled: BAFF levels are elevated only when tissue B cells start to be depleted and, as B cells recover, serum BAFF levels drop back to baseline. The increase in BAFF levels significantly correlated with loss of mature B cells. When BAFF was elevated 5-fold during the treatment of MAb, B cell depletion was not affected. However, treatment with BAFF-R-Fc during B cell reconstitution resulted in a block of mature B cell regeneration. Consequently, spleen mature B cells were 90% lower in the BAFF-R-Fc treated group compared to the control group.

Summary: A newly developed MAb effectively depletes murine B cells even in the presence of high BAFF levels, supporting its use in autoimmune disease settings. Changes in serum BAFF level after MAb treatment reflect the loss of B cells. Lastly, increased BAFF levels promote B cell recovery and maturation, consistent with the known function of BAFF in regulating B cell survival and homeostasis. Future studies of changes in BAFF levels and functions in B cell depletion are warranted in the clinical trials.

Elimination of Autoantibody Producing Plasma Cells Using CXCR4 Antagonist AMD3100. Jason Weinstein[4], Yuan Xu[1], Matthew Delano[3], Yi Li[2], Lijun Yang[1], Eric S. Sobel[2], Lyle Moldawer[1] and Westley H. Reeves[2]. [1]University of Florida, [2]University of Florida, Gainesville, FL, [3]Universsity of Florida, [4]Yale University

Background: Autoantibodies cause disease either directly by interacting with target antigens in cells or tissues or by forming immune complexes that cause inflammation. B cell therapy has been only partially successful because autoantibody producing plasma cells do not express surface molecules, such as CD20, that are targets for the therapeutic mAbs. The chemokine CXCL12 (SDF1) retains plasma cells in stromal cell "niches" where they can survive for many years. We asked whether an antagonist of CXCR4, the receptor for SDF1, could be used to eliminate autoreactive plasma cells.

Methods: Anti-Sm/RNP autoantibodies were induced in BALB/c mice using pristane. Serum autoantibodies to the U1A protein were measured by ELISA. Anti-U1A antibody producing cells were detected by ELISPOT assay using recombinant U1A. Anti-U1A memory B cells were detected by culturing B cells with/without LPS for 5 d followed by ELISPOT assay. Ectopic lymphoid tissue (ELT) arising in the peritoneum after pristane injection was transplanted from untreated or AMD3100 pre-treated anti-U1A+ mice into the peritoneum of naïve recipients and serum anti-U1A levels were monitored for 35 d (ELISA).

Results: Numerous anti-U1A cells were found in the bone marrow (BM), spleen, and ELT of mice with serum anti-Sm/RNP autoantibodies induced by pristane. The BM contained memory B cells but few plasma cells, probably due to a striking reduction of SDF1 expression caused by inflammation. In contrast, ELT expressed high levels of SDF1 and contained many anti-U1A plasma cells but no memory cells. When transplanted into naïve recipients, anti-U1A plasma cells in the ELT continued to secrete anti-U1A antibodies, which could be detected in the recipients' serum. However, if the donor mice were pre-treated with AMD3100, plasma cells were absent by flow cytometry and anti-U1A autoantibody production in the recipients was abolished.

Conclusion: The induction of lupus with pristane generates two populations of anti-Sm/RNP B cells: plasma cells accumulate in the ELT, whereas memory cells accumulate in the BM. Using a transplantation system, autoantibody production from anti-Sm/RNP (U1A) plasma cells residing in ELT can be examined in isolation from memory B cells. AMD3100 (plerixafor), a drug approved for cancer therapy, can be used to eliminate these autoantibody-producing plasma cells. In combination with anti-CD20 mAb treatment, complete depletion of both memory B cells and plasma cells producing autoantibodies may be feasible.

Expression of the Idiotope 9G4 on Autoantibodies and B Cells from Patients with Rheumatoid Arthritis (RA): Description of a New B Cell Phenotype. Inmaculada De la Torre[1], Rita Moura[2], Maria J. Leandro[3], Jonathan C. W. Edwards[3] and Geraldine Cambridge[3]. [1]Hospital Gregorio Maranon, Madrid, Spain, [2]Instituto de Biologia Molecular, Lisbon, Portugal, [3]University College London, London, UK

Background: The rat monoclonal antibody 9G4 recognises an idiotope on V4–34-derived immunoglobulins(Ig). Antibodies encoded by V4–34 region are inherently autoreactive against red blood cell determinants. An estimated 15% of naïve B cells are 9G4+ but <1% of circulating Ig are 9G4+ in healthy controls (HC). In HC, 9G4+ B cells of a mature pre-switch phenotype (IgM+IgD+CD27+) are found in splenic marginal zones (MZ). 9G4+ B cells are also in tonsils from HC but excluded from germinal center (GC) reactions. Whereas in patients with lupus, post-GC memory B cells (IgD−CD27+) are present, suggesting defective B cell censoring (1). In RA, there is also some evidence that B cell tolerance is affected.

Objective: To determine whether RhF from RA and disease controls express 9G4 and to examine the phenotype of 9G4+ B cells in peripheral blood.

Methods: 9G4-expression on RhF and on total serum IgM and IgG were measured by ELISA in 22 seropositive RA and 20 RhF+ve 1o Sjogrens Syndrome (SS). Peripheral blood CD19+ B cells from 24 patients with RA and 7 HC were obtained by negative selection using MACs columns and stained to distinguish 9G4 expression on CD5 and CD27 populations and also within naïve (IgD+CD38+), transitional (IgD+CD38++), memory post-GC (IgD-CD38+), memory resting (IgD−CD38) and plasmablast (IgD−CD38+++) populations. Analyses were by Mann Whitney rank sum test.

Results: RhF levels and expression of 9G4 on total IgM and IgG were minimally higher in RA than SS patients ($p<0.05$). However 9G4 expression on RhF was significantly greater ($p<0.0001$) in RA vs SS patients. Percentages of 9G4+CD19+ B cells in HC and RA patients were similar (mean %: 6.36 vs 6.45) and most had a naïve phenotype (means: 44%, 42% respectively). Post-GC B cells and plasmablasts had means of 14.5% and 3.5% for NC and, for RA, 29.5% and 9.2% respectively. Gating on the 9G4+ population, CD5−CD27− phenotype was the most common in NC and RA (58.7% vs 55.7%). However a distinct population was described with a CD5+CD27+ B cell phenotype with similar proportions in HC and RA (13.1% vs 17.4%). Further, in some RA patients, a negative correlation was found between the percentage of B cells expressing CD5+CD27+ and 9G4 expression on RhF in the same sample.

Conclusions: Although post-GC 9G4+ B cells were not found in RA tonsils, we found 9G4 on RhF in patients with RA but not in SS. As RhF from patients with SS do not utilize V4–34, this suggests breakdown of 9G4 censoring in patients with RA, perhaps in areas outside secondary lymphoid tissue such as in the spleen or inflamed joints. We also found that HC and RA patients had circulating 9G4+ memory B cells and plasmablasts and describe a new B cell phenotype, CD19+CD5+CD27+, which often carries the 9G4 idiotope. CD5 is found on B cells in splenic MZ and is lost from B cells before entry into late stages of a GC. Also, CD27+ B cells have been shown to be predominantly CD5−CD23−. We suggest that retention of CD5 expression on 9G4+CD27+ B cells, whilst allowing development of a mature phenotype may be a self-censoring mechanism preventing access to GCs (perhaps by affecting BCR signaling) and hence antibody production from these potentially 'dangerous' autoreactive cells.

Expression of ZAP-70 in B-Cell Is a Feature of Peripheral Blood Repopulation after Rituximab Therapy in Rheumatoid Arthritis. Francesca Faustini, Barbara Tolusso, Giusy Peluso, Elisa Gremese, Silvia Canestri, Graziella D'Antona, Antonella Laria and Gianfranco Ferraccioli. Division of Rheumatology, Catholic University of the Sacred Heart, Rome, Italy

Background: The expression of ZAP-70 in B cells derived from synovial fluid of rheumatoid arthritis (RA) patients seems to define a subset of these cells characterized by increased survival and shows a correlation with the inflammatory and autoimmune phenotype. Aim of the study: to evaluate the expression of ZAP-70 by different subsets of peripheral blood B-cells before and after treatment with Rituximab (RTX) in a cohort of RA patients during a 24 months follow-up and, the relationship between ZAP-70 expression in B cells overtime and clinical response.

Methods: B-cell phenotype was analysed in 16 patients at baseline and at T6, T12 and T24 respectively. Flow cytometric analysis was performed by incubating PBMCs with anti-human monoclonal antibodies (CD19, IgD, CD38, CD27, CD5, CD23) as surface markers and intracellular ZAP-70. Demographic and clinical data were collected at baseline and every three months. The response to therapy was assessed through DAS score based on EULAR criteria. 15 healthy controls were enrolled in the study.

Summary of Results: The assessment of B cell subpopulations according to both IgD-CD38 and IgD-CD27 staining did not reveal significant differences in B cell distribution between patients at baseline and controls. We observed a significant decrease of the percentage of CD19+ cells at 6 (3.4±7.2 vs 9.5±3.5% at baseline, $p<0.001$), 12 (1.6±1.9%, $p<0.001$) and 24 months follow-up (2.2±2.9%, $p<0.001$) and an increase of the Bm2+Bm2′/eBm5+Bm5 ratio from baseline (2.4±2.7 vs 8.7±10.0 at 6 months FU, $p=0.08$; 6.9±7.9 at 12 months, $p=0.04$; 7.6±7.2 at 24 months, $p=0.02$). IgD-CD27 staining confirmed these findings by revealing a significant decrease of the percentage of IgD-CD27+ B cells at 6 months FU (19.5±14.8% at baseline vs 9.4±7.8%,$p=0.01$), IgD−CD27− (12.6±5.5% at baseline vs 7.6±5.2% at 6 months, $p=0.02$ and 8.0±6.6% at 12 months, $p=0.01$). In addition, a parallel decrease of CD38+/CD27+% during FU (9.0±5.9 at baseline vs 3.6±2.7% at 6 months, $p=0.005$; 5.0±6.0% at 12 months, $p=0.02$; 3.9±4.2% at 24 months, $p=0.004$) was observed. The percentage of CD19+/ZAP-70+ cells showed a significant increase at 6 months (2.6±3.6% at baseline vs 9.4±12.4%, $p= 0.005$), 12 months (10.6±8.4%, $p=0.001$) and 24 months (15.3±13.6%, $p=0.001$) after RTX treatment The baseline percentage of CD19+/ZAP-70+ was lower in good responders (0.5±0.2%) compared to poor responders at 6 months FU (3.0±1.0%, $p=0.02$) even if the difference was not confirmed at 12 months analysis.

Conclusions: In RA patients, regeneration of B-cells after BCDT is characterized by a significant decrease of the memory subset along with an increase of the percentage of B-cells expressing ZAP-70.

In Vivo Effects of Tocilizumab on Peripheral B Cells in Patients with Rheumatoid Arthritis. Petra Roll[2], Khalid Muhammad[2], Mathias Schumann[2], Stefan Kleinert[2], Thomas Dörner[1] and Hans-Peter Tony[2]. [1]Rheumatology and Clinical Immunology Charite Universitätsmedizin Berlin and DRFZ Berlin, Berlin, Germany, [2]Rheumatology/Clinical Immunology, University of Würzburg, Würzburg, Germany

Purpose: Interleukin (IL)-6 receptor inhibition by tocilizumab was recently licensed for the therapy of active rheumatoid arthritis (RA). IL-6 has been originally described to induce differentiation of B cells into antibody forming cells. However the in vivo effects of IL-6 inhibition by tocilizumab on the B cell compartment are currently not known.

Methods: 16 patients with active RA were treated with monthly intravenous infusion of 8 mg/kg tocilizumab. Immunphenotyping was performed at baseline, week 12 and 24.

Results: pre-treatment data indicate a higher proportions of pre-(IgD+/CD27+) and post-switch (IgD-/CD27+) memory B cells in RA patients compared to healthy donors(n=21). During tocilizumab treatment, proportion of both memory B cell subsets declined significantly at week 24 compared to baseline. In detail, pre-switch memory B cells decreased from median 19.6% (range: 3.4–39.0%) to 12.3% (5.5–38.1%, $p=0.04$) and post-switch memory B cells declined from 18.6% (7.1–32.2%) to 15.0% at week 24 (6.7–24.5%, $p=0.04$) respectively. The proportion of IgG+ B cells declined significantly from 6.7% to 4.9% ($p=0.02$) and 2.8% ($p=0.006$) at week 24. The proportion of IgA expressing B cells fell from 9.7% to 4.8% at week 12 ($p=0.03$) and to 2.7% at week 24 ($p=0.004$). Absolute numbers of IgA+ B cells also showed a significant decrease at week 12 ($p=0.01$) and at week 24 ($p<0.001$). In accordance with these results the levels of serum immunoglobulins IgA and IgG were also diminished at week 24 ($p<0.05$). In the naïve B cell compartment a significant increase in relative and absolute numbers of CD38hi/IgD+/CD10+ transitional type B cells is observed indicating that the B cell regeneration capacity is not altered under IL-6 receptor inhibition.

Conclusion: Our results indicate that IL-6 receptor inhibition by tocilizumab alters B cell homeostasis by significantly reducing peripheral pre- and post-switch memory B cells in rheumatoid arthritis. A marked reduction of CD19+/IgA+ and CD19+/IgG+ B cells parallels the significant decline of serum immunoglobulin IgA und IgG levels. The results indicate a reduction of B cell hyperactivity in RA by therapeutic IL-6 receptor inhibition.

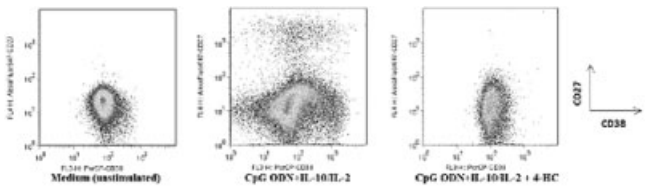
Predominant Suppression of Plasmablasts by Cyclophosphamide in Patients with Systemic Lupus Erythematosus: A Possible Therapeutic Mechanism. Yuko Okamoto[1], Yasuhiro Katsumata[5], Yasushi Kawaguchi[2], Manabu Kawamoto[5], Sayumi Baba[5], Kae Takagi[5], Takahisa Gono[5], Yuko Ota[5], Masako Hara[4] and Hisashi Yamanaka[3]. [1]Tokyo Women's Medical University, Tokyo, Japan, [2]Tokyo Women's Medical University, Tokyo, Japan, [3]Tokyo Women's Medical University, Shinjuku-ku, Tokyo, Japan, [4]Tokyo Women's Medical University, Kamakura Kanagawa, Japan, [5]Tokyo Women's Medical University

Purpose: Cyclophosphamide (CY) has remained the treatment of choice for major organ involvement in systemic lupus erythematosus (SLE). Although CY is generally considered to nonspecifically inhibit the inflammatory immune response, its precise therapeutic mechanism in SLE remains to be elucidated. We aimed to clarify the effect of CY on human B cell subsets *in vivo* and *in vitro*.

Methods: We analyzed 6 patients with recent onset of SLE without prior treatment and 6 normal healthy controls (NHCs). Peripheral blood mononuclear cells (PBMCs) were isolated from heparinized whole blood of these subjects by density gradient centrifugation. Immunofluorescence staining of PBMC for flow cytometry was performed using anti-CD19, anti-CD27, and anti-CD38 antibodies. Multi-color analyses were performed using FACSCalibur and FlowJo software. For *in vitro* assays, $CD19^+$ B cells were positively selected form PBMCs of normal healthy donors by MACS. To mimic B cell homeostasis in active SLE *in vivo*, B cells were cultured with CpG ODN 2006 plus IL-10/IL-2 in the presence or absence of 4-hydroperoxycyclophosphamide (4-HC), activated congener to CY. B cell proliferation, differentiation, and antibody secretion were determined as described below.

Results: The frequencies of plasmablasts ($CD19^+/CD27^{high}/CD38^{high}$) were significantly higher in active untreated SLE patients than in NHCs (13±8% and 1.4±1.2%, respectively; $p = 0.01$) whereas the frequencies of memory B cells ($CD19^+/CD27^+/CD38^{low}$) were significantly lower in active SLE patients than in NHCs (20±11% and 38±9%, respectively; $p = 0.01$). The frequencies of plasmablasts in active SLE patients significantly decreased when re-analyzed 2 weeks after the initiation of IV CY (0.5 g/m^2 of body surface bolus; oral prednisolone was also administered several days ahead) than those before treatment (2.2±1.7% and 12±7%, respectively; $p = 0.006$). In the B cell proliferation assay using tetrazolium salt as a chromogenic indicator for NADH, the O.D. values of the stimulated cells were significantly higher than in those of the unstimulated cells and this proliferation was significantly inhibited by 4-HC (0.66, 0.13, 0.11, respectively). The frequencies of plasmablasts were significantly lower in the unstimulated cells and the 4-HC-treated cells than in the stimulated cells.



The production of IgM and IgG in the culture supernatants were also significantly inhibited by 4-HC: the mean concentrations of IgM and IgG were 62.0 μg/ml and 18.8 μg/ml, respectively in the culture supernatants of the stimulated cells whereas those of the unstimulated cells and the 4-HC-treated cells were under the assay ranges by ELISA.

Conclusions: This study shows that administration of CY predominantly suppresses activation and viability of plasmablasts *in vivo* and *in vitro*. These findings may indicate that therapeutic effect of CY on SLE is at least partly exerted through this mechanism.

Progesterone Receptors Regulate Humoral Immunity. Alan Wong, Chang Li, Ed Clark and Grant Hughes. University of Washington

The immunological mechanisms linking female reproduction and autoimmune diseases like systemic lupus erythematosus are poorly understood. In humans and genetically susceptible mice, estrogen increases disease development. In the same settings, progesterone (Pg) appears to decrease the risk of disease. How this occurs is unknown but likely involves differential regulation of IFN-α, Th1-related signals and B cell differentiation. Under physiologic conditions, Pg's immunomodulatory effects are thought to be mediated by two Pg receptor types expressed in mouse and human leukocytes: intracellular Pg receptors (PRs) that are ligand-activated transcription factors, and membrane-bound Pg receptors (mPRs) that are linked to inhibitory G proteins and unrelated to PRs. Very little is known about the differential immune functions of PRs vs. mPRs. Recently, Pauklin and Petersen-Mahrt (J Immunol, 2009) demonstrated that Pg, via PR, inhibits B cell class switch recombination (CSR) through transcriptional repression of the activation-induced deaminase (AID) gene in vitro. Here, we show the first genetic evidence linking Pg and PR signaling to adaptive humoral immunity in vivo.

To investigate the role of PRs in antibody (Ab) responses, we used mice in which signaling through PR was genetically ablated (PRKO) by targeted disruption. Female PRKO mice are infertile due to reproductive organ abnormalities. Male PRKO mice are fertile. To assess a role for PR in Ab responses, we measured primary thymus-dependent (TD) Ab responses to alum-adsorbed DNP-KLH and primary thymus-independent type 2 (TI-2) responses to DNP-Ficoll. Female PRKO mice generated significantly more (up to 5 fold) anti-DNP IgM, IgG1, and IgG2a compared to their wild type (WT) female littermates after immunization with DNP-KLH in alum. Thus, PR regulates T cell-dependent humoral immune responses in vivo. Interestingly, these differences were more pronounced in male mice, indicating that PR regulates humoral immunity regardless of sex. PRKO and WT mice did not differ in total serum Ig levels and or numbers of spleen B cells, T cells, and DCs before immunization, and thus differences in Ab responses were not simply due to underlying differences in lymphocyte/DC development. We also observed no differences in anti-DNP Ab responses after TI-2 immunization, suggesting that Pg, via PR, may regulate T cells, B cells or responses to alum. We detected no consistent differences in the ability of PRKO vs. WT purified spleen B cells to undergo CSR in vitro, either to T-cell associated signals (anti-CD40) or LPS. However, CD4+ T cells from PRKO mice produced more IFN-γ, but not IL-4, in response to anti-CD3/CD28 stimulus compared to WT T cells. Thus, the elevated IgG2a responses in PRKO mice may be due to dysregulated Th1 differentiation. This work supported by NIH grant AI073739 and an ARRA supplement to AI073739.

SLAP Deficiency Alters Both Central and Peripheral B Cell Tolerance Leading to Decreased Autoantibody Production. Lisa K. Peterson[2], Laura A. Shaw[2], Luke F. Pennington[1] and Leonard L. Dragone[2]. [1]Denver, CO, [2]National Jewish Health, Denver, CO

Background: Intrinsic defects in lymphocyte signaling have been implicated in the pathogenesis of autoimmunity. Manipulation of B cell function by altering BCR complex-mediated signaling could be a viable strategy to treat autoimmune disease. Src-like adaptor protein (SLAP) has been shown to influence BCR levels and signaling in developing B cells. We hypothesized that SLAP deficiency through increasing BCR levels and strength of signal through the BCR complex can enhance receptor editing, anergy and/or the negative selection of autoreactive B cells and prevent the development of autoimmune disease.

Methods: To test this hypothesis we utilized two models of autoantibody production. First, we bred the 3H9H/E56R (56R) mice, which express an anti-dsDNA reactive BCR heavy chain that leads to BCR editing and anergy induction, to SLAP-deficient mice to examine the effects of SLAP deficiency on central tolerance. Second, we immunized SLAP-deficient and wild-type BALB/c mice with a peptide mimetope for dsDNA that causes the development of a germinal center dependent anti-dsDNA antibody response that leads to a lupus-like autoimmune disease to examine the effects of SLAP deficiency on peripheral B-cell tolerance mechanisms.

Results: SLAP deficiency (SLAP−/−) led to a significant decrease in serum levels of dsDNA in E56R mice. Compositional analysis of bone marrow revealed a decrease in kappa usage by pre-B cells in SLAP−/− 56R mice, suggesting increased receptor editing. However, splenic B cell subsets and kappa vs. lambda light chain usage were similar between 56R and SLAP−/− 56R mice, indicating that anergy could also be responsible for the decreased production of autoantibodies. To determine if SLAP deficiency leads to enhanced receptor editing verse anergy, hybridomas were generated. Consistent with enhanced receptor editing, less of the SLAP−/− 56R hybridomas produced antibodies reactive with dsDNA compared to the 56R hybridomas. The decreased number of hybridomas secreting anti-dsDNA was due to a qualitative change in light chain repertoire in SLAP−/− 56R mice. The light chain repertoire of SLAP−/− 56R hybridomas was biased toward Vκ21D, an efficient editor of anti-dsDNA reactivity. In contrast, incomplete editors of anti-dsDNA reactivity, Vκ38C and Vκ20, predominated in 56R hybridomas. In the mimetope model of lupus-like autoimmunity, despite the production of an equivalent level of anti-peptide antibodies compared to BALB/c controls, SLAP-deficient mice did not produce anti-dsDNA antibodies upon immunization with a peptide mimitope of dsDNA.

Conclusions: These data show that enhanced signaling through the BCR complex could be a general strategy to treat autoimmune disease by eliminating autoreactive B cells that are either maintained as a result of inefficient receptor editing or failed negative selection upon germinal center formation. Our studies are the first step in defining signaling networks downstream of the BCR signaling complex that can be targeted to enhance the negative selection of autoreactive B cells and possibly prevent or treat antibody-mediated systemic autoimmune disease.

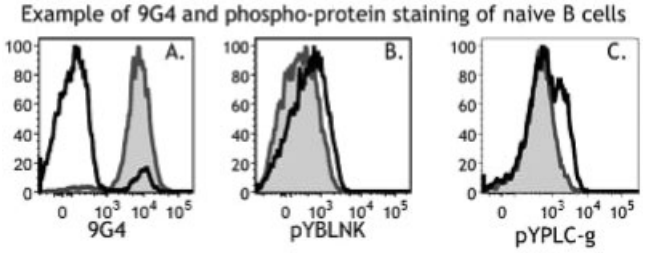
SLE Anti-CD45/B220 9G4 Autoantibodies Induce Attenuated BCR Signaling: Implication for Disease Pathogenesis. Scott A. Jenks[2], Anna E. Schroeder[1] and Ignacio Sanz[2]. [1]Duke University, Durham, NC, [2]Univ of Rochester, Rochester, NY

Background and Purpose: It has long been known that anti-lymphocyte autoantibodies (ALA) are frequently present in SLE patients. One well characterized and prevalent group of ALA are VH4.34-encoded antibodies recognized by the rat anti-human idiotype antibody 9G4 (9G4+ antibodies). In addition to recognition of I/i blood group antigens, these antibodies also bind the glycosylation isoforms of CD45 (B220+) found predominately on naive B cells. In a subset of SLE patients, close to 100% of *ex vivo* naive B cells are positive for the 9G4 idiotype and when naive B cells from healthy controls are incubated with serum from these patients they also become positive for 9G4. Since CD45 is a phosphatase that can alter signaling, binding of 9G4 antibodies to naive B cells may directly change signaling in these cells. Supporting this idea, we have observed that B cells from an SLE patient with strong *ex vivo* 9G4 binding showed poor B cell receptor (BCR) induced phosphorylation as compared to healthy control B cells. The goal of this study was to directly test the hypothesis that binding of 9G4+ antibodies to CD45/B220 will decrease BCR signaling in naive B cells.

Methods: Lymphocytes from healthy control donors were incubated with serum from SLE patients with strong *ex vivo* 9G4 staining on the majority of naive B cells (shaded histogram), SLE patients without strong 9G4 staining (open histogram), and healthy control serum. These cells were then stimulated through the BCR with antibodies against IgM. After fixation and permeabilization, 9G4 staining was measured flow cytometrically (Fig A) and BCR signaling was quantified by measuring induced phosphorylation of BLNK (pY84,) (Fig B) and pPLC-γ2 (pY759) (Fig C).

Results: Anti-IgM induced phosphorylation in naive B cells was substantially reduced in cells incubated with serum from SLE patients with *ex vivo*

9G4 binding, as compared to healthy control serum, or serum from SLE patients without strong 9G4 staining. The reduction in signaling correlated with the degree of 9G4 binding detected. Furthermore this attenuation was dependent on 9G4 immunoglobulin, since purified immunoglobulin was sufficient to reduce phosphorylation and serum depleted of 9G4 no longer had this effect.



Conclusions: Several alterations in BCR signaling have been described in human SLE. While some of these changes are likely due to genetic alterations of signaling molecule expression or function, others may be a direct result of the disease process. These findings describe a novel mechanism by which SLE ALA can directly modulate signaling. These changes in signaling may alter B cell, proliferation, survival, and differentiation and thus help explain some of the abnormalities in B cell homeostasis observed in SLE. Reduced BCR signaling may also result in impaired clonal deletion and reduced RAG upregulation and receptor editing thereby contributing to the increased generation of auto-antibodies.

Specific Histone Deacetylase (HDAC2) Inhibition in B Cells May Protect Lupus. Nilamadhab Mishra[1], Kristen Delany[3] and Issac Snowhite[2]. [1]Wake Forest Univ Health Scienc, Winston-Salem, NC, [2]Wake Forest Univ Health Science, [3]Wake Forest Univ Health Sciences

Background: Systemic lupus erythematosus (SLE) is characterized by polyclonal B cell activation, autoantibody production, and glomerulonephritis. The mechanisms how autoreactive B cells are produced in lupus are incompletely understood. Using genome wide mass spectrometry analysis, we have recently demonstrated that there exists histone hypoacetylation in splenocytes from MRL/lpr mice compared to controls. Based upon these findings, we hypothesize that environmental factors trigger epigenetic alternations such as histone modifications to induces autoreactive B cells by up regulating epigenetic modulators histone deacetylases (HDAC).

Material and Methods: Naive B cells isolated from either MRL/lpr or C57BL6(B6) mice (6–7 wk) spleens by CD43+ depletion with MACs beads followed by separation with a non-continuous percoll gradient. The cells were incubated with TLR agonist: TLR-3 poly I:C (5mg) TLR4-LPS (E.coli 111:B4) 25mg/ml, TLR-7,imiquimod (1mg/ml) TLR-9 CpG (3mM) or CpC control, anti-IgM, anti-Cd40, IL-4 etc. Cells were harvested for RNA and protein at six hours post-stimulation. Western blot were performed for different histone deacetylases. MRL/lpr mice were treated with valproic acid that selectively affects HDAC2.

Results: Stimulation of naïve B-cells with agonist for TLR 3, 4, 7 or 9 results in increased mRNA and protein expression of HDAC2 among the HDAC tested. We confirmed the activation status of B cells by measuring IL6 and IL-10. We also examine the major transcriptional regulators MTA3, MITF, XBP1 and IRF4, which are systematically down regulated or up-regulated upon activation. The levels of these proteins were overexpressed in MRL/lpr mice compared to C57/Bl6 mice splenocytes. All mice in the valproic acid treatment group did not develop skin disease whereas all mice in the placebo group developed skin disease. Ninety percent of mice on the treatment arm had grade I proteinuria compared to 20 percent in the vehicle group. The mean renal activity score was 4.833 $\pm$0.654 in the treatment group compared to 8.00 $\pm$0.00 in the vehicle group. The serum anti-dsDNA autoantibodies levels were decreased in valproic acid treatment group. There was no change in serum Ig subtype between vehicle vs treatment group.NZB/W F1 mice treated with valproic acid have decreased proteiuria, kidney disease and autoantibody production In vivo treatment with valproic acid decreased HDAC2 in spleen. Genetic knock down of HDAC2 in B cells by using mice MB1 and CD19 cre trasgenic mice demonstrated that HDAC2 is required for early B cell development. HDAC2 deficient mice have decreaed Pro-B cells in bone marrow and decreased follicular and marginal zone B cells in spleen.

Conclusion: These data suggest that isoform specific histone deacetylase inhibitors may be beneficial for lupus by blocking B cell development.

The Effects of the Anti-CD22 Monoclonal Antibody Epratuzumab on B-Cell Surface Proteins. Anthony Shock[1], Derek Brown[2], Kenneth Crook[2] and Timothy Bourne[2]. [1]UCB, Slough, Berkshire, Slough, United Kingdom, [2]UCB, Slough, Berkshire, UK

Background: Epratuzumab is a humanized monoclonal antibody against CD22 that is currently being evaluated clinically in systemic lupus erythematosus (SLE). Epratuzumab treatment of SLE patients has been shown to reduce CD22 cell surface expression on B cells (Jacobi A, et al. Ann Rheum Dis 2008;67:450–457). The aim of the current study was to investigate the kinetics of internalization on B cells from healthy volunteers in vitro and to look at a range of other cell surface proteins.

Methods: In vitro studies used B cells that were purified by negative selection from human blood and incubated with a concentration range of epratuzumab or an isotype control antibody over time, washed and then stained with fluorescently-labeled antibodies specific to a range of B-cell surface proteins and analyzed by flow cytometry. In order to assess the expression of CD22 in the presence of epratuzumab, a non-competing anti-CD22 antibody (S-HCL-1-PE) was employed. CD22 internalization was also evaluated in a qualitative manner in confocal microscopy experiments employing Alexa488-labeled epratuzumab. Whole blood flow cytometry was used to assess CD22 levels on B cells from SLE patients dosed with epratuzumab.

Results: Epratuzumab caused rapid internalization of B-cell surface CD22 in a range of in vitro experiments. Maximal internalization occurred in 30–60 min at concentrations above 1–2 μg/mL but the level of internalization typically did not exceed 50–70%, even at higher antibody concentrations, suggesting that some B-cell surface CD22 is resistant to epratuzumab-induced internalization. Internalization was prevented by prior cell fixation with paraformaldehyde and was reduced at a lower temperature. Internalization of CD22 on B cells in response to epratuzumab treatment was also confirmed using confocal microscopy. Although epratuzumab was capable of modulating the expression of CD22 in B-cell cultures, it had no consistent effect on several other B-cell markers including IgM, IgD, CD19, CD20, CD27, CD32, CD38, CD69, CD79b, CD95, and HLA-DR Class II measured at a variety of time points up to 6 days. Internalization of CD22 was observed on a number of B-cell subsets following treatment of SLE patients with epratuzumab.

Conclusions: Epratuzumab stimulated rapid internalization of its target, CD22, on human peripheral blood B cells in vitro and in vivo but had no consistent effect on a range of other B-cell markers. This could lead to modulation of B-cell functional responses that are regulated specifically by CD22, which may be relevant in the context of SLE.

752

The Effects of the Anti-CD22 Monoclonal Antibody Epratuzumab on Peripheral Blood B Cells and Immune Responses In Vivo, and Immunoglobulin Production In Vitro. Anthony Shock[1], Derek Brown[2], Kenneth Crook[2], Stevan Shaw[2], Timothy Bourne[2], Roland Foulkes[2] and Geoffrey Rose[2]. [1]UCB, Slough, Berkshire, Slough, United Kingdom, [2]UCB, Slough, Berkshire, UK

Background: Epratuzumab is a humanized monoclonal antibody against CD22 currently being evaluated clinically in patients with systemic lupus erythematosus (SLE). The aim of the current study in cynomolgus monkeys was to investigate the effects of epratuzumab on circulating B cell numbers and on the immune response to the challenge antigens keyhole limpet hemocyanin (KLH) and tetanus toxoid (TT). Additionally, the effect of epratuzumab on immunoglobulin production from human B cells in culture was assessed.

Methods: In one study, cynomolgus monkeys received 4 weekly doses of epratuzumab at 10, 60, or 160 mg/kg and peripheral blood CD20+ B cell numbers were enumerated by flow cytometry. In a second study, cynomolgus monkeys received epratuzumab at 3 different dose levels (1 $\times$ 60 mg/kg, 1 $\times$

10 mg/kg or 4 × 60 mg/kg), or saline. The primary immune response to administered KLH and the secondary immune response to TT were then monitored over time using ELISAs to measure anti-TT and anti-KLH titers in serum. Human peripheral blood mononuclear cells (PBMC) or purified B cells from human tonsils were cultured in vitro with a range of stimuli and the effect of epratuzumab on IgG and IgM production, assessed by ELISA, was monitored after 5 days in culture.

Results: There was a 50–60% reduction in the numbers of circulating B cells in cynomolgus monkeys after treatment with epratuzumab at all doses tested, which occurred within 24 hours of dosing. Animals treated with saline showed a primary anti-KLH response, with an increase in both IgG and IgM antibody levels. Epratuzumab did not inhibit this response at any dose tested, and there was no significant difference between the groups when area under the curve of the response over time for each animal was assessed. A robust IgG anti-TT was demonstrated but, again, no significant difference was observed between the differently dosed groups and saline controls. The production of IgG and IgM from human PBMC or tonsil B cells in culture was unaffected by incubation with a range of concentrations of epratuzumab.

Conclusions: Epratuzumab treatment caused a reduction in B cells but had no effect on the capacity to raise an antibody response to challenge antigens in cynomolgus monkeys in vivo. The production of immunoglobulin by B cells in culture was also unaffected by epratuzumab. This might indicate that the efficacy of epratuzumab in SLE patients is unlikely to be accompanied by a gross effect on the capacity to generate an adaptive immune response.

753

TNF Blockade Impairs the Induction of T-Cell Dependent Antibody Responses. Gabriela Franco Salinas[1], Leen De Rycke[2], Sophie Brouard[4], Vojislav Jovanovic[4], Frederique Moizant[4], Tineke Cantaert[2], Mirjam van der Burg[3], Barbara Barendregt[3], Paul Peter Tak[2], Jean-Paul Soulillou[4] and Dominique Baeten[2]. [1]Academisch Medisch Centrum, University of Amsterdam, Amsterdam, Noord Holland, The Netherlands, [2]Academisch Medisch Centrum, University of Amsterdam, Amsterdam, The Netherlands, [3]Immunology, Erasmus Medical Center, Rotterdam, Netherlands, [4]Institut de Transplantation et Recherche en Transplantation, INSERM U643, Nantes, France

Objectives: TNFα blockade induces anti-nuclear antibodies in patients with Spondylarthritis (SpA) and Rheumatoid Arthritis. These antibodies are related to increased levels of circulating nuclear antigens, restricted to IgM autoantibodies and directed to T cell independent (TI) but not T cell dependent (TD) antigens. Based on this observation, we tested in experimental models and in arthritis patients whether TNF blockade impairs the maturation of TD humoral responses.

Methods: Cardiac allografts from LEW.1W rats were transplanted to LEW.1A rats treated with either anti-TNF or control antibody. Alloantibodies and graft rejection were monitored for 25 days. Transplanted hearts were assessed by histology, immunohistochemistry, and qPCR. In humans, PBMCs from SpA patients treated with TNF blockade or NSAIDs were collected for analysis of somatic hypermutation, lymphocyte phenotype, expression of costimulatory molecules and in vitro assays. After 12 weeks of treatment, both patient groups were vaccinated with a TD vaccine to Hepatitis B and a TI vaccine to S. Pneumoniae. Vaccine-specific antibody titers were determined in serum.

Results: In the rat allotransplantation model, anti-TNF treatment at the day of transplantation inhibited the induction of IgM ($p=0.004$) and IgG ($p=0.020$) alloantibodies as well as IgG deposition in the graft ($p=0.015$). Accordingly, leucocyte infiltration was decreased and graft architecture was better preserved in treated animals ($p=0.015$), resulting in prolonged graft survival ($p=0.020$). In this model, TNF blockade did not affect the Th1/Th2 balance, TLR expression nor the expression of regulatory molecules like TGF-beta, IDO and FoxP3, suggesting that the beneficial clinical effects may be primarily related to the inhibition of the humoral response.

In human arthritis, the antibody response against the TD vaccine was almost completely blocked ($p=0.010$) during TNF blockade in SpA patients whereas TI responses were less affected. An effect on the germinal center (GC) reaction was suggested by a decreased degree of somatic hypermutation of peripheral B cells in SpA patients treated with anti-TNFα blockers versus controls ($p=0.040$). In addition, we observed an increased number of circulating memory B cells ($p=0.001$) but a decrease in plasmablasts ($p=0.039$) in anti-TNF treated patients. This was not due to an intrinsic B cell defect as B cells obtained after TNF blockade in vivo did not display defective differentiation towards plasma cells in vitro. Neither could we evidence a defective B cell activation as the post-GC B lymphocytes of anti-TNF treated patients displayed an increased expression of CD40 and HLA-DR ex vivo and a normal expression of CD80 and CD86 after TD stimulation in vitro. Further studies on the underlying mechanisms will focus on extra-follicular B cells as well as B cell migration.

Conclusion: TNF blockade impairs the induction of humoral responses in rodents and humans, with the most pronounced effect on TD responses. Whereas the exact mechanism is currently under investigation, these data reveal a novel mechanism of action of anti-TNF with potential relevance for several fields of clinical immunology.

ACR Poster Session B
Epidemiology and Health Services Research: MSK, CTD and SLE Focus
Tuesday, November 9, 2010, 9:00 AM–6:00 PM

754

A Systematic Literature Review of the Direct Costs of Systemic Lupus Erythematosus (SLE) in the United States (US). Katherine A. Slawsky[1], Ancilla Fernandes[2], Susan Manzi[3], Lauren Fusfeld[1] and Thomas F. Goss[1]. [1]Boston Healthcare Associates, Inc., Boston MA and Washington DC, [2]MedImmune LLC, Gaithersburg, MD, [3]West Penn Allegheny Health System, Pittsburgh, PA

Background: SLE is a chronic autoimmune disorder characterized by acute flares and remissions. Patients are generally managed with multiple medications depending on disease severity, tolerance, and organ system affected. SLE is thought to be associated with high symptom and economic burden; here, we review annual direct medical costs associated with SLE among adults in the US.

Methods: English-language studies published between 01/2000 and 04/2010 were systematically reviewed from both MEDLINE PubMed and the Cochrane databases. Studies were included if they reported direct medical costs of SLE among adults in the US.

Results: Nine studies reporting direct costs associated with SLE in the US and published since 01/2000 were identified, Five were excluded: one focused on a pediatric population, a review with no pooled- or meta-analyses, one study that reported no actual cost estimates and two studies that applied Canadian costs to US patients. A summary of the selected four studies is presented in **Table 1** below.

Table 1. Results Summary

Data Source	Study 1: Commercial Claims	Study 2: Commercial Claims	Study 3: Medicaid Claims	Study 4: Patient Self-reported Resource Utilization
Sample size	6,269	15,590	2,298	815
Year of data analysis*	2005	2006	2006	2004
Mean annual direct cost per SLE patient (all patients) (SD)	$20,926 ($45,093)	N/A	$17,009 ($27,531)	$13,735 ($25,792)
Mean annual direct cost per SLE patient without nephritis (SD)	$16,575 ($29,300)	$12,273 ($27,096)	$13,758	N/A
Mean annual direct cost per SLE patient with nephritis (SD)	$62,651 ($106,745)	$31,274 ($52,800)	$29,034 ($41,876)	N/A
Mean annual direct cost per control patient (SD)	$7,794 ($22,014)	N/A	$9,788 ($18,078)	N/A

*All costs included to 2009 values using the GDP calculator, available http:GDP.html

Studies examined main cost categories of inpatient, outpatient, and pharmacy services, all of which contributed substantially to total costs, although the relative contribution of each main cost category varied. Median costs were consistently lower than means reported, suggesting outliers may skew overall mean costs. With the exception of study 4, all studies examined annual costs of newly diagnosed or newly active patients. No identified studies explicitly examined costs of specific treatments or disease manifestations (other than nephritis), or disease severity. Methodologies varied across studies, with patient self-reported resource

utilization generating the lowest estimates vs. claims analyses; Medicaid claims analyses generated lower incremental cost estimates for SLE patients vs. control patients compared to commercial claims analysis.

Conclusions: SLE is associated with substantial annual direct cost burden in the US; however, little research has been done examining costs associated with specific treatments, cost variation by disease severity, and disease manifestations. It is important to investigate the variation in costs due to disease severity and manifestations as newer and more expensive biologic therapies continue to emerge.

A Systematic Review To Appraise the Quality of Cost-Effectiveness Studies of Biologic Agents for the Treatment of Rheumatoid Arthritis. Maria A. Lopez-Olivo[1], Yomei Shaw[2] and Maria E. Suarez-Almazor[3]. [1]The University of Texas M.D. Anderson Cancer Center, Houston, TX, [2]The University of Texas M.D. Anderson Cancer Center, [3]University of Texas, MD Anderson Cancer Center, Houston, TX

Background: Recently, evidence has shown outstanding advances in the therapeutic approach of rheumatic diseases. The use of cost effectiveness (CE) analyses in this area has increased rapidly due to the elevated costs of the newer agents. We conducted a systematic literature review to describe the methodology reported and integrate findings from publications concerning CE in the treatment of rheumatoid arthritis with biologic agents.

Methods: We searched for cost effectiveness studies (including cost-utility) on the use of infliximab, etanercept, adalimumab, golimumab, certolizumab, tocilizumab, rituximab, abatacept and anakinra for the treatment of rheumatoid arthritis, published through September, 2009. Sources included electronic databases (MEDLINE, EMBASE, BIOSIS, etc.) and pertinent websites. Review of 2957 citations revealed 29 CE analyses. Two independent reviewers evaluated development methods of selected studies using the Quality of Health Economic Studies (QHES) tool, which was adapted using the OMERACT criteria for economic evaluations in RA.

Results: Of the 29 publications, 14 reported CE in etanercept, 12 in infliximab, 7 in adalimumab, 3 in abatacept, 2 in rituximab and 1 anakinra. Dates of publication ranged from 2002 to 2009. The studies varied in the clinical trials they cited as evidence for their models (1 to 9 RCTs) and with respect to the costs reported. There was also disparity in how studies were modeled and reported. 82% of the included studies fulfilled 75% or more of the quality of reporting criteria obtaining a "good" quality score. Studies failed to report perspective of the analysis (76%), discounting rate (35%), and pre-specification of groups at the beginning of the study -if estimates came from a subgroup analysis (72%). Studies published after 2006 scored higher in most quality domains than those published before (55%) and also those studies evaluating RA over a time period of >1 year (83%). Studies funded by industry tend to score lower (<75%) than those conducted by agencies (NS). Only 1 study did not specify the source of funding (QHES 81.5%). Figure 1 shows that 80% of the studies funded by industry concluded a cost-effective intervention versus 54% of those funded by agencies (NS).Overall, treatments included in the studies were consider cost-effective (ICERs reported in the studies were within or below 50,000 USD, even after adjusting for inflation and differences in currencies).

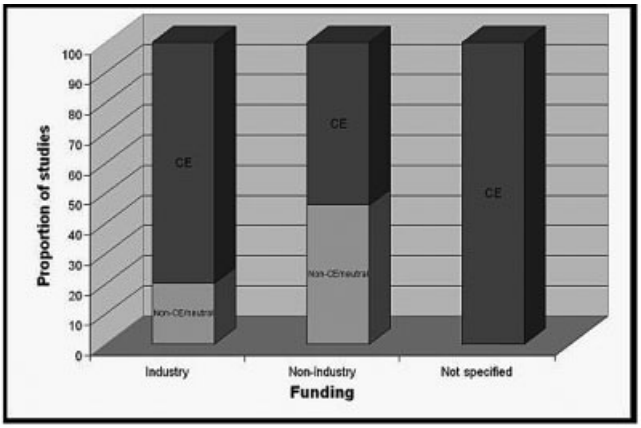

Figure 1. CE* per source of funding.
*as described by the authors

Conclusion: Quality scores of CE articles published were rated acceptable. However, several differences in the design, key assumptions, and model structure were observed among studies. There is a need for more uniformity and transparency in the methodology reported in economic evaluations of biologic agents for the treatment of rheumatoid arthritis to help decision makers make better informed decisions.

Agreement between Tuberculin Skin Test and Interferon-γ Assay in Korean Patients with Rheumatoid Arthritis and Ankylosing Spondylitis before Initiation of Anti-Tumor Necrosis Factor Therapy. Yong-Geun Jeong[1], Ji-Min Kim[3], Su-Jin Moon[3], Seung-Ki Kwok[3], Ji-Hyeon Ju[3], Kyung-Su Park[3], Sung-Hwan Park[2] and Ho-Youn Kim[1]. [1]Seoul St. Mary's Hospital, The Catholic University of Korea, Seoul, Republic of Korea, [2]Seoul St. Mary's Hospital, The Catholic University of Korea, Seoul, Korea, Republic of, [3]Seoul St. Mary's Hospital, The Catholic University of Korea, Seoul, South Korea

Purpose: To evaluate the responsiveness to tuberculin skin test (TST) in patients with rheumatoid arthritisis (RA) and ankylosing spondylitis (AS) before initiating tumor necrosis factor α blockade (TNF-blocker) therapy, and assess its association with clinical feature and interferon-γ (IFN-γ) assay result.

Method: We retrospectively reviewed the medical records of 483 patients (251 RA, 227 AS, 5 Psoriatic arthritis, PsA) who were treated with TNF-blockers in the department of rheumatology in Seoul St. Mary's Hospital between January 2003 and April 2009 and then analyzed the clinical characteristic and the result of TST and IFN-γ assay.

Results: TST results of 483 patients (251 RA, 227 AS, 5 PsA) were examined. The mean diameter of induration was smaller in RA patients than in AS patients (3.88mm±6.24 versus 7.52mm±8.24, $p< 0.001$). TST positive rate was higher in AS compared to RA (41.4% vs 20.7%; $p<0.001$). Both in RA patients and AS patients, there were no significant difference between positive TST group and negative TST group in terms of disease activity, age, past history of tuberculosis and steroid usage. The positive rate of IFN-γ assay was comparable between RA and AS (41.3% versus 45.8%, $P=0.768$). The agreement rate between TST and IFN-γ assay was 71.9% (kappa=0.422) in the whole group, 68.3% (kappa=0.319) in RA, and 76.2% (kappa=0.533) in AS. IFN-γ assay was positive in 26.2% of RA patients and 4.5% of AS patients in whom TST result was negative. Tuberculosis prophylaxis was done in 22.0% of RA patients and 39.1% of AS patients ($p < 0.001$).

Conclusion: There was difference in the TST positive rates between Korean patients with RA and AS. In RA patients, lower TST positive rate gave rise to the low rate of tuberculosis prophylaxis before TNF-blocker therapy compared to AS patients. Interferon-γ assay could identify patients with latent tuberculosis despite negative TST result and should be performed with TST for diagnosis of latent tuberculosis before TNF-blocker therapy, especially in RA patients.

Riedel[5], George Goldberg[4], Damon L. Bass[1] and Gregory J. Dennis[3]. [1]GlaxoSmithKline, King of Prussia, PA, [2]GlaxoSmithKline, Research Triangle Park, NC, [3]Human Genome Sciences, Rockville, MD, [4]i3 Innovus, Eden Prarie, MN, [5]i3 Innovus, Eden Prarie, NC

Background: Disease severity and disease flares are based primarily on clinical presentation in patients with systemic lupus erythematosus (SLE). Disease severity is not clearly defined but physicians often describe it as a relationship between disease activity and the organs involved. In clinical trials, disease activity and disease flares are usually assessed by composite scores which integrate both clinical and serologic variables. The ability to describe and evaluate populations of SLE patients in real-world settings has been limited due to the lack of validated methodology to identify disease severity or flares in administrative claims data.

Objective: To develop and validate algorithms to identify SLE disease

severity and the occurrence and severity of SLE flares using administrative claims.

Methods: This retrospective, observational study (BLM001HO) used medical and pharmacy data (1/1/2004 to 12/31/2008) from a large managed care health plan. Patients meeting the following criteria were included in the analysis: at least 3 years of continuous enrollment in the health plan (1 year pre-index baseline period and 2 years follow up period); were between the ages of 18 and 64; and evidence of SLE. Evidence of SLE during the study period was based upon a combination of diagnosis code (ICD-9 code 710.0x), visits to rheumatologists, and filled prescriptions for lupus treatment medications (corticosteroids, antimalarials, and immunosuppressives).

Results: A total of 2990 SLE patients were identified in the claims database (92% female, mean age 44 years). Initial algorithms for identifying SLE disease severity and flare severity were developed based upon the literature and clinical consultation with 2 rheumatologists and 1 internal medicine physician. Medical and pharmacy claims for a random sample of SLE patients were reviewed to understand the patients' profile of health services utilization, conditions diagnosed, use of services, types of providers visited, and medication use. Following evaluation of these patient profiles, the initial algorithms were further refined. The resulting disease severity and flare algorithms were applied to the SLE patients identified in the claims database.

SLE Disease Severity Algorithm

Mild	**Not Moderate or High Severity**
Moderate	**Moderate Rx OR Moderate Medical Condition**
Rx	• Oral corticosteroid dose ≥7.5 mg/day to <60 mg/day • Immunosuppressive agent (excluding cyclophosphamide)
Medical Condition:	• *Cardiorespiratory:* myocarditis, pericarditis, pleurisy/ pleural effusion, vasculitis (excluding aortitis) • *Constitutional:* hepatitis (non-viral) • *Gastrointestinal:* acute pancreatitis, lupus enteritis/colitis • *Hematology:* hemolytic anemia • *Musculoskeletal:* ischemic necrosis of bone • *Neuropsychiatric:* demyelinating syndrome/acute inflammatory demyelinating polyradiculoneuropathy, mononeuropathy/polyneuropathy, myelopathy, pseudotumor cerebri, seizure
High	**Intensive RX OR Severe Medical Condition**
Rx:	• Oral corticosteroid dose ≥60 mg/day • Cyclophosphamide • Rituximab
Medical Condition:	• *Cardiorespiratory:* aortitis, arterial/ venous thrombosis, cardiac tamponade, pulmonary hemorrhage, stroke/TIA • *Gastrointestinal:* intestinal pseudo-obstruction • *Neuropsychiatric:* acute confusional state/psychosis, aseptic meningitis, cranial neuropathy • *Ophthalmic:* optic neuritis • *Renal:* end stage renal disease (ESRD)

SLE Flare Severity Algorithm

Mild	
RX Initiation	• Hydroxychloroquine or other antimalarial • Oral corticosteroid with prednisone-equivalent dose of ≤7.5 mg/day • Non-immunosuppressive therapy (NSAIDS, androgens)
Moderate	
RX Initiation	• Oral corticosteroid with prednisone-equivalent dose >7.5 mg/day & ≤ 40 mg/day • Immunosuppressive therapy (excluding cyclophosphamide)
Medical	• ER visit with primary diagnosis of SLE (710.0x) or SLE-related condition • Office visit for new SLE-related condition*
Severe	
RX Initiation	• Oral corticosteroid with prednisone-equivalent dose >40 mg/day • Cyclophosphamide
Medical	• Hospital stay with primary diagnosis of SLE (710.0x) or SLE-related condition*

***SLE-related conditions:** disease severity conditions above or any of following: arthritis/arthralgia, dry eye/tear film insufficiency, rash, low white blood cell count (leukopenia, neutropenia, lymphocytopenia), lymph node enlargement, myalgia/ myositis, urticaria

Applying the algorithm, 26% of patients were classified as mild, 52% were moderate and 22% had high disease severity over the 2 year follow-up period. Over the 2-year period, 71% of patients had at least one mild flare, 86% had at least one moderate flare and 20% had one or more severe flares.

Conclusions: This study has identified an algorithm that may be used to identify SLE disease severity and the occurrence and severity of SLE flares, using a combination of medical and pharmacy administrative claims. Applying this clinically-based algorithm to other claims-based studies of patients with SLE may enable an improved evaluation of SLE patients in real-world populations.

Colonization and Infection by Staphylococcus Aureus among Those Using Biologic Therapy. Cara Varley[1], Atul A. Deodhar[1], Benjamin Ehst[1], Antony Bakke[1], Andrew Blauvelt[1], Robert Vega[2] and Kevin Winthrop[1]. [1]Oregon Health & Science University, Portland, OR, [2]Oregon State Public Health Laboratory, Hillsboro, OR

Purpose: While much emphasis has been placed on preventing opportunistic infections in patients with inflammatory arthritis on biologic therapy, it is clear that most serious infections are due to "routine" organisms like Staphylococcal aureus. In an ongoing prospective study we investigated the relationship between rates of new and persistent colonization, new infections with S. aureus, use of biologics and underlying disorder.

Methods: We prospectively enrolled patients with autoimmune inflammatory diseases from the rheumatology and dermatology clinics of our University. Patients receiving or being considered for biologic therapy (etanercept, infliximab, adalimumab, rituximab, abatacept) were surveyed for the presence of S. aureus infection risk factors and assessed for S. aureus colonization. Specimens collected from the bilateral nares and inguinal folds were cultured using standardized laboratory isolation procedures and screened for the presence of methicillin-resistant S aureus (MRSA) utilizing Spectra™ MRSA test media (Remel Scientific®) and mannitol salt agar containing 4 mcgs of oxacillin (MSAO, Remel Scientific). We actively sought to follow up patients to assess persistence of colonization, new colonization, or infections with S. aureus, and their relationship with underlying disease and therapy.

Results: We enrolled a total of 392 patients (rheumatoid arthritis n=103 (26.3%), psoriasis or psoriatic arthritis n=205 (52.3%), ankylosing spondylitis n=29 (7.4%), combination of two or more n=15 (3.8%), other n=40 (10.2%). At baseline, 156 (39.8%) were colonized with S. aureus, of which 19 (12.2%) had MRSA. Our baseline colonization rates of S. aureus (39.8%) and MRSA (4.8%) were significantly higher than previously reported for the general population (30.8% and 0.8%, $p<0.01$ for both). Colonization rates were similar between biologic users and non-users (40.1% and 39.5%, $p=0.90$) but were significantly higher for psoriasis patients compared to those with RA (43.4% and 30.1%, $p=0.02$). 184 patients, of which 122 (66.3%) were on biologic therapy, completed follow up (mean 1 year, range 0.2–2.3 years). Biologic agents did not increase the risk of persistent (colonized at baseline and follow up) or new colonization (see table). Self reported infections were more common in persistently colonized patients compared to those newly, transiently or never colonized (RR=4.25, 95% CI 0.99–18.25, $p=0.05$).

Conclusion: Inflammatory arthritis patients at our center have higher rates of S. aureus colonization than the general population, and the risk of new colonization is not modified by biologic therapy. Prospective follow up shows a trend towards increased risk of subsequent infections in those with persistent S aureus colonization.

Colonization and Self Reported Staph Infections at Follow-up, N = 184

	Persistent Staph Colonization	No Staph Colonization	Self Reported Staph Infection

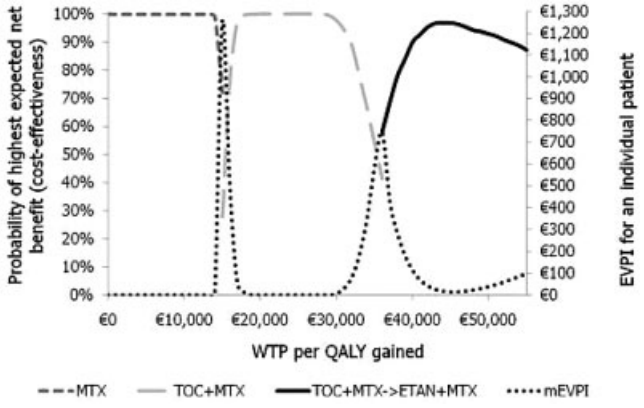
Comprehensive Health Economic Assessment of Sequenced Treatment with Biologics in Moderate-to-Severe Rheumatoid Arthritis: Analysis Based on ACR50 and ACR70 Responses. Erkki J. O. Soini[1], Taru A. Hallinen[1], Markku J. Kauppi[3], Ville Vihervaara[4] and Kari Puolakka[2]. [1]ESiOR Oy, Kuopio, Finland, [2]Lappeenranta Central Hospital, Lappeenranta, Finland, [3]Päijät-Häme Central Hospital, Lahti, Finland, [4]Roche Oy, Espoo, Finland

Purpose: To assess the cost-utility and multinomial expected value of perfect information (mEVPI) of sequenced treatment with biologics in moderate-to-severe rheumatoid arthritis (msRA) after failure of traditional disease modifying antirheumatic drug(s) (tDMARD).

Methods: A probabilistic, individual sampling (microsimulation) model was developed to compare ten different treatment sequences among 3,000 hypothetical Finnish msRA patients in a lifetime scenario. Adalimumab+methotrexate (MTX), etanercept+MTX or tocilizumab+MTX were used as first biologics followed by up to three other biologics. Best supportive care including tDMARDs was assumed to be used after exhaustion of treatment options with biologics. Treatment with MTX alone was added as further comparator. The clinical outcomes (no ACR50, ACR50 and ACR70 responses conditional to the use of biologic drugs) were obtained from a recently published mixed treatment comparison and quality-adjusted life-years (QALY) were estimated based on the Health Assessment Questionnaire (HAQ) scores using a nonlinear equation: $EQ5D = 0.82 - 0.11*HAQ - 0.07*HAQ^2$. Resource use was estimated based on HAQ scores from published references and valued with Finnish unit costs (euro, year 2009). Analyses were performed from payer perspective (productivity losses were excluded) using 3% annual discount rate.

Results: Compared to MTX alone, treatment with tocilizumab+MTX was more cost-effective than treatment with etanercept+MTX. Both tocilizumab+MTX and etanercept+MTX dominated adalimumab+MTX. An additional QALY gained with tocilizumab+MTX costs euro15,478 (mEVPI euro1,258/patient) compared with MTX alone. An additional QALY gained with tocilizumab+MTX followed by etanercept+MTX costs euro35,543 (mEVPI euro748/patient) compared with tocilizumab+MTX. According to cost-effectiveness acceptability frontier (Figure, which presents the optimal treatment options, their probabilities of cost-effectiveness and mEVPI), only MTX alone, tocilizumab+MTX or tocilizumab+MTX followed by etanercept+MTX should be considered, if willingness to pay is euro0–50,000 per QALY gained.



With euro30,000 per QALY gained, tocilizumab+MTX had 97.6% probability of being cost-effective. The results were relatively robust in sensitivity analyses. mEVPI indicated that the value of additional research information is relatively low.

Conclusions: After tDMARD failure, tocilizumab+MTX or tocilizumab+MTX followed by etanercept+MTX were the most cost-effective biologics for patients with msRA.

Correlations between 3 Work-Related Patient-Reported Outcome Instruments for Patients with Ankylosing Spondylitis. Annelies Boonen[2], Walter P. Maksymowych[3], Sumati Rao[1], Naijun Chen[1] and Mary Cifaldi[1]. [1]Abbott Laboratories, Abbott Park, IL, [2]University Hospital Maastricht, Maastricht, Netherlands, [3]University of Alberta, Edmonton, AB

Background: Several instruments have been proposed to measure work productivity but comparative studies of these instruments for rheumatic diseases are lacking. We assessed correlations between 3 work-related patient-reported outcome (PRO) instruments and the Bath Ankylosing Spondylitis Functional Index (BASFI) for patients with ankylosing spondylitis (AS). We further evaluated the percentage of productivity loss and the impact on cost between the 3 PRO measures of presenteeism, defined as the impact of disease on a patient's ability to perform at work.

Methods: Data were obtained from the Patient-Reported Outcomes Survey in Employment (PROSE) study, a longitudinal, observational study of AS and work productivity. Participants diagnosed with AS completed an online patient survey that included 3 measures of work productivity: 1) the Work Productivity and Activity Impairment Questionnaire (WPAI), 2) the Work Limitations Questionnaire (WLQ), and 3) the Quality-Quantity Method (QQ). The WPAI measures absenteeism, presenteeism, overall work productivity impairment, and activity impairment related to AS, whereas the WLQ has 4 subscales (time management, physical demands, mental–interpersonal demands, and output demands) that assess effects of health problems on job performance (ie, presenteeism) and are combined into an overall productivity loss score. The QQ measures overall quantity and quality of work. Spearman correlation coefficients between mean scores for the WPAI components and the WLQ and QQ scores were calculated at baseline.

Results: Mean changes in WPAI presenteeism and WLQ productivity loss scores represented 22% and 5.5% work productivity loss, respectively. WPAI presenteeism was significantly correlated with WLQ time management ($r=0.59$; $p<0.0001$) and mental–interpersonal demands ($r=0.59$; $p<0.0002$) subscales as well as the overall productivity loss score ($r=0.63$; $p<0.0001$). BASFI was correlated with WPAI absenteeism ($r=0.29$, $p<0.0005$), presenteeism ($r=0.63$, $p<0.0001$), overall impairment ($r=0.65$, $p<0.0001$), and WPAI activity impairment ($r=0.69$, $p<0.0001$); WLQ time management ($r=0.50$, $p<0.0001$), mental–interpersonal demands ($r=0.49$, $p<0.0001$), output demands ($r=0.55$, $p<0.0001$), and productivity loss ($r=0.58$, $p<0.0001$); and QQ quality ($r=-0.44$, $p<0.0001$) and quantity ($r=-0.45$, $p<0.0001$). BASFI was not correlated with the WLQ physical demands subscale. Using the more sensitive, disease-specific 22% reduction in WPAI presenteeism (assuming a 40-hour work week at $18/hr),[1] potential work productivity loss for patients with AS could result in loss of $158/wk per patient with AS.

Conclusion: Although the 3 work-related PRO instruments are highly correlated with each other, there are important differences between the absolute values used to estimate productivity loss. Independent of the approach, loss of work productivity is strongly correlated with BASFI. Further research is required to assess full aspects of validity between the 3 work-related PRO instruments.

Costs for Health Care, Prescribed Drugs, and Sick Leave Differ for Patients with Different Types of Spondylarthropathy. Ann B. I. Bremander[1], Aleksandra Turkiewicz[2], Martin Englund[2], Emma Haglund[3], Gisela Kobelt[2], Ingemar F. Petersson[2] and Britta Strömbeck[2]. [1]Musculoskeletal Research Center, Dept. of Orthopedics, Clinical Sciences, Lund University, Lund, Research and Development Cente at Spenshult Hospital for Rheumatic Diseases, Oskarstrom, Sweden, [2]Musculoskeletal Research Center, Dept. of Orthopedics, Clinical Sciences, Lund University, Lund, Sweden, [3]Musculoskeletal Research Center, Dept. of Orthopedics, Clinical Sciences, Lund University, Lund, Sweden, Research and Development Cente at Spenshult Hospital for Rheumatic Diseases, Halmstad, Sweden

Background: The spondylarthropathy (SpA) group includes ankylosing spondylitis (AS), psoriatic arthritis (PsA), SpA associated with inflammatory bowel disease (IBD), undifferentiated SpA (USpA), and reactive arthritis

(ReA). It has earlier been established that patients with AS have increased costs for health care and sick leave compared with the background population, but data for other types of SpA are scarce.

Objectives: To estimate the costs for health care, prescribed drugs, and sick leave for the different SpA diagnoses.

Methods: The Skåne Health Care Register (SHCR) in southern Sweden is a legislative, mandatory register based on physicians ICD-10 diagnoses and covers all in- and outpatient health care (total population 1.2 million). We identified all subjects having received a diagnosis of SpA during the years 2003–2007. To increase specificity we required all cases to be diagnosed at least once by a rheumatologist/internist or having had at least two clinic visits with the diagnosis by any other physician. Costs due to health care consumption, prescribed drugs and sick leave were retrieved from the SHCR, the Prescribed Drug Register, and the Swedish Social Insurance Agency for the years 2006–2007, including all patients 15 to 65 years of age.

Results: 3 561 patients with SpA (1 758 men and 1 803 women), mean age (SD) 47 (12) years were identified. The IBD patients had the highest costs for health care (mean €8 057, SD €10 545), prescribed drugs (mean €4 360, SD €6 610), and sick leave (mean € 11 570, SD €10 415) whereas PsA patients had the lowest cost for health care (€4 757, SD €7 080) but the second highest for prescribed drugs (mean €2 986, SD €6 391) and sick leave (mean € 9 224, SD €11 222) (Table).

Table. Cost is Euro (€) for health care, prescribed drugs, and sick leave per patient with Spondylarthropathy (SpA) over 2 years.

	N	Age Mean (SD)	Sex Men/ Women	Cost for health care Mean (SD) Median (range)	Cost for prescribed drugs Mean (SD) Median (range)	Cost for sick leave Mean (SD) Median (range)
All SpA	3.561	47 (12)	1.758/1803	5.234 (9.350)	2.557 (5.917)	8.542 (11.130)
				2.510 (0–158.830)	178 (0–58244)	1188 (0–47595)
AS	793	48 (11)	532/261	5547 (9765)	2872 (6021)	9191 (11535)
				2627 (0–140359)	187 (0–38587)	1751 (0–47.595)
PsA	1.578	49 (12)	704/874	4757 (70)	2986 (6.391)	9.224 (11.222)
				2.477 (0–77.428)	301 (0–58.244)	1.974 (0–455)
IBD	84	49 (11)	24/60	8.057 (10.545)	4.360 (6.610)	11.570 (10.415)
				4.079 (263–58.057)	1.251 (0–25.761)	10.837 (0–36851)
USpA	613	44 (11)	251/362	5.371 (9.120)	2.018 (5.511)	7.740 (10.827)
				2.445 (0–83.805)	97 (0–45.449)	503 (0–42.145)
ReA	493	43 (14)	247/246	5.604 (12.436)	1.044 (3.871)	5.791 (10.108)
				2.346 (0–158.831)	23 (0–53.395)	0 (0–39.348)

Conclusion: The different clinical forms of SpA are also seen as different cost patterns for health care, prescribed drugs, and sick leave due to disease consequences and treatment traditions.

Disclosure: A. B. I. Bremander: None; **A. Turkiewicz:** None; **M. Englund:** None; **E. Haglund:** None; **G. Kobelt:** None; **I. F. Petersson:** None; **B. Strömbeck:** None.

762

Dietary Intake of Vitamin D during Adolescence and Risk of Adult Onset Systemic Lupus Erythematosus and Rheumatoid Arthritis. Linda T. Hiraki[3], Karen H. Costenbader[1], Kassandra Munger[4] and Elizabeth W. Karlson[2]. [1]Brigham & Women, Boston, MA, [2]Brigham and Womens Hospital, Boston, MA, [3]Harvard School of Public Health, Boston, MA, [4]Harvard School of Public Health

Introduction: Early life exposures have been implicated in the etiology of rheumatoid arthritis (RA) and systemic lupus erythematosus (SLE). Vitamin D has immunomodulatory effects with implications as an etiologic and therapeutic factor in several autoimmune diseases including SLE and RA. There are no studies on vitamin D intake during adolescence and the risk of adult onset SLE and RA.

Objectives: We examined the relationship between reported vitamin D intake during adolescence and incidence of adult onset RA and SLE in two prospective cohort studies, the Nurses' Health Study (NHS) and Nurses' Health Study II (NHSII).

Methods: Previously validated food frequency questionnaires (FFQ) on high school diet, completed by 75,458 NHS participants in 1986 and 45,948 NHSII participants in 1998 (maximum recall of 47 and 35 years respectively), were used to calculate nutrient intakes during adolescence. Incident RA and SLE cases were confirmed by medical record review. Cox-proportional hazards regression relative risks (RR) and 95% CI were calculated for quintiles of adolescent dietary vitamin D intake and incident RA, incident SLE. Calorie adjusted and multivariate adjusted analyses were completed, with adjustment for demographic, dietary and sun-exposure related factors. Random effects models were used to obtain a single combined estimate of association across the two cohorts.

Results: Incident RA was confirmed in 652 NHS and 126 NHSII participants (total 778), and incident SLE was confirmed in 122 NHS and 52 NHSII participants (total 174) over a mean followup of 329 and 207 months for NHS and NHSII respectively. Calorie-adjusted and multivariate-adjusted models did not show significant associations between adolescent vitamin D intake and risk of adult onset RA and SLE when comparing the 5th quintile of vitamin D intake to the 1st quintile (Table 1).

Table 1. Estimated Hazard Ratios and 95% CI of Association between adolescent vitamin D intake and incident RA and SLE

	NHS	NHSH	Pooled
Number of RA cases	652	126	778
HR (95% CI) Energy adjusted Total Vitamin D	1.03 (0.8, 1.32)	1.06 (0.62, 1.82)	1.03 (0.82, 1.3)
HR (95% CI) Multivariate adjusted Total Vitamin D	0.87 (0.6, 1.26)	0.96 (0.51, 1.81)	0.87 (0.64, 1.13)
Number of SLE cases	122	52	174
HR (95% CI) Energy adjusted Total Vitamin D	1.09 (0.62, 1.95)	1.08 (0.47, 2.45)	1.03 (0.65, 1.63)
HR (95% CI) Multivariate adjusted Total Vitamin D	1.16 (0.52, 2.56)	0.69 (0.25, 1.88)	0.87 (0.5, 1.46)

Conclusions: We did not find associations between reported dietary intake of vitamin D during adolescence and risk of RA or SLE in adulthood. This may be due to inaccurate reporting of adolescent diet, focus on a short time period of exposure, unavailable serum vitamin D levels during this exposure period of interest or lack of effect of dietary intake of vitamin D. Small numbers of incident cases also reduced our power to detect an association if one existed.

Direct and Indirect Costs of Spondlyoarthritis Patients Pre- and Post-Diagnosis. Noam Kirson[2], Howard Birnbaum[2], Sumati Rao[1], Elyse Swallow[2], Tracy Waldman[2], Elias Dayoub[2] and Mary Cifaldi[1]. [1]Abbott Laboratories, Abbott Park, IL, [2]Analysis Group, Inc., Boston, MA

Background: Spondyloarthritis (SpA) includes 5 related clinical conditions: ankylosing spondylitis (AS), psoriatic arthritis (PsA), undifferentiated SpA (uSpA), reactive arthritis (ReA), and enteropathic arthritis (EA). Prior research reports significant economic burden associated with subtypes of SpA, but little is known about the profile of direct (medical and prescription drug) and indirect (work loss) costs over time. This study examines direct and indirect costs of SpA patients in the US during a 3-year period starting 2 years before SpA diagnosis.

Methods: Patients aged 18–64 years with ≥2 diagnoses for a subtype of SpA (ICD-9-CM: 720.0, AS; 696.0, PsA; 720.9, uSpA; 099.3 or 711.1x, ReA; or 713.1, EA) were identified in a private insurance claims database (covering 40 employers; ~9,000,000 lives) in the US (1999–2007). Patients had continuous enrollment 24 months before and 12 months after first (index) SpA diagnosis, and no claims for rheumatoid arthritis unless diagnosed with PsA. SpA patients were demographically matched to controls with no history of SpA. Per-patient direct costs for all SpA patients (N=2,194) and indirect costs (absenteeism and disability) for an employee subset (N=737) were compared with controls for 12 consecutive 3-month periods. Bootstrapping was used to compare excess costs (SpA vs. controls) within periods.

Results: Mean excess direct (medical plus drug) costs for SpA patients ranged from \$781 ($P<0.01$) to \$2,565 ($P<0.01$). Mean excess medical costs increased during the year prior to index, peaked at \$1,890 ($P<0.01$) in the 3 months after diagnosis, and decreased approximately 60% in months 4–12 post-index. Increased rheumatologist costs persisted in the post index period (excess \$176 to \$132, $P<0.01$), while total outpatient and inpatient costs fell approximately 40% and 70%, respectively, 3 months after diagnosis. Mean excess drug costs accelerated sharply post index, peaking at \$786 ($P<0.01$), driven largely by an increase in TNFα inhibitor costs (excess \$490, $P<0.01$, 9–12 months post-index). Mean excess indirect costs rose during the year prior to index, peaked in the 3 months following diagnosis (\$789, $P<0.01$), but fell during the subsequent year to levels similar to those 6 months pre-index (\$388, $P<0.01$). A decline in absenteeism accounts for >90% of the fall in indirect costs post index.

Conclusion: Despite post-index increases in costs associated with SpA-targeted treatment (e.g., TNFα inhibitors, rheumatologist visits), total direct

and indirect costs decline considerably 3 months after diagnosis and return to pre-index levels. Further research is necessary to determine the causal relationship between treatment and potential direct and indirect cost savings.

Distinguishing Levels of Disease Flare in Patients with Systemic Lupus Erythematosus Using Administrative Claims Data. Nicole Engel-Nitz[5], James Burke[5], Cindy P. Garris[3], Priti Jhingran[1], Damon L. Bass[2] and Gregory J. Dennis[4]. [1]GlaxoSmithKline, [2]GlaxoSmithKline, King of Prussia, PA, [3]GlaxoSmithKline, RTP, NC, [4]Human Genome Sciences, [5]i3 Innovus

Background: Systemic lupus erythematosus (SLE) is a chronic, autoimmune disorder affecting multiple organ systems of the body, characterized by acute exacerbations (flares) and remissions. Disease activity indices have been shown to be reliable when used in clinical trials but have limited application with claims data.

Objective: To differentiate between patients with mild, moderate, and severe SLE flares using a claims-based flare severity algorithm.

Methods: This retrospective observational study used administrative claims from a large managed care health plan (1/2004 - 12/2008). SLE patients 18–64 years of age were included in the analysis if they had continuous enrollment in the health plan for at least 3 years with medical and pharmacy benefits. A diagnosis of SLE was defined by any of the following criteria: a) 3 or more rheumatologist visits on separate dates (no time requirement) with a diagnostic code for SLE (ICD-9 code 710.0x); b) 2 or more rheumatologist visits ≥60 days apart with a diagnostic code for SLE; or c) 2 or more rheumatologist visits on separate dates with a diagnostic code for SLE AND 1 or more filled prescriptions for a medication typically used for the treatment of SLE. Claims-based algorithms consisting of disease activity and medications prescribed were developed and used to identify and classify disease severity (mild, moderate, high) and flares by severity (mild, moderate, severe) for each patient over a 2-year period. Patients with multiple flares could be counted more than once in each flare severity group during the period of observation. Cost of a flare episode was analyzed by flare severity.

Results: A total of 2,990 patients met the inclusion criteria of which 22% were classified as having high severity, 52% with moderate and 26% with mild disease severity. Over the 2 year period, 86%, 99% and 99.5% of patients with high, moderate, and disease severity, respectively, had at least 1 flare ($p<0.001$). Of patients in the high disease severity group, 61% experienced at least 1 severe flare, compared to 13% of patients with moderate and 1% of patients with mild disease severity ($p<0.001$) over the 2 year period. Mean number of flares over 2 years was 4.1, 7.0 and 8.0 for patients with mild, moderate and high disease severity, respectively ($p<0.001$). The cost of a severe flare is approximately 18 times higher than a mild flare and 11 times higher than a moderate flare.

Conclusions: Nearly all patients with SLE had at least one flare identified in the claims data. The mean number of flares was higher for patients with moderate and severe disease compared with mild disease. The cost of a severe flare is substantially higher than moderate or mild flares. Averting a severe flare may be associated with significant cost savings.

Does Cigarette Smoking Affect Disease Phenotype in Systemic Lupus Erythematosus. Meenakshi Jolly[2], Rachel A. Mikolaitis[4], Joel A. Block[4] and Michelle Petri[1]. [1]John Hopkins University, [2]Rush University Medical Center, Chicago, IL, [3]Rush University Medical Center, Chicago, IL, [4]Rush University Medical Center

Purpose: We previously reported a greater prevalence of cutaneous activity and damage among smokers than nonsmokers, in a predominantly African American cohort of patients with Systemic Lupus Erythematosus (SLE). We now present the results from a larger SLE cohort comprised of the HOPKINS Lupus Database and PROSE Database (Patient Reported Outcomes in Systemic Lupus Erythematosus). We aimed at determining if any differences in disease activity and/or damage were observed based on patients current smoking status in this large ethnically heterogeneous SLE cohort.

Methods: Cross sectional data from 1,467 SLE patients meeting the ACR criteria were analyzed based on their self report of current smoking status (Yes/No). Variables tested included demographics (age, gender, ethnicity, marital status), auto-antibodies, disease activity (SELENA-SLEDAI) and damage score (SDI). Two independent sample t tests or Mann Whitney test were used to compare continuous variables based on data distribution. Chi square test were used to compare discrete data. Odds ratio was obtained using Mantel-Haenszel method. A p value of ≤ 0.05 was considered significant on two tailed test.

Results: 94% of SLE patients were women. 41% were African American, 53% Caucasian, 1% Hispanics and 6% others. 366/1,467 reported currently smoking status. Age was similar in both groups; however ethnicity and marital status (OR 0.45 for married, 95% CO 0.36, 0.57) were associated with smoking status. There were no significant differences in the total SLEDAI scores. On comparison of itemized disease activity in the past 10 days, we found mucosal ulcers (OR1.8, 95% CI 1.2, 2.6, $p=0.002$) and pleurisy OR 1.6, 95% CI 1.1, 2.1, $p=0.01$) to be more prevalent among smokers and than nonsmokers. Thrombocytopenia was less prevalent among smokers as compared to nonsmokers (OR 0.35, 95% CI 0.14, 0.89, $p=0.02$).

Nonsmokers had a significantly lower total damage score (mean$\pm$ SD, median) as compared to smokers: 2.05 ± 2.43, 1 vs. 2.34 ± 2.45, 2, $p=0.008$. Pulmonary fibrosis was more prevalent among nonsmokers (OR 0.56, 95% CI 0.32, 0.96), while myocardial infarction was more prevalent among current smokers (OR 2.4, 95%CI 1.4, 4.2, $p=0.001$). Skin damage was more prevalent among smokers (scarring/alopecia OR 3.2, 95% CI 2.0, 5.0; extensive scarring/panniculum OR 5.4, 95% CI 3.1, 9.5, $p=0.001$). A trend towards greater peripheral vascular disease among smokers was also noted (OR 2.4, 95% CI 0.8, 6.4, $p=0.07$).

Conclusions: This is the largest study thus far on smoking and its association with disease manifestations in SLE. Smoking is strongly associated with disease activity related mucosal ulceration and pleurisy. A strong association with overall disease damage and especially pulmonary, cardiac and cutaneous damage exists. This study was possible through data sharing between institutions.

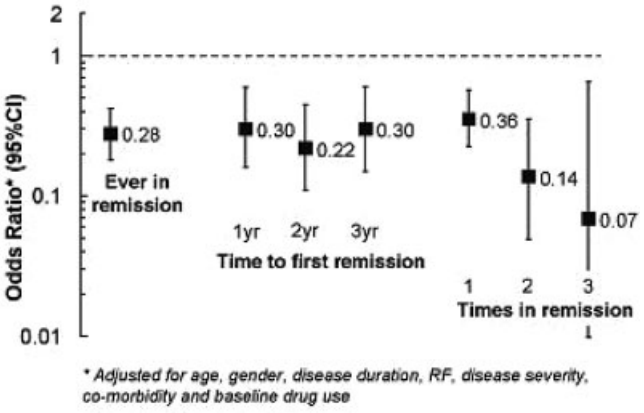
Early and Persistent Clinical Remission Reduces Long-Term Disability in Inflammatory Polyarthritis: Results from the Norfolk Arthritis Register. Carlo Alberto Scirè[2], Suzanne M. Verstappen[1], Hoda Mjriafari[1], Diane Bunn[3], Mark Lunt[1], Ian Bruce[1], Carlomaurizio Montecucco[2] and Deborah P. Symmons[4]. [1]Arthritis Research UK Epidemiology Unit, Stopford Building, The University of Manchester, Manchester, United Kingdom, [2]Department of Rheumatology, IRCCS Policlinico San Matteo Foundation, University of Pavia, Pavia, Italy, [3]Norfolk Arthritis Register, Norfolk and Norwich University Hospital, Norwich, United Kingdom., [4]Univ of Manchester, Manchester, United Kingdom

Background: Remission is an increasingly achievable objective when treating patients with inflammatory arthritis (IP) and its subset rheumatoid arthritis (RA). Although achieving the state of remission is thought to prevent long-term detrimental outcomes, the effect of remission on long-term disability has not yet been systematically investigated. In this study we have tested the predictive validity of a pragmatic definition of remission in terms of long-term disability in patients with IP.

Methods: Consecutive patients with early IP from a primary-care based inception cohort, recruited between 1990 and 1994 (first cohort) and between 2000 and 2004 (second cohort), were included this study. The 51- and 28-tender and swollen joint counts (JC) were assessed at 1, 2 and 3 yr after registration in these cohorts. Remission was defined as the absence of clinically detectable joint inflammation (swollen 51-JC = 0 and tender 51-JC = 0) at each of these time points. Less stringent definitions of remission were based on 28-JC. A 5 yr HAQ-score ≥1 (moderate disability) was chosen as the primary outcome measure. The effect of remission on subsequent disability was analysed by logistic regression. The results are shown as odds ratios (OR) and 95%CI. All analyses were adjusted by baseline confounders and missing data were imputed applying multiple imputations.

Summary of the Results: A total of 1,366 patients, 847 from the first cohort and 519 from the second cohort completed 5 yrs of follow-up. At 5 yrs, 336 (39%) and 248 (48%) of subjects from the first and second cohort respectively had developed moderate disability; 193 (24%) and 202 (36%)

fulfilled the predefined 51-JC remission criteria at least once within the first 3 yrs. In the first cohort, patients with at least one episode of remission were less likely to become disabled compared to patients who never experienced remission (OR 0.28 95%CI 0.18, 0.42) (see Figure 1).



The number of times in remission resulted proportionally decreased odds of disability, with a mean decrease in the probability of disability of about 62% for each time point in remission (OR 0.38 95%CI 0.28, 0.52). The time to the first remission within the first 3 yrs did not discriminate between patients with moderate functional disability and those with no functional disability. Similar results were observed in the second cohort. The association between the less stringent criteria of remission and future disability was weaker.

Conclusions: Patients with IP who achieve a state of remission early in their disease process are less likely to show long-term deterioration of function compared to patients who never achieve remission. Patients with the most persistent remission and under the more stringent definition of remission, have the lowest probability of long-term disability.

Economic Evaluation of Rituximab Versus Alternative Anti-Tumor Necrosis Factor (TNF) Therapy after Failure of Anti-TNF for Treatment of Rheumatoid Arthritis in Mexico. Fernando Carlos[2] and Patricia Clark[1]. [1]Hospital Infantil Federico Gómez México, Mexico City, Mexico, [2]R A C Salud Consultores, S.A. de C.V.

Background: About 30% of rheumatoid arthritis (RA) patients treated with an anti-TNF agent failed to achieve an improvement of 20% in American College of Rheumatology (ACR) response. Recent clinical practice guidelines recommend the use of rituximab after failure of one anti-TNF instead of cycling between these agents. We aimed to evaluate the cost-utility of different treatment strategies in severe RA after anti-TNF failure from the perspective of the public health care system in Mexico.

Methods: A microsimulation Markov model was used to compare life-time costs and quality-adjusted life years (QALY) of 12 different treatment pathways for one million simulated patients aged 40 years (70% women, mean weight 66.67 Kg) with failure to etanercept (ETA) [Model 1], adalimumab (ADA) [Model 2], or infliximab (INF) [Model 3]. Competing interventions included giving rituximab (RTX) first, followed by a sequence of the two alternative anti-TNF agents or to administrate RTX after complete cycling between anti-TNF agents. RTX (1 course, consisting of 2 infusions of 1g each) given 9 months apart; INF 3 mg/Kg weeks 0, 2, 6, 14 and 22, and then 4.5 mg/Kg given 8 weeks apart starting from week 30; ETA 25mg twice a week; and ADA 40mg every other week, were all combined with methothrexate (MTX) 15mg weekly. Baseline Health Assessment Questionnaire (HAQ) score was sampled from a Normal distribution [mean 1.88; S.D. 0.58). Indirect comparison techniques were used to adjust 6-month ACR responses rates found in 9 clinical trials. HAQ scores dropped accordingly to the magnitude of ACR response. Median duration times were taken from published literature. Once treatment stops, the entire initial gain in HAQ is assumed to be lost instantly. Patients are then allocated to the next available treatment option until the sequence is exhausted. At this point, all patients receive single MTX, until they reach 100 years of age or death. Direct costs included acquisition of biologic drugs besides infusion cost for RTX and INF plus medical attention of each health state into the model. Ambulatory resource use was estimated by an experts' panel of 10 specialists. Inpatient days were estimated on the basis of HAQ score. Unit costs were gathered from official sources. Mortality rates were derived from Mexican life tables and a risk multiplier of 1.33^{HAQ}. A quadratic equation was used to link HAQ score with utility weights. Costs and QALY were discounted at an annual rate of 3%. All costs were calculated in 2009 Mexican Pesos and then expressed in US dollars (12.729 MXP per USD).

Results: Starting therapy with RTX was a dominant (both more effective and less costly) option than switching to another anti-TNF agent, leading to cost-savings that ranged from 862 to 1,365 USD per patient and gains of 8.67 to 16.18 QALY per 1,000 patients. If retreatment with RTX is set at 6 months (keeping all other parameters constant), most of estimates for the incremental cost per QALY gained with initial RTX instead of using alternative anti-TNF agents would fall below 50,000 USD.

Conclusions: This study suggests that starting therapy with RTX after previous failure of one anti-TNF agent is a cost-effective strategy compared to cycling between anti-TNF agents.

High Level of Disease Activity in Chronic Inflammatory Rheumatisms Increases the Rate of Indeterminate Interferon-Gamma-Release Assay Results for Latent Tuberculosis Infection Detection. Félicie Costantino[2], Gilbert Faure[1], Marcelo De Carvalho[1], Anne-Christine Rat[2], Hervé Dinginger[2], Damien Loeuille[2] and Isabelle Chary-Valckenaere[2]. [1]Immunology (EA RHEM4369) Department, Nancy University Hospital, Vandoeuvre-lès-Nancy, France, [2]Rheumatology department, Nancy University Hospital, Vandoeuvre-lès-Nancy, France

Purpose: Screening for latent tuberculosis infection (LTBI) is mandatory before initiating TNF-alpha blocker treatment. Recent studies established that interferon gamma release assay (IGRA) have better specificity than Tuberculin Skin Test (TST) for LTBI diagnosis. However, little is known about practical use of IGRA in patients with chronic inflammatory arthritis.

The aim of the study was to identify factors that may influence IGRA results in patients with chronic inflammatory conditions and candidates for TNFalpha-blockers.

Patients and Methods: consecutive patients from one Rheumatology department treated for chronic inflammatory arthritis and candidate for biologics were prospectively enrolled over a 5-years period (July 2004 - July 2009). Clinical data (disease diagnosis, duration and activity), biologic parameters (ESR and CRP), treatment and risk factors for LTBI were recorded at inclusion. All patients underwent TST according to Mantoux method (Tubertest® 5 units, SANOFI PASTEUR MSD, SNC, Lyon, France), chest-x-ray (CXR) and IGRA (T-SPOT.TB®,Oxford Immunotec, UK).

Results: 590 patients were included: 294 (49.8%) with rheumatoid arthritis (RA), 271 (45.9%) with spondyloarthritis (SPA) and 25 (4.2%) with other inflammatory diseases. History of BCG vaccination was present in 460 patients (78%). TST was positive (induration $\geq$5 mm) in 201 patients (34.1%), negative in 335 (56.9%) and non available in 54 cases (9%). T-SPOT.TB® assay was positive in 125 patients (21.2%), negative in 372 (63.0%) and indeterminate in 93 (15.8%). A higher age, previous active TB, the absence of BCG vaccination, TST positivity and CXR abnormalities were associated with T-SPOT.TB® positivity as shown in table 1. Among risk factors for LTBI, only the presence of CXR abnormalities was significantly associated with TST positivity ($p=0.031$). A high level of disease activity, whatever the diagnosis, (i.e. DAS28 for RA and BASDAI for SPA) was statistically associated with more frequent indeterminate results (5.4 vs 4.9, $p=0.008$ and 58.5 vs 50.0, $p=0.022$, respectively). Concordance between T-SPOT.TB® and TST was low ($K=0.17$). The negativity of TST, but not that of T-SPOT.TB® results, was significantly associated with female gender ($p=0.003$), rheumatoid arthritis ($p=0.005$), previous TNF-alpha blockers ($p=0.016$), DMARDs ($p=0.012$) and current corticosteroids treatment ($p=0.001$).

Table 1. Factors influencing T-SPOT.TB® results.

	Negative (n = 372)	Positive (n = 125)	p
Age (years), median (Q1–Q3)	49.0 (38.0–57.0)	53.0 (40.0–61.0)	0.0246
Previous active TB, n (%)	4 (33.3)	8 (66.7)	0.0026
No prior BCG vaccination, n (%)	64 (59.3)	44 (40.7)	<0.0001
TST positivity, n (%)	116 (66.3)	59 (33.7)	0.0002
CXR abnormalities, n (%)	8 (38.1)	13 (61.9)	<0.0001

Conclusion: In RA and SPA patients eligible for biologics, high disease activity increased the rate of indeterminate T-SPOT.TB® results and the difficulty of LTBI diagnosis. TNF-alpha blockers, DMARDs and corticosteroids are associated with negative TST but do not seem to affect T-SPOT.TB® results.

Improving Health-Related Quality of Life in Patients with Systemic Lupus Erythematosus (SLE): The Role of Disease Control, Steroid Reduction and Smoking Cessation. Mark J. Harrison[5], Nicola Dale[1], Sahena Haque[2], Joanna Shelmerdine[6], Lee-Suan Teh[4], Yasmeen Ahmad[3] and Ian N. Bruce[1]. [1]Arthritis Research UK Epidemiology Unit, The University of Manchester, Manchester, United Kingdom, [2]Arthritis Research UK Epidemiology Unit, The University of Manchester, Manchester, United Kingdom, [3]Betsi Cadwaladr University Health Board-West, Rheumatology, Llandudno, United Kingdom, [4]Department of Rheumatology, Royal Blackburn Hospital, Blackburn, United Kingdom, [5]Health Sciences Research Group, The University of Manchester, Manchester, UK, [6]The Kellgren Centre for Rheumatology, Central Manchester Foundation Trust, Manchester, UK

Purpose: Longitudinal studies of cohorts of SLE patients have shown that poor HRQoL does not change significantly over time, despite modern manegement. We aimed to describe changes over a 5-year period in a cohort of outpatient SLE patients and compare the clinical characteristics of sub-groups of patients experiencing clinically important improvement or deterioration.

Methods: Female patients with SLE (≥4 ACR criteria) were recruited from routine outpatient clinics at 2 time points 5 years apart. At baseline and 5 years patients had a clinical assessment including the SLEDAI 2000 and SLICC damage index (SDI). Patients also completed the RAND Medical Outcome Study 36-Item Short-Form Survey version 1 (MOS SF-36), which allowed the SF-6D to be calculated, at both time points. The change in SF-6D over 5 years was assessed in relation to the minimum important difference (MID) of the measure (0.024). The characteristics of patients who experienced >MID improvement, >MID deterioration, or no change (ΔSF6D ≤MID), were compared using the t-test and ANOVA or chi-square test as appropriate.

Results: 107 patients had SF-6D scores both at baseline and at 5 years. The mean(SD) age was 49 (9) years and mean (SD) disease duration 13 (10) years. At baseline, 15% were current smokers. The SF-6D score at baseline (n=107) was 0.62. The mean change in SF-6D over the 5-year period for the longitudinal cohort was 0.00 (SD 0.10). 39% (n=42) of patients in the cohort improved (mean 0.10) and 37% (n=40) of patients worsened (mean −0.10) by more than the MID. SLEDAI scores were significantly different across groups (p=0.001); decreasing in improved patients (−1.5), but increasing in unchanged (1.7) or worsened (2.4) patients. A higher proportion of improved patients stopped steroid treatment (27% vs 5%) or stopped smoking (15% vs 1%). Stopping smoking or steroids were both associated with important gains in SF-6D (0.07 vs −0.01, p=0.022) (0.08 vs −0.02, p=0.127) respectively. SDI scores did not differ between the groups.

Conclusions: While the mean SF-6D scores in this SLE cohort did not change over a 5-year follow-up period, there are groups of patients who experience clinically important improvement or deterioration in HRQOL within this population. Better disease control while targeting a reduction/stopping of steroid therapy and smoking cessation all may contribute to large health gains for SLE patients.

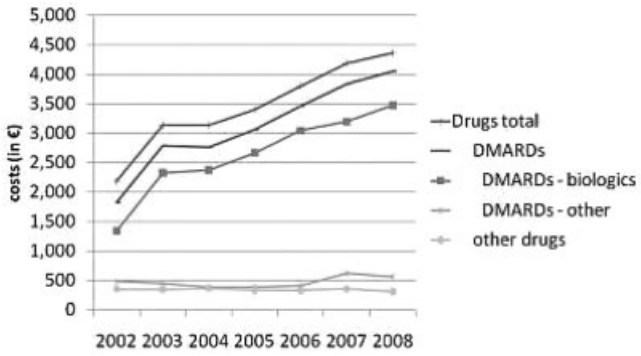
Increase in Direct and Decrease in Indirect Costs of Rheumatoid Arthritis in Germany between 2002 and 2008. Dörte Huscher[2], Katja Thiele[2], Andrea Pfaefflin[2], Sascha Bischoff[2], Rieke Alten[4], Ulrich von Hinueber[3], Matthias K. Schneider[5] and Angela Zink[1]. [1]German Rheumatism Research Centre and Charité University Hospital, Berlin, Germany, [2]German Rheumatism Research Centre, Berlin, Germany, [3]Hildesheim, Germany, [4]Schlosspark-Klinik KG, Department of Internal Medicine II, Rheumatology, Clinical Immunology Osteology, Berlin, Germany, [5]University Hospital Düsseldorf, Duesseldorf, Germany

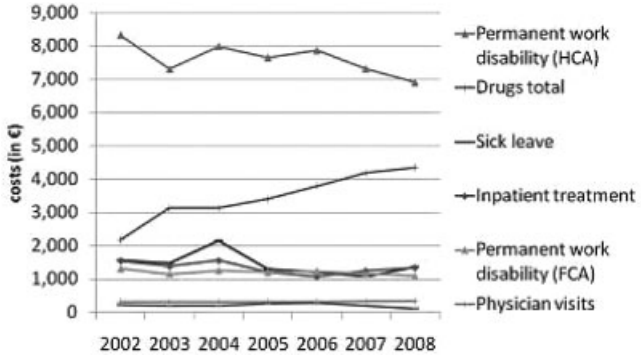
Objective: We recently observed a remarkable reduction in disease activity (DAS28) in patients with RA treated in German rheumatology during the past decade. The frequency and duration of hospitalization and sick leave decreased, whereas the work participation improved. We now analysed how these trends influenced direct and indirect costs.

Methods: We used data from the national database of the German Collaborative Arthritis Centres. An earlier cost analysis used data from the year 2002 which were less detailed than those available now. DMARD and glucocorticoid treatment has been collected now with dosages and exact duration which allows more accuracy in estimating figures of this major cost domain. For the years 2002–2004 these details were not available, and were imputed with median doses and median treatment durations from the following years. Non-pharmacological treatments were calculated for an assumed 9-months period per year. Cost components for hospitalization, sick leave and work disability were calculated by means of the German annual statistical yearbook. For indirect costs, both human capital approach (HCA) and friction cost approach (FCA; 58 days replacement period) were considered. Only those rheumatological units who had participated in all consecutive years were selected for analysis.

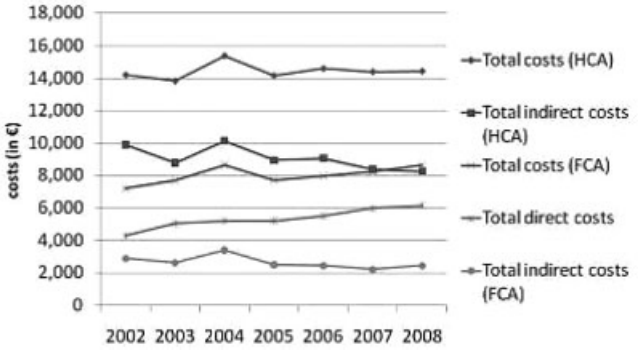
Results: Drug treatment was the cost domain with the highest increase between 2002 and 2008 (Fig. 1). This increase was almost entirely caused by biologic therapies.



Comparing the main cost domains, these risen costs were accompanied by slightly decreasing costs for inpatient treatment and sick leave, and depending on the calculation approach a slight (FCA) or remarkable (HCA) decrease for permanent work disability (Fig. 2).



Accordingly, total costs showed a moderate increase (FCA) or remained almost stable (HCA) (Fig. 3).



Conclusion: We have seen a continuous increase of costs for drug treatment, mainly caused by the growing use of biologics. Depending on the health economic approach for the calculation of indirect costs, these risen direct costs were partially counterbalanced when using the friction cost approach, and were almost entirely compensated when using the human capital approach.

Increased Risk of Valvular and Nonvalvular Cardiovascular Disease in Younger Individuals with Ankylosing Spondylitis: A Population-Based Study. Adrian R. Levy[3], Shelagh M. Szabo[3], Sumati Rao[1], Diane V. Lacaille[2], Mary Cifaldi[1] and Walter P. Maksymowych[4]. [1]Abbott, [2]Arthritis Research Ctr Canada, Vancouver, BC, Canada, [3]Oxford Outcomes, [4]University of Alberta, Edmonton, AB, Canada

Background: Increased risk of valvular cardiovascular disease for patients with ankylosing spondylitis (AS) are well-documented. However, data on the association of AS with other types of cardiovascular and cerebrovascular disease are equivocal. While some cross-sectional clinic-based studies report an increased risk of nonvalvular CV disease with long-standing AS, others have concluded that routine cardiologic evaluation is not indicated. No longitudinal population-based data on the risk of CV disease in patients with AS compared with individuals without AS have been presented.The objective was to estimate the population-based prevalence and increased risk of valvular and nonvalvular CV disease among individuals with AS in the Canadian province of Québec.

Methods: A retrospective cohort study was conducted using the population-based administrative physician-billing database maintained by the Régie de l'Assurance Maladie du Québec. The cohort included individuals with at least 1 International Classification of Diseases, 9th Revision, (ICD-9) billing code for AS between 1996 and 2006. A comparison cohort was generated using a 1% random sample of individuals without AS. CV diseases were classified according to ICD-9 code and grouped into 6 categories: valvular (aortic and non-aortic) disease, ischemic heart disease, congestive heart failure, cerebrovascular, and other CV disease. Age- and sex-stratified prevalence, and standardized prevalence ratios, of cardiovascular or cerebrovascular disease in AS compared with the general population were calculated.

Results: There were 8,616 individuals with AS; 55% were male and the median age at diagnosis was 42.5 years. The age-specific prevalence of experiencing any cardiovascular or cerebrovascular disease increased from 18.7 to 81.5 cases per 1,000-person-years among male AS patients aged 20 to 39, to >60 years, over the period. Prevalence was greater with increasing age for all disease subgroups. The prevalence ratios (95% CI) for experiencing any CV disease was greatest for younger AS patients, and ranged from 1.6 (1.5–1.8) for males aged 20 to 39 years to 1.1 (1.1–1.2) for those aged >60 years. These findings were consistent across all CV disease categories, and were similar for females. The standardized prevalence ratios (SPRs) of experiencing cardiovascular or cerebrovascular disease, for patients with AS compared with the general population, was 1.3 (1.3–1.4). SPRs for the disease subgroups ranged from 1.6 (1.4–1.8) for non-aortic valvular disease, to 1.3 (1.2–1.4) for cerebrovascular disease.

Conclusions: Patients with AS are at increased risk for many types of cardiovascular or cerebrovascular disease. The excess risk is greatest for young AS patients. This data supports consideration for cardiovascular risk assessment in the clinical evaluation of patients with AS.

Is There an Advantage for a Lupus Specific Quality of Life Measure over SF-36? Zahi Touma[2], Dafna D. Gladman[3], Dominique Ibanez[2] and Murray B. Urowitz[1]. [1]The Toronto Western Hospital, Toronto, ON, Canada, [2]Toronto Western Hospital, Toronto, ON, Canada, [3]Toronto Western Hospital, Toronto, ON, Canada

Objective: The LupusQoL questionnaire is a disease-specific instrument for adults with lupus. We aimed to assess whether the LupusQoL contributed additional information not obtained using the SF-36 and to compare the responsiveness of both questionnaires over time in patients in patients who changed clinically.

Methods: 41 patients seen at a single centre were followed at monthly intervals for 12 months. Both questionnaires were co-administered monthly. Lupus activity was determined by Systemic Lupus Erythematosus Disease Activity Index (SLEDAI-2K) 30 days. We compared the mean scores for the 4 comparable domains in both questionnaires in all patient-visits. For the 4 non-comparable domains of the LupusQoL we determined the correlation between each domain with the Physical Component Score (PCS) and the Mental Component Score (MCS) of the SF-36.

The effect size (ES) and the standardized response mean (SRM) were used to compare the responsiveness of both questionnaires in patient-visits with lupus flare (SLEDAI-2K≥4), improvement (reduction in SLEDAI-2K >3) and remission (SLEDAI-2K=0) from previous visit.

Results: Among the 41 patients (F 37/M 4), 59% were Caucasian, 17% Black, 7% Asian, and 17% other. The mean age at SLE diagnosis was 30.5±10.3 years. At study visit the mean age was 45.3±13.2 and disease duration 14.8±10.3 years; SLEDAI-2K 2.59±2.41 and SDI 2.12±2.48. 376 patients-visits were recorded. Quality of life assessed by both questionnaires is low among SLE patients. Quality of life assessed by both questionnaires is low among patients. There was no statistically significant difference between the mean scores of comparable domains; Physical Health/Physical Functioning, Emotional Health/Mental Health, Pain/Bodily Pain and Fatigue/Vitality. For the 4 non-comparable domains of the LupusQoL, there was a correlation between Body Image/MCS-SF-36 r=0.61, Planning/MCS-SF-36 r=0.68, Intimate Relationships/PCS-SF-36 r=0.73, and Burden to Others/MCS-SF-36 r=0.70.

Both questionnaires displayed responsiveness as determined by SE and SRM among patients who flared (SF-36: SRM moderate effect 0.64 Role Physical, small effect 0.42 Social Functioning and 0.30 PCS; LupusQoL: SRM moderate effect 0.67 Fatigue and small effect 0.49 Burden to others) and improved (SF-36: SRM moderate effect 0.60 MCS and small effect 0.43 Mental Health, 0.40 General Health, 0.30 Vitality, 0.30 Role Physical, 0.24 Social Functioning and 0.23 Physical Functioning; LupusQoL: SRM moderate effect 0.73 Pain, 0.53 Fatigue and 0.51 Physical Health, and small effect 0.45 Emotional Health, 0.39 Body Image, 0.37 Burden to others and 0.36 Planning) but not among patients in remission when compared to previous visit. There was no significant difference in the responsiveness of both questionnaires in patients with lupus flare and improvement when compared to previous visit.

Conclusions: There is no superiority of LupusQoL over SF-36 in assessing lupus patient's quality of life. Both questionnaires are responsive instruments of lupus quality of life in patients with flare and improvement. The utility of LupusQoL needs to be evaluated in future studies in patients with moderate to severe disease activity.

Life Expectancy, Standardized Mortality Ratios and Causes of Deaths of Six Rheumatic Diseases in Hong Kong, China. Chi Chiu Mok[1], Raymond C. L. Kwok[2], Ling Yin Ho[1], Pak To Chan[1] and Paul S. F. Yip[2]. [1]Tuen Mun Hospital, [2]University of Hong Kong

Objectives: To study the life expectancy, standardized mortality ratios (SMRs) and causes of deaths of six rheumatic diseases in Hong Kong

Methods: The number of patients with the International Classification of Disease (ICD)-9 diagnostic codings of systemic lupus erythematosus (SLE), rheumatoid arthritis (RA), ankylosing spondylitis (AS), psoriatic arthritis (PSA), systemic vasculitides (SV) and systemic sclerosis (SSc) who were followed in our hospital between year 1999 and 2008 were retrieved by the hospital registry called the Clinical Data Analysis and Reporting System (CDARS). The number of patients with these disease codings who died during follow-up was also retrieved by the hospital death registry. The SMRs were calculated by comparing the rate of mortality of each disease entity (observed deaths) with the mortality rate of the general population gathered from the population census and the general death registry (expected deaths). The causes of death were evaluated and compared across these six rheumatic diseases. Life expectancy of each disease was calculated by abridged life table analysis using the prevalence and death data in the CDARS and data reported for the Hong Kong population within the same study period.

Results: The causes of deaths of 348 patients between year 1999 and 2008 were analyzed. The distribution of the underlying diseases was: RA (50%), SLE (23%), SV (14%), AS (7%), SSc (4%) and PSA (1%). The mean age at the time of death was 65.5±17.3 years and 240 patients (69%) were women. The age at death was highest with RA (74.1±12.1 years) and lowest with SLE (49.0±15.7 years). The mean SMR of both sexes and all age groups was highest for SLE (24.3 [22.2–26.4]), followed by SSc (18.3 [15.3–22.1]), SV (11.1 [9.9–12.3]), AS (8.8 [7.6–10.3]), RA (8.3 [7.9–8.8]) and PSA (7.5 [5.7–9.8]). The principle causes of deaths were, in descending order of frequency, infections (34%), cancers (18%), cardiovascular / cerebrovascular complications (16%), renal failure (6%), pulmonary pathologies (4%), liver and gastrointestinal complications (4%), accidents (1%) and suicide (1%). Infections were the commonest cause of death in SLE, RA and AS but not in other three diseases. Cardiovascular death was most frequent in patients with SSc and PSA. Cancer deaths were highest in patients with SV, followed by PSA and AS. Renal failure as a cause of death was reported in SLE and RA only. Cases of suicide occurred exclusively in SLE. In female patients, the loss in life expectancy was greatest with SSc (34.1 years), followed by SV (19.3 years), SLE (19.7 years), RA (6.9 years), PSA (6.5 years) and AS (1.2 years). In male patients, the loss in life expectancy was greatest with SV (28.3 years), followed by SLE (27 years), SSc (16 years), AS (7 years) and RA (5.2 years).

Conclusions: Patients with rheumatic diseases have a higher mortality risk than the general population, leading to a significant loss in life expectancy. Among the six diseases studied, SLE has the highest SMR and female SSc patients had the greatest loss in life expectancy. Infection is the commonest cause of death in SLE, RA and AS; but cancer is the leading cause of death in SV. Cardiovascular deaths are more common in patients with SSc and AS.

Lower Body Mass Index Is Associated with an Increased Risk of Giant Cell Arteritis. Karin Jakobsson[3], Lennart T. H. Jacobsson[2], Kenneth J. Warrington[1], Eric L. Matteson[1], Kimberly P. Liang[5], Olle Melander[4] and Carl Turesson[3]. [1]Mayo Clinic, Rochester, MN, [2]Skåne University Hospital, Malmo, Sweden, [3]Skåne University Hospital, Malmö, Sweden, [4]Skåne University Hospital, [5]University of Pittsburgh, Pittsburgh, PA

Background: There is limited data on predictors of giant cell arteritis (GCA). In a previous case-control study of women with GCA, a history of smoking, low body mass index (BMI) and several hormonal factors were associated with GCA. Smoking and a low level of formal education have been found to predict other chronic inflammatory disorders, including rheumatoid arthritis.

Objective: To examine potential risk factors of GCA in a nested case-control study based on two prospective health surveys.

Methods: We studied two population based health surveys performed in the same catchment area, the Preventive Medicine Program (PMP) and the Diet Cancer Study (DCS). In the PMP, 33346 subjects (22444 men and 10902 women) were included between 1974 and 1992, and in the DCS, 30447 subjects (12121 men and 18326 women), were included between 1991 and 1996. Information on medical history and life style factors was obtained using standard physical examinations and self-administered questionnaires. From this population, individuals who developed GCA after inclusion were identified by linking the PMP and DCS databases to the local patient administrative register and the national hospital discharge register. A structured review of the medical records of all identified cases was performed. Patients were classified according to the ACR criteria for GCA and the date of diagnosis was noted. Four controls for every confirmed case, matched for sex, year of birth and year of screening, who were alive and free of GCA when the index person was diagnosed with GCA, were selected from the PMP and DCS databases, respectively. For cases who had participated in both surveys, the screening closest preceding the diagnosis of GCA was used. The impact of potential predictors of GCA, including BMI, smoking, and other lifestyle factors, was examined in conditional logistic regression models.

Results: Eighty-three patients (70 % women, 64 % biopsy positive, mean age at diagnosis 71 years) had a confirmed diagnosis of GCA after inclusion in the PMP or the DCS. The median time from screening to GCA diagnosis was 10.6 years (range 0.3–28.2). BMI at screening was lower in GCA cases than in matched controls (mean 24.3 vs 25.6 kg/m^2). In logistic regression analysis, a higher BMI was associated with a significantly reduced risk of subsequent development of GCA [Odds ratio (OR) 0.91 per kg/m^2; 95 % confidence interval (CI) 0.84–0.98]. Individuals who were overweight (BMI>25 kg/m^2) had a lower risk for GCA (OR 0.39, 95 % CI 0.21–0.70) compared to those with a normal or low BMI. There was no significant association between current smoking at screening (OR 1.36; 95 % CI 0.77–2.57) or a history of early menopause (before age 46) (OR 1.76; 95 % CI 0.71–4.39) and GCA. Level of formal education and breast-feeding history did not predict GCA. In multivariate analysis, adjusted for smoking and level of formal education, the association between higher BMI and reduced risk of GCA remained significant (OR 0.91 per kg/m^2; 95% CI 0.85–0.99)

Conclusion: In this study, subsequent development of GCA was predicted by a lower BMI at baseline. Potential explanations include an effect of adipose tissue on hormonal pathways regulating inflammation in the context of GCA.

Obstetrical and Neonatal Outcomes in Rheumatic Disease. Cheryl C. M. Barnabe, Peter Faris and Hude Quan. University of Calgary, Calgary, AB, Canada

Background: Adverse maternal and neonatal outcomes have been documented in women with rheumatic disease. Our objective was to determine if this situation has improved in the era of better rheumatic disease treatment and prenatal management.

Methods: An inpatient dataset provided obstetrical admission details for a cohort of women with rheumatic disease (including RA, SLE, ankylosing spondylitis, systemic sclerosis, inflammatory myopathies and JIA) and a comparison group matched on maternal age and year of delivery. Maternal outcomes include mean length of stay, and the proportion experiencing pregnancy-related hypertension, instrumentation at delivery or cesarean section, and postpartum infections. Neonatal outcomes include the mean length of stay and the need for special care unit admission. We also examined the proportion of neonates born prematurely, small for gestational age (SGA) or with congenital defects. Conditional logistic regression was used to calculate the crude odds ratio (OR) and the 95% confidence intervals (CI) for the dichotomous outcomes of interest, with adjustments made for known confounders (if occurring in at least 5% of the sample).

Results: 161 singleton pregnancies occurred in 141 women with rheumatic disease, predominantly with RA and SLE. There were a total of 6 stillbirths, 3 in each group. Reasons for readmission particular to rheumatic disease during the first year postpartum included 2 women with flares of SLE, and 1 woman who required 2 arthroscopic procedures. Neonates of women with rheumatic disease were not at increased risk of readmission. There was no evidence of excess congenital defects in babies born to women with rheumatic disease (1.2% vs 2.1%).

Table 1. Summary of Maternal Outcomes

Outcome	Women with Rheumatic Disease n = 161	Women without Rheumatic Disease n = 635
Length of stay (days), mean (SD)	3.7 (4.3)	2.3 (2.0)
Pregnancy-related hypertension, n (%)	27 (16.8)	52 (8.2)
Instrumentation for delivery, n (%)	42 (26.1)	136 (21.4)
Cesarean section, n (%)	70 (43.5)	146 (23.0)
Postpartum infection, n (%)	7 (4.3)	6 (0.9)
1 year readmission, n (%)	22 (13.7)	32 (5.0)

Table 2. Summary of Neonatal Outcomes

Outcome	Neonates of Women with Rheumatic Disease n = 161	Neonates of Women without Rheumatic Disease n = 635
Prematurity, n (%)	44 (27.3)	47 (7.4)
Length of stay (days), mean (SD)	3.6 (4.8)	2.4 (2.0)
Requiring intensive care, n (%)	49 (30.4)	74 (11.7)
Length of stay, intensive care (days), mean (SD)	1.8 (5.1)	0.6 (2.8)
Small for gestational age, n (%)	37 (23.0)	67 (10.6)
1 year readmission, n (%)	14 (8.7)	33 (5.2)

Table 3. Crude and Adjusted Odds Ratios for Maternal and Fetal Outcomes, Comparing Women with Rheumatic Disease to Those Without Rheumatic Disease

Outcome	Crude OR	95% CI	Adjusted OR	95% CI	p value
Maternal					
- Pregnancy-related hypertension	2.25	1.36–3.71	2.33	1.38–3.91	<0.001
- Instrumentation	1.30	0.87–1.95	1.26	0.87–1.93	0.280
- Cesarean section	2.71	1.85–3.95	3.02	1.87–4.86	<0.001
- Postpartum infection	4.47	1.50–13.3	2.99	0.85–10.5	0.087
Neonatal					
- Prematurity	4.51	2.85–7.13	4.38	2.73–7.05	<0.001
- Small for gestational age	2.52	1.60–3.96	2.50	1.59–3.93	<0.001

Conclusions: In our cohort, women with rheumatic disease continue to have increased odds of developing pregnancy-related hypertension, and a large proportion deliver by cesarean section. Neonates of women with rheumatic disease are more likely to be premature, and small for gestational age. These findings are entirely in keeping with the previous literature, and do not appear to have improved over time. Additionally, women with rheumatic disease demonstrate a trend to an increased risk of postpartum infections, which has not been previously documented.

Patient Perceptions and Access to Resources Influence Patient Decisions To Attend Rheumatology Appointments. Valerie Milne[2], Robin Kearns[1] and Andrew A. Harrison[3]. [1]University of Auckland, New Zealand, New Zealand, [2]University of Otago, Wellington, Wellington, New Zealand, [3]University of Otago, Wellington, New Zealand, New Zealand

Purpose: Patients referred to rheumatology clinics with symptoms of inflammatory arthritis (IA) miss the opportunity for early DMARD treatment when they do not attend their first specialist assessment (FSA). This study aimed, through patient interviews, to understand the social, economic and geographic determinants of FSA attendance at a public rheumatology service.

Method: A purposive sample of 21 people with IA was selected from private clinics, public clinics and the local community. Beliefs about IA and experiences of the condition and its treatment, including the referral process, were elicited in one-on-one interviews. Contradictions and commonalities in patient narrative were thematically coded using QSR Nvivo qualitative software. A narrative approach was informed by the collective lifestyles framework[1], which aims to locate individual health behaviours within a social context.

Results: The context provided by the collective lifestyles framework for discourse about patient circumstance helps explain non-attendance at the FSA. Barriers to attendance revealed by patient interviews were: 1) how patients perceived their symptoms and possible treatment; 2) social support and economic resources 3) the geographic attributes of the residential area and 4) the structure of the rheumatology service. Patients' self-perception and an inaccurate assessment of the risk of DMARDs compared with the benefits of treatment can lead patients to reject rheumatology care. Among people who reported inadequate social and economic resources; childcare, work commitments, and availability of help with impairment and transport were cited as factors affecting attendance. Descriptions of severe pain and impairment associated with long wait time gave some insight as to why patients cancel their public appointment in favour of a private appointment with a shorter wait, despite additional costs.

Conclusion: Patients' narratives suggest that altering the booking procedure from an administrative process to an assessment process to include early assessment of pain, impairment and patient support and co-ordination with the family physician to address these factors could improve non-attendance and cancellation rates. Providing information about the rheumatology service before the FSA could address patients' fears about impairment and reduce negative perceptions of possible treatment options. More general publicity about IA or specifically tailored information to patients with suspected IA may enable patients to make more informed decisions about accepting rheumatology care.

Objective: To evaluate the disease course and performance of patient-reported outcome measures in patients with polymyalgia rheumatica (PMR)

Methods: The study population included 88 patients with new onset PMR who were initially treated with prednisolone/prednisone dose of 15 mg daily

tapered gradually, and assessed at baseline and weeks 1, 4, 12 and 26 following start of steroid therapy. Data were collected on personal and family history, clinical signs and symptoms, laboratory results, treatment details, ultrasound evaluation of shoulders and hip, disability (MHAQ), quality of life (SF36), and patient reported outcomes (PRO) of global pain, PMR pain, shoulder pain and fatigue obtained using visual analog scales (VAS). Complete response to treatment was defined as ≥70% improvement from baseline on patient report of shoulder pain by VAS at each study visit. Spearman methods were used to assess correlations between improvement measures.

Results: At initial presentation, 99% patients had shoulder pain, 70% had hip pain and 96% had abnormal c-reactive protein (CRP) or erythrocyte sedimentation rate (ESR). Median duration of morning stiffness was 120 minutes with median MHAQ 1.1, median global VAS 65, PMR VAS 69 and fatigue VAS 60. Within 4 weeks, all PRO parameters improved dramatically (≥ 70% improvement) in majority of the patients (72% of patients for global VAS, 80% for PMR VAS and 60% for fatigue VAS); median change in MHAQ at 4 weeks was −0.875. Median change at 26 weeks was −0.94. Similarly, 62% of patients had normal CRP/ESR values at 4 weeks. However, few additional patients showed improvement from 4 weeks to 26 weeks. Complete steroid response at 4 weeks was seen in 70% of patients and the response was sustained in 85% of responders at 26 weeks. As planned, the median prednisone dose decreased from 15 mg at baseline to 5.5 mg at 26 weeks. Response to treatment (% improvement in shoulder pain VAS at weeks 4 and 26) was highly correlated with % improvement in other VAS measures (correlation>0.55 and $p<0.001$ at weeks 4 and 26) and % change in ESR ($p<0.001$ at week 4 and $p=0.04$ at week 26), but weakly correlated with % change in CRP ($p=0.07$ at week 4 and $p=0.30$ at week 26) and change in steroid dose ($p=0.39$ at week 4 and $p=0.04$ at week 26).

Conclusions: PRO measures including MHAQ, global, PMR and fatigue VAS, and inflammatory markers performed well in assessing disease activity in patients with PMR. Percent improvement in PRO measures were highly correlated with each other, but ESR and CRP correlated less strongly. We suggest that a minimum set of outcome measures consisting of PROs of shoulder pain and function and an inflammatory marker be used in practice and clinical trials in PMR.

Psychometric Properties of a Self-Administered Early Inflammatory Arthritis Detection Tool. Mary J. Bell[3], Joel P. Scarf[2] and Ruben Tavares[1]. [1]McMaster University, Hamilton, ON, Canada, [2]Sunnybrook Health Science Ctr, Toronto, ON, Canada, [3]Sunnybrook Health Sciences Ctr, Toronto, ON, Canada

Background: A self-administered tool for the detection of early inflammatory arthritis (EIA) has been developed and is under validation in primary care settings in Canada. The history-based tool consists of 11 questions with binary Yes/No responses, covering dimensions of pain, stiffness and swelling. The objective of this study is to evaluate the discriminant validity, comprehensibility, test-retest reliability and internal consistency of the EIA Detection Tool.

Methods: Of 148 patients (minimum of 37 in each group) planned for recruitment by September 2010, a total of 125 adult English-literate outpatients attending Sunnybrook Health Sciences Centre have participated in one of four study groups: 1.EIA (n=15): A rheumatologist's assessment of, or established diagnosis of either AS, PsA, RA, ReA, other SpA or undifferentiated IA with a symptom duration of six to 52 weeks; 2.Established Inflammatory Arthritis (IA) (n=40): A rheumatologist's assessment of established IA with more than 52 weeks of symptom duration; 3.Musculoskeletal (MSK)/non-IA (n=49): A rheumatologist's established diagnosis of osteoarthritis, osteoporosis, fibromyalgia, arthralgia, bursitis, tendonitis, or other rheumatologist-determined and documented, established non-inflammatory MSK condition; and 4.Non-IA/non-MSK (n=21): Hospital outpatients without bone or joint complaints and no history of arthritis, willing to consult with a study rheumatologist. **Discriminant validity** is reported using a Kruskal-Wallis test for non-parametric differences in total questionnaire Yes responses (Score) between groups including Mean (+/− SD), and Median (+ range). **Comprehensibility** is defined as the percentage of patients who agree or strongly agree with the comprehension of the tool. The EIA Detection Tool is delivered a second time (T2), at one to 2 weeks after the first time (T1) to ascertain **Test-Retest reliability**, (Kappa +/− SD). Patients who report a change in symptoms will be omitted from the assessment of reliability. To measure **Internal Consistency**, one question is repeated within the tool, (Kuder-Richardson-20, binary equivalent to Cronbach Alpha). Study participants will be blinded to the specific purpose of the study.

Results: Discriminant Validity for Group 1.EIA: Mean score 6.7+/−2.8 Median 7 (0–11); 2.Established IA: Mean score 5.2+/−2.3 Median 5 (2–10); 3.MSK/non-IA: Mean score 5.0+/−2.9 Median 5 (0–11); 4. Non-IA/non-MSK: Mean score 2.7+/−3.1 Median 2 (0–9) $p=0.006$. Over all groups Comprehensibility ranged from 94.6%–97.1%, while within Group 1.EIA, Comprehensibility ranged from 91.3%–100.0%. Kappa = 0.85+/−0.08 across all questions for Test-Retest reliability. Finally, Internal Consistency had a value of KR-20=0.990 at T1 and KR-20=0.985 at T2.

Conclusions: The EIA Detection Tool shows very good discriminate validity between the four study groups, and excellent Comprehensibility, Test-Retest reliability and Internal Consistency. Further analyses will be conducted in September 2010 when the dataset is complete to determine if weighting scales and/or decision rules may be imposed on the EIA Detection Tool to improve its discriminative properties.

Reproductive History and Functional Outcome in Women with Recent-Onset Inflammatory Polyarthritis. Elizabeth M. Camacho[1], Mark Lunt[1], Tracey M. Farragher[1], Mark Harrison[1], Suzanne M. Verstappen[1], Diane K. Bunn[2] and Deborah P. Symmons[3]. [1]Arthritis Research UK Epidemiology Unit, Stopford Building, The University of Manchester, Manchester, United Kingdom, [2]Norfolk Arthritis Register, School of Medicine Health Policiy & Practice, University of East Anglia, Norwich UK, [3]Univ of Manchester, Manchester, United Kingdom

Background: The incidence of rheumatoid arthritis (RA) among women is approximately twice that in men. There have been a number of studies suggesting that female reproductive factors, such as parity or menopause status, may impact upon a woman's likelihood of developing RA and her subsequent disease severity. However little is known about the effects of reproductive factors on long-term disease outcome in women with inflammatory polyarthritis (IP) and its subset RA. Our aim was to investigate the influence of reproductive history before symptom onset on disease outcome over time in a cohort of women with recent onset IP.

Methods: 1873 women, with no subsequent pregnancies, were registered with the Norfolk Arthritis Register (NOAR) between 1990 and 2004, and followed-up for a median of 5 years. Functional disability was assessed using the Stanford Health Assessment Questionnaire (HAQ). At baseline, blood samples were tested for rheumatoid factor (RF) and anti-citrullinated peptide antibodies (ACPA). The number and calendar year of past live births were recorded. Linear random effects models were used to examine differences in HAQ score over time, by parity and time since last live birth (latency), adjusted for age at symptom onset and symptom duration. Results were then stratified for RF and ACPA status.

Results: 1553 (83%) women had at least one pre-symptom-onset live birth, and 319 (17%) women were nulliparous before symptom onset. The median (IQR) latency to symptom onset in parous women was 26 (16–35) years. The median age at symptom onset was comparable in parous (54 years; IQR 44.6–65.2) and nulliparous women (54 years; IQR 36.4–70.0). A marginally higher proportion of nulliparous women who tested positive for RF (34% vs. 29%) or ACPA (33% vs. 30%) compared to parous women. Parous women had significantly lower HAQ scores over time than nulliparous women (−0.19; 95% CI −0.32, −0.06). HAQ score increased by an average of 0.006 (95% CI 0.002, 0.010) per year increase

in time since last pregnancy; the mean HAQ score of women with a latency of approximately 32 years was the same as the mean HAQ score of nulliparous women. The influence of autoantibody status was negligible. The difference in HAQ score by parity in RF- or ACPA-women was the same as for the whole cohort (RF −0.19; 95% CI −0.36, −0.02; ACPA −0.19; 95% CI −0.36, −0.02). Parity was also associated with lower HAQ scores in RF+ and ACPA+ women, although neither reached statistical significance (RF −0.13; 95% CI −0.39, 0.13; ACPA −0.16; 95% CI −0.44, 0.12).

Conclusion: Parous women have better functional outcome over time than nulliparous women. Increasing delay between last live birth and symptom onset (latency) was associated with increasing HAQ score over time, suggesting that the beneficial effect of pregnancy diminishes with time. Autoantibody status did not appear to have an impact on the relationship.

Rheumatic Diseases among Oklahoma Tribal Populations. Jasmine R. Gaddy[8], Amy B. Dedeke[4], Wendy Klein[3], Fabio Mota[2], Tina Cooper[2], M. Sohail Khan[1], Virginia Roberts[5], Jeremy Levin[5], Scott Stewart[5], Rebecca Stormont[6] and Judith A. James[7]. [1]Cherokee Nation, [2]Chickasaw Nation, [3]Oklahom Research Foundation, OKC, OK, [4]Oklahoma Medical Research Foundation, OKC, OK, [5]Oklahoma Medical Research Foundation, [6]University of Oklahoma HSC, [7]University of Oklahoma HSC, Oklahoma Medical Research Foundation, OKC, OK, [8]University of Oklahoma HSC, Oklahoma Medical Research Foundation, Veteran's Affairs Medical Center, OKC, OK

Background: Rheumatic diseases cause significant morbidity within American Indian populations. Oftentimes, clinical disease presentations overlap and historically associated autoantibodies are not useful in making a diagnosis or assessing prognosis. The purpose of this study is to identify autoantibody associations in Oklahoma tribal populations with rheumatic disease. With this knowledge we seek to create a tailored approach to diagnosing and treating Oklahoma Native American patients which may also translate to the Native American population at large.

Methods: Tribal-based rheumatology clinics were established and staffed with tribal personnel and a consulting rheumatologist. Patients with presentations concerning for rheumatic disease were referred by primary care providers. 220 Oklahoma tribal members were enrolled (110 with rheumatic disease and 110 controls). A rheumatologist assessed patients for clinical features, including disease criteria, activity measures and revised treatment programs. Medical records were reviewed to extract ACR classification criteria for rheumatic disease. Samples were tested for: ANA and anti-dsDNA [IIF]; anti-CCP, rheumatoid factor and aPLs [ELISA] and other lupus autoantibodies (anti-Ro, anti-La, anti-Sm, anti-RNP and anti-Jo) [precipitins]. Statistical analysis was conducted using chi-square and ANOVA methods.

Results: Rheumatic diseases included: 39 (35%) Rheumatoid Arthritis [RA], 17 (15%) Systemic Lupus Erythematosus [SLE], and 8 (7%) Scleroderma [SCL]. Additional diagnoses were comprised of osteoarthritis, Sjogren's Syndrome or fibromyalgia. The remaining patients have rheumatic conditions or symptoms some of which did not meet ACR criteria for disease. Included are inflammatory eye disease (3%), sclerodactyly (1%), undifferentiated connective tissue disease (5%) inflammatory polyarthritis (8%) and polyarthralgia (8%). RA patients were over nineteen times as likely as non-RA patients to be anti-CCP positive (56% vs 2%, $p<0.001$) and almost six times more likely to be RF (by IgM) positive (59% vs 10%, $p<0.001$). Moreover, 18 of 39 patients with RA were both anti-CCP and RF positive. By multivariate logistic regression, together anti-CCP and RF were better predictors of RA than by either test alone ($p=0.007$). Scleroderma patients also exhibited anti-dsDNA, anti-Ro and anti-Jo-1 antibodies which are typically not seen in Scleroderma sera. In addition, anti-Ro, anti-La and anti-dsDNA were also detected in RA patients. Anti-phospholipid antibodies were found across several rheumatic diseases. Finally, autoantibodies against unidentified antigens (UILs) were seen in over 5% of rheumatic patients.

Conclusion: Clinical presentations of rheumatic disease within Oklahoma tribal members are oftentimes overlapping and difficult to define by ACR criteria. Unique autoantibodies were identified in patients meeting ACR criteria for disease. Anti-CCP is a better RA predictor in tribal communities and warrants changes in current diagnostic practices. Other autoantibodies (aPLs and UILs) are found in a variety of American Indian rheumatic disease and clinical significance will need to be established.

Rheumatoid Arthritis (RA) Impact on Work and RA-Related Indirect Costs during the First Three Years after RA Diagnosis. An Economic Analysis from the ESPOIR Cohort. Sabrina Dadoun[6], Sandy Lucier[2], Marie De Rosa[2], Alain Saraux[3], Francis Berenbaum[4], Isabelle Durand-Zaleski[2], Francis Guillemin[1], Karine Chevreul[7] and Bruno Fautrel[5]. [1]Nancy, France, [2]Paris, France, [3]CHU de la Cavale Blanche, Brest Cedex, France, [4]Faculty of Medicine P&M Curie, Paris, France, [5]Pitie Salpetriere Hospital, Paris, France, [6]Pitie Salpetriere Hospital, Paris, France, [7]URC Eco, Paris, France

Background: Rheumatoid arthritis (RA) has often dramatic impact on work and incur for substantial indirect costs. In this field, only few data are available about patients just starting the disease.

sick leaves, invalidity and job retention.

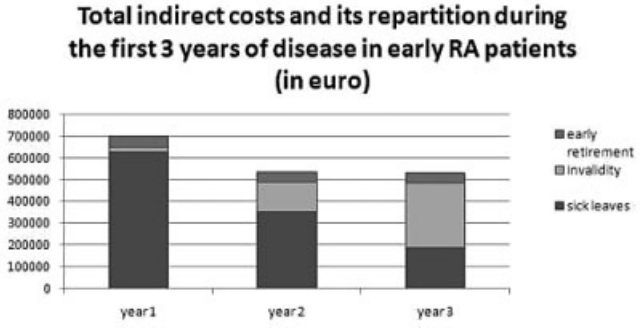
Objective: To assess the impact on work and the indirect costs attributable to RA in early arthritis patients included in the ESPOIR early arthritis cohort and to identify predictors of high indirect costs as soon as the early steps of RA.

Methods: The nationwide ESPOIR cohort included 811 patients with early arthritis (female 77%; mean age 48 years; mean HAQ 1.0; DAS28 5.2; IgM RF+ 47 %; anti-CCP+ 39 %; structural damage on X-ray 22 %; satisfaction of 1987 ACR criteria 71%)[1].

Among this population, people participating on the market place were identified and RA-induced absenteeism was assessed after having defined 4 work states: temporary sick leave, long-term sick leave, permanent disability / invalidity, and early retirement. For each state, the number of patients and the total number of days off work were calculated for every year of follow-up.

The valorization of RA-related absenteeism was estimated from the payer perspective. Daily wages were stratified on patient socio-economic profile and sex. Indirect cost drivers were assessed by using univariate then multivariate analysis in 2 steps: 1) logistic regression to identify predictors of indirect costs versus no indirect costs; then 2) linear regression after log-transformation of indirect costs (skewed cost distribution) to identify predictors of the highest costs.

Results: On the 398 patients participating in the work force at diagnosis, 91% had a paid job and 71% still worked after 3 years of disease. During the first 3 years, 241 patients had at least one temporary sick leave and 54 patients got compensated disability status. Mean number of days in sick leave decreased from 118 days the first year to 71 days the third year, whereas mean number of days in invalidity almost doubled over the three years (figure).



Mean annual cost was €1476 (table). 169 patients had no indirect costs. Predictive factors of indirect costs were disease severity at baseline (DAS28>5.1), HAQ>1, male sex and manual job ($p<0.05$ in the univariate analysis). The linear model showed a significant relation between indirect costs and age at diagnosis, HAQ and DAS28>5.1.

Conclusion: Only a few patients lost their job in the first 3 years of the disease but most of them experienced at least one sick leave (60%). Indirect costs did not show any meaningful decrease during the first 3 years of treatment, mainly because the reduction in sick leave was counterbalanced by an increase in compensated invalidity.

782

Screening for Latent Tuberculosis Infection (LTBI)–Performance of Tuberculous Skin Test and Interferon-gamma Release Assays (IGRA) under Real Life Conditions. Stefan Kleinert[7], Hans Peter T. Tony[7], Klaus Krueger[6], Jacqueline Detert[1], Frank Mielke[4], Gerd R. Burmester[2], Roland Diel[3], Martin Feuchtenberger[8] and Christian Kneitz[5]. [1]Charité-Universitätsmedizin Berlin, Dep. of Rheumatology and Clinical Immunology, CC12, [2]Charité Berlin, [3]Department of Pneumology, Medical School (MHH) Hannover, [4]Gemeinschaftspraxis Innere Medizin, Dres. Mielke, Berlin, [5]Klinik für Innere Medizin II (Klinische Immunologie und Rheumatologie, Klinikum Südstadt Rostock), [6]Praxiszentrum St.Bonifatius München, [7]Rheumatology / Clinical Immunology, Med. Klinik 2, University of Wuerzburg, Wuerzburg, Germany, [8]Rheumatology / Clinical Immunology, Med. Klinik 2, University of Wuerzburg

Introduction: Treatment of LTBI has greatly reduced Tb reactivations under anti-TNF therapy. Screening has been based on patient history, chest x-ray, BCG vaccination status and tuberculous skin test (TST). The introduction of IGRAs has improved screening procedures and some national guidelines recently favour IGRA testing over a TST.

This study is a real-life, multicentric approach to compare IGRAs versus TST for detection of LTBI in a large cohort of patients with rheumatic diseases under immunosuppressive therapy.

Methods: 62 centers in Germany evaluated 1529 consecutive patients for LTBI prior to therapy with biologics. TST was performed in all patients. Additionally, an IGRA was performed, either TSPOT.TB assay (TSPOT, n=844) or Quantiferon TB Gold assay (QFT, n=685)), whichever was available in the local laboratory.

Results: Patient distribution was 852 RA, 215 PsA, 294 AS, 92 undiff. SpA, 76 various. 254 patients were previously BCG vaccinated. TST was positive in 173 patients (11.3%), IGRA was positive in 120 patients (7.9 %), 8.3 % (n=70) in the TSPOT group and 7.3% (n=50) in the QFT group. 50 TST positive patients where previously BCG vaccinated. The *prevalence of LTBI defined by a positive TST without previous BCG vaccination* was 8.0% (123 pts) and based on the IGRA 7.9% (120 pts)

The patient group identified by TST (n=123) or IGRA (n=120) predominantly described different patients. Of the 123 TST positive patients only 56 were IGRA positive. Of 120 IGRA positive only 66 were TST positive.

Clinical risk factors for LTBI were found in 122 patients (34 *history* of own Tb, 81 close *contact*, 27 chest x-ray (*cxr*) suggestive of LTBI). A compound risk factor (*rf*) was defined as at least one of these risk factors being present. Uni- and multivariate logistic regression revealed influence of *rf* on TST (OR 6.6; KI 4.41 – 9.96, p<0.001) and BCG status (OR 3.2; KI 2.19 – 4.60, p<0.001). QFT and TSPOT results were influenced by *rf* but not by BCG status (QFT: Rf OR 2.9; KI 1.31– 6.27, p=0.021. BCG OR 0.4, KI 0.17–1.13, p=0.080. TSPOT: Rf OR 8.8; KI 4.93–15.78, p< 0.001. BCG OR 1.69, KI 0.8–3.56, p=0.165).

Conclusion: The study revealed a significant prevalence of LTBI in patients evaluated for biologic therapy in a country with low incidence of Tb. Prevalence for LTBI based on TST was 8%, based on IGRA 7.9 %. Using both test systems, prevalence increased to 11.1% since 40% of TST positive patients were IGRA negative and vice versa. In multivariate analysis TSPOT was strongly influenced by clinical risk factors, followed by TST and QFT. IGRAs were not influenced by prior BCG vaccination, proving its superiority in these patients. Screening procedures based upon TST have been shown to be effective in reducing tuberculosis reactivation by TNF inhibitors. The exclusive use of IGRAs may leave patients at risk.

Seasonal Variation in Vitamin D Levels in Patients with Psoriatic Arthritis from Northern and Southern Latitudes and Its Association with Clinical Outcomes. Zahi Touma[5], Lihi Eder[4], Devy Zisman[1], Joy Field[1], Vinod Chandran[5], Cheryl Rosen[5], Hua Shen[2], Richard Cook[2] and Dafna D. Gladman[3]. [1]"Lin" Medical Centre, Clalit Health Service, Carmel Medical Centre, Haifa, Israel, [2]Division of Biostatistics, University of Waterloo, Waterloo, ON, Canada, [3]Toronto Western Hospital, Toronto, ON, Canada, [4]University of Toronto Psoriatic Arthritis Clinic, Toronto Western Hospital, Torotn, ON, Canada, [5]University of Toronto Psoriatic Arthritis Clinic, Toronto Western Hospital, Toronto, ON, Canada

Background: Vitamin D has emerged as an important factor in the pathogenesis of several autoimmune diseases including psoriasis and inflammatory arthritis. Hypovitaminosis-D seems to be a pandemic problem. Studies showed that it is more common in inhabitants of high latitude compared to low latitude areas.

Objective: We aimed to determine the prevalence of vitamin D deficiency/insufficiency in patients with psoriatic arthritis (PsA), its seasonal and geographic variation, association with demographic and lifestyle characteristics, and with disease activity.

Methods: This study was conducted in a center in a northern geographic area (N;North) and a center in a subtropical region (S;South), from March 2009 to August 2009. Most subjects were assessed in both winter and summer. Patients completed a vitamin D questionnaire developed to assess lifestyle determinants of vitamin D levels. Demographic, clinical data, skin type (Fitzpatrick classification), serum 25(OH) vitamin D, creatinine, calcium, phosphorus and liver enzymes were determined. Vitamin D levels were categorized as deficient < 30, insufficient 30– 74 and adequate >75 ng/ml.

A multivariate linear mixed model that included demographic/lifestyle and clinical variables, latitude, season as covariates, was used to assess the relationship with vitamin D levels.

Results: 302 PsA patients were enrolled: 258 winter (201 in N/57 in S), 214 summer (140 N/74 S). Vitamin D levels (winter/summer) were adequate (N: 41.3/41.4%; S: 42.1/35.1%), insufficient (N: 55.7/58.6%; S: 50.9/62.2%) and deficient (N: 3/0%; S: 3.8/0.9%) among patients (Table 1).

Table 1. Patients' characteristics and vitamin D level distribution

Variables/Sites	North n = 201	South n = 101	Season	Vitamin D	North n = 201	South n = 101	North and South n = 302
Age at visit	51.8 ± 12.5	56.4 ± 13.4	Winter	Adequate	41.3%	42.1%	41.5%
				Insufficient	55.7%	50.9%	54.7%
				Deficient	3%	7%	3.8%
Age at onset of Psoriasis	28.2 ± 14.6	37.1 ± 16.0	Summer	Adequate	41.4%	35.1%	39.3%
				Insufficient	58.6%	62.2%	59.8%
				Deficient	0%	2.7%	0.9%
Age at onset of PsA	36.5 ± 12.9	46.4 ± 14.4					
Sex							
M	128 (63.7%)	59 (58.4%)					
F	73 (36.3%)	42 (41.6%)					
Race							
Caucasians	189 (95.0%)	101 (100%)					
South Asian	1 (0.5%)						
Chinese	4 (2.0%)						
Filipino	2 (1.0%)						
Others	3 (1.5%)						
Skin classification							
1	12 (6.2%)	11 (13.8%)					
2	58 (30.1%)	40 (50.0%)					
3	67 (34.7%)	15 (18.8%)					
4	39 (20.2%)	13 (16.2%)					
5	17 (8.8%)	1 (1.2%)					

Multivariate regression showed that subjects who had suntanned and received phototherapy, in the past three months, has significantly higher vitamin D levels (p=0.012 and p=0.030 respectively). Taking multivitamins increased vitamin D levels (p=0.014) and vitamin D supplementation was independently associated with higher vitamin D levels p<0.001. Fish oil supplementation was also associated with higher levels of vitamin D (p=0.036). Males were more likely to have lower vitamin D levels p=0.02. There was no association between vitamin D levels, geographic and seasonal interaction, race, employment status and skin type, and disease activity as measured by PASI score for psoriasis and active joint count, dactylitis and inflammatory spinal pain for PsA in both seasons. No association between disease activity in summer and vitamin D levels in winter could be found.

Conclusion: A high prevalence of vitamin D insufficiency among PsA patients was found. There is no seasonal variation in vitamin D level among PsA patients in the southern and northern sites. No association could be established between disease activity and vitamin D level. However, lifestyle and demographic determinants such as having a suntan and intake of vitamin D supplements did have an effect on vitamin D level.

Sedentarity Is an Independent Cardiovascular Risk Factor in Rheumatologic Patients. Marco Antivalle[1], Cecilia Imperio[2], Michele Battellino[2], Alessandra Mutti[2], Maria Chiara Ditto[2], Alberto Batticciotto[2], Fabiola Atzeni[2] and Piercarlo Sarzi-Puttini[2]. [1]Rheumatology Unit, L. Sacco University Hospital Milano, MIlano, Italy, [2]Rheumatology Unit, L. Sacco University Hospital Milano, Italy

Background: There is ample demonstration that physical inactivity is a strong cardiovascular (CV) risk factor in the general population. While several reports suggest that patients with RA and other chronic rheumatic diseases have a reduced level of physical activity (PA) compared with the general population, few studies have evaluated physical activity and the risk of CVD in patients with rheumatic diseases (1).

Aim of the study: To study the relationship between low PA and other cardiovascular risk factors in patients affected by rheumatic diseases.

Methods: PA and CV risk factors were studied in 282 patients with rheumatic diseases (216 Females and 66 Males, mean age 53.5 years). 71.4% of patients had inflammatory diseases. The level of PA was assessed by the IPAQ questionnaire, which allows the estimate of total weekly energy expenditure in MET-minute/week, and the categorization of patients into 3 levels of activity - Low (< 600 MET/m/w), Moderate (< 3000 MET/m/w), and High (=> 3000 MET/m/w)-. Metabolic syndrome (Mets) was assessed by the International Diabetes Federation definition (3).

Results: Average PA energy expenditure was 1654 MET-m/w. Overall, a low level of PA was recorded in 47.3%, MetS in 22.6 %, and smoking in 26.1% of patients. Only 21.8% of patient reported walking at least 30 minutes/5 days/week according to cardiovascular prevention recommendations (4). More than 1 risk factor was present in 24.1% of patients. The distribution of risk factors was different in the 2 sexes, females showing a higher prevalence of LPA and males a higher prevalence of MetS. By logistic regression, MetS prevalence was significantly correlated only to sex (p=0.014) and age (p=0.003), but not to the level of PA (Fig. 1), to the type of rheumatic disease (inflammatory vs non inflammatory), nor to disease duration.

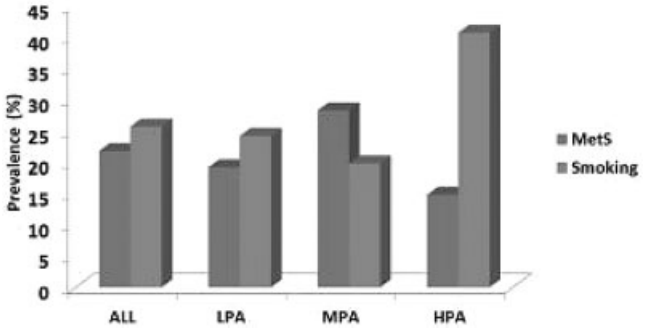

Fig. 1. Prevalence of metabolic syndrome and cigarette smoking according to levels of physical activity.

Conclusions: Sedentarity is very prevalent in rheumatic diseases, and in only 21% of patients weekly exercise meets levels recommended for CV prevention. Low levels of physical activity in this population seem to be unrelated to other cardiovascular risk factors. Preventive strategies to reduce cardiovascular risk in this population should include programs to improve physical fitness.

Sex Differences in Pain Level and Location in Inflammatory Arthritis: A Systematic Review and Meta-Analysis. Cheryl C. M. Barnabe[2], Louis Bessette, Cathy Flanagan, Sharon LeClercq[3] and Vivian P. Bykerk[1]. [1]Mt Sinai Hospital, Toronto, ON, Canada, [2]University of Calgary, Calgary, AB, Canada, [3]University of Calgary

Background: Patient sex may influence the disease experience for patients with inflammatory arthritis (including rheumatoid arthritis (RA), ankylosing spondylitis (AS), psoriatic arthritis (PsA) and spondyloarthropathy (SpA)), with implications for treatment expectations and predicted response. Our objective was to determine if there are differences in the baseline level, location of pain, and the response to treatment, between females and males with inflammatory arthritis.

Methods: A search of PubMed (1950 to April 2010) and EMBASE (1980 to April 2010) was supplemented by manual searches of conference abstracts. We identified studies reporting sex-stratified pain measures (visual analogue scale (VAS), bodily pain component of the 36-item Short Form Health Survey (SF-36BP)) or pain location, in biologic naïve populations. Effects analyzed were a) standardized mean difference (SMD) for pain measures (cross-sectional analyses), b) percentage improvement in pain measure (longitudinal analyses), and c) proportion reporting pain at a particular location. The systematic review for pain measures includes 26 cohorts and 1 randomized controlled trial, and for pain location includes 12 publications. The meta-analysis for pain measures includes 16 cohorts reporting pain by VAS and 3 cohorts reporting pain by SF-36BP.

Results: Meta-analysis revealed a significant difference in the SMD in pain levels measured by VAS in RA (SMD 0.21 (95%CI 0.16–0.26), p<0.001) (Figure 1). This held when stratified by disease duration at measurement (RA < 1 year SMD 0.30 (95%CI 0.15–0.45), established RA SMD 0.20 (95%CI 0.14–0.25)). The SMD for SF-36BP was not significant (SMD −0.14 (95%CI −0.49, 0.20), p=0.411). In longitudinal studies, females improved to a greater degree than males, but still had higher mean pain values at any time point. Males had more inflammatory back pain and females had more peripheral arthritis (Table 1).

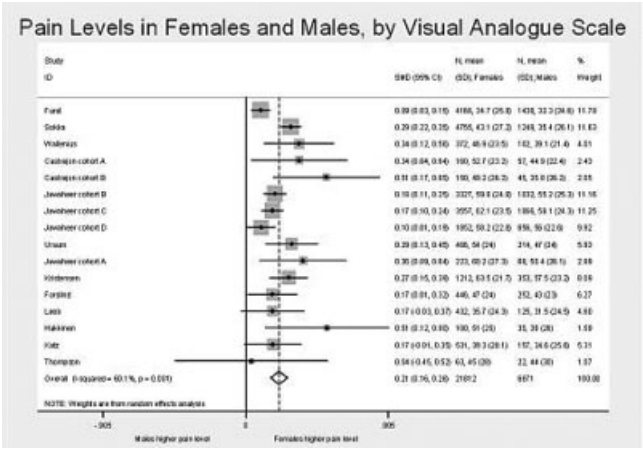

Figure 1. Meta-Analysis of studies reporting sex-stratified VAS pain scores.

Table 1. Studies Reporting Sex-Stratified Pain Location

Author, Year	Disease	Spinal Pain, Females	Spinal Pain, Males	Peripheral Arthritis, Females	Peripheral Arthritis, Males
Marks, 1983	AS	NR	NR	40%	16%
Braunstein, 1982	AS	34%	71%	NR	NR
Coughlan, 1993	AS	37%	69%	42%	17%
Gran, 1985	AS	59%	67%	29%	29%
Jimenez-Balderas, 1993	AS	37%	51%	78%	73%
Kidd, 1988	AS	77%	87%	97%	67%
Maldonado-Cocco, 1985	AS	NR	NR	28%	27%
Mathew, 1989	AS	80%	47%	NR	NR
Resnick, 1976	AS	NR	NR	83%	41%
Queiro, 2001	Ps SpA	43%	49%	24%	11%
Gladman, 1992	Ps SpA	100%	100%	NR	NR
Boyer, 2000	SpA	54%	50%	72%	85%

Conclusions: Females with RA experience higher pain levels than males, but do have a greater degree of improvement with treatment. Although this analysis does not explore confounding factors that may explain sex differences in inflammatory arthritis, it does alert the clinician that pain management is a significant issue in particular for female patients. In AS, females will develop peripheral arthritis more frequently, with fewer manifestations of inflammatory back pain. This may have diagnostic implications in the clinical setting.

Sleep Disturbances in Adults with Arthritis: Prevalence, Mediators, and Subgroups at Greatest Risk. Grant H. Louie[2], Maria G. Tektonidou[1], Alberto J. Caban-Martinez[4] and Michael M. Ward[3]. [1]National University Health System, Singapore, Athens, Greece, [2]NIH, Bethesda, MD, [3]NIH, NIAMS, IRP, Bethesda, MD, [4]University of Miami Miller School of Medicine, Miami, FL

Background: Sleep disturbance is a common medical condition that may adversely affect daily functioning, vocational performance, and health-related quality of life. Few studies have examined the prevalence of sleep disturbances in adults with arthritis in a nationally-representative sample, mediators of sleep disturbances, and subgroups of individuals with arthritis at greatest risk.

Methods: Using data on U.S. adults aged ≥ 18 years participating in the 2007 National Health Interview Survey, we estimated the prevalence of three measures of sleep disturbance (insomnia, excessive daytime sleepiness, and sleep duration < 6 hours) among persons with physician-diagnosed arthritis. We used hierarchical logistic regression analysis to examine if the association of arthritis and sleep disturbances was independent of sociodemographic characteristics and comorbidities, and to identify potential mediators. We used classification trees to identify subgroups at highest risk.

Results: In the sample of 23,134 individuals, 19.9% (representing 44.3 million civilian, noninstitutionalized U.S. adults) reported having arthritis. Adults with arthritis had a mean (± standard error of the mean) age of 59.6 ± 0.3 years, and were more likely women (58.0%), non-Hispanic white (79.1%), and overweight or obese (71.8%). Age-, sex-, race-, and disease-adjusted prevalence of insomnia was 23.1%, excessive daytime sleepiness 11.0%, and sleep duration < 6 hours 7.3%. Adjusted prevalences were similar to those with other chronic diseases, such as diabetes and cardiac disease. Adults with arthritis were 2.9-fold more likely than those without arthritis to report insomnia, but adjustment for sociodemographic characteristics and comorbidities attenuated this association (Table). The association between arthritis and insomnia was further attenuated after adjusting for joint pain and limitation due to joint pain, suggesting pain mediated the relationship between arthritis and insomnia. Similarly, adults with arthritis were significantly more likely to report excessive daytime sleepiness and sleep duration < 6 hours in univariate and multivariate analyses. Adjusting for joint pain and limitation due to pain attenuated these associations. Among adults with arthritis, those with depression and anxiety were at highest risk for sleep disturbance.

Table. Association between sleep disturbances and presence of arthritis (compared to absence of arthritis) among adult participants in the 2007 National Health Interview Survey. Odds ratios (OR) with 95% confidence intervals (CI).

	Unadjusted		Adjusted for sociodemographic characteristics and comorbidities		Further adjusted for joint pain and limitation due to joint pain	
	OR	95% CI	OR	95% CI	OR	95% CI
Insomnia						
+ Arthritis (vs. − Arthritis)	2.92	2.68–3.17	1.53	1.36–1.71	1.06	0.93–1.21
Excessive daytime sleepiness						
+ Arthritis (vs. − Arthritis)	2.48	2.23–2.76	1.37	1.16–1.61	0.96	0.80–1.16
Sleep duration < 6 hrs						
+ Arthritis (vs. − Arthritis)	1.79	1.58–2.03	1.38	1.18–1.62	1.09	0.91–1.29

Conclusions: Up to 23% of the U.S. adult population with arthritis, representing 10.2 million persons, report having a sleep disturbance. The association appears to be mediated by joint pain and limitation due to pain. Among individuals with arthritis, those with depression and anxiety are at greatest risk.

The Comparative Responsiveness of the EQ-5D and SF-6D to Change in Patients with Early Arthritis: Results from the ESPOIR Cohort. Cécile Gaujoux-Viala[1], Anne-Christine Rat[2], Francis Guillemin[2], René-Marc Flipo[5], Patrice Fardellone[4], Pierre Bourgeois[3] and Bruno Fautrel[3]. [1]1INSERM, CIC-EC CIE6 2CHU Nancy, Epidemiologie et Evaluation Cliniques 3Nancy-University, Metz University, Paris Descartes University, EA 4360 Apemac 4Paris 6 – Pierre et Marie Curie University; Rheumatology, Pitie-Salpêtriere Hospital, [2]1INSERM, CIC-EC CIE6, Nancy, France 2CHU Nancy, Epidemiologie et Evaluation Cliniques, Nancy, France 3Nancy-University, Paul Verlaine Metz University, Paris Descartes University, EA 4360 Apemac, Nancy, France, [3]Paris 6 – Pierre et Marie Curie University; Rheumatology, Pitié-Salpêtrière Hospital, Paris, France, [4]Rheumatology, Amiens University, France, [5]Rheumatology, Lille University 2, France

Background: The revolution of early aggressive therapy have fueled the search for better approaches to establish the cost-utility ratio in early arthritis (EA). The EQ-5D and the SF-6D are indirect preference-based health related quality of life instruments increasingly used for economic evaluation of clinical interventions and health programs. Comparative evidence regarding the responsiveness of the EQ-5D and SF-6D in arthritis patients is conflicting and insufficient.

Objective: To compare the responsiveness of the EQ-5D and SF-6D in a large multicenter prospective cohort of patients with EA to guide the choice of instruments and their interpretation.

Methods: The ESPOIR cohort is a nationwide cohort that included 813 patients with EA with a high suspicion of rheumatoid arthritis, between 2002 and 2005. Data, including EQ-5D and SF-6D, were collected every 6 months during the first 2 years then every year. Responsiveness was tested using the standardised response mean (SRM) at 6 and 12 months for the entire sample and for subgroups categorized by their evolution (DAS28 improvement or deterioration>0).

Results: The EQ-5D provided larger absolute mean change estimates with greater variance than the SF-6D whatever the direction of change. The SF-6D and the EQ-5D SRM were higher for improvement than for deterioration of the DAS28 response at 12 months: SRM= 0.83 and 0.55 for the 2 instruments respectively. The SF-6D and the EQ-5D did not respond well to deterioration in patients with early arthritis: SRM= 0.08 and 0.2 in patients with deterioration of the DAS28 at 12 months, respectively (Table).

Das28 improvement at 12 months	Mean change at 12 months	STD of change at 12 months	SRM
DAS28	*−2.20*	*1.30*	*1.67*
HAQ	−0.508	0.652	0.78
SF6D	0.105	0.127	0.83
EQ5D	0.173	0.313	0.55
Das28 deterioration at 12 months			
DAS28	*0.68*	*0.55*	*1.25*
HAQ	0.129	0.518	0.25
SF6D	−0.008	0.097	0.08
EQ5D	−0.053	0.259	0.20

The SF-6D was more responsive to improvement and the EQ-5D more responsive to deterioration. The results were similar at 6 months.

Conclusion: The comparative responsiveness of the EQ-5D and SF-6D differs according to the direction of change. The SF-6D was more responsive than the EQ-5D in case of improvement. However both utility measures were less responsive to deterioration than improvement. The level of mean change of the EQ-5D relative to the SF-6D has implications for cost-effectiveness analysis. Use of the SF-6D in patients with early arthritis may be more appropriate.

The Economic Burden of Uveitis. S. E. Kirbach, O. A. Hayes and M. A. Cifaldi. Abbott Laboratories

Background and Purpose: Uveitis is a common extra-articular manifestation of rheumatic conditions (including ankylosing spondylitis and juvenile idiopathic arthritis). It often recurs and is associated with potentially serious sequelae that greatly increase the risk of vision loss.[1] Uveitis is responsible for ≥10% of blindness in the United States and is associated with a total direct

cost of approximately $2.74 billion.[2,3] Despite this financial burden, there is a dearth of literature examining the economic burden specific to uveitis, especially with regard to the impact of uncontrolled disease and the presence of blindness and vision loss. We determined the average annual medical costs for individuals newly diagnosed with noninfectious uveitis based on location of inflammation, presence of blindness, and number of subsequent uveitis-related medical visits.

Methods: Patients (N=26,079) with noninfectious uveitis (based on ICD-9 codes) and ≥2 years of continuous enrollment (≥1 year before and after diagnosis of first episode) were identified in the MedStat MarketScan database (2000–2008) and categorized by uveitis type (anterior vs. intermediate/posterior/panuveitis [IPP]), incident and prevalent blindness, and number of uveitis-related medical visits (1, 2, 3, or >3 visits). Average annual medical costs were calculated for the year following the initial diagnosis of uveitis. Patients with health maintenance organization, point of service with capitation, or missing insurance plans were excluded from cost summations.

Results: The average annual cost for all individuals with noninfectious uveitis was $8,450 vs. $4,688 for nonuveitis controls. For all patients with uveitis, those with IPP uveitis incurred greater costs than those with anterior uveitis ($12,149 vs. $7,834, respectively). Patients who became blind during the observation period had greater costs than those who maintained their sight ($21,384 vs. $8,236, respectively) and those who were blind at the start of the follow-up period ($14,404). The largest driver of medical costs for patients with noninfectious uveitis was outpatient hospitalizations (29% of all costs) followed by drug costs (22% of all costs). In terms of uveitis-related medical visits, medical costs uniformly increased with number of visits (table).

Annual Medical Costs for Noninfectious Uveitis Patients by Type, Presence of Blindness, and Number of Uveitis-Related Medical Visits

	All ($)	1 Visit ($)	2 Visits ($)	3 Visits ($)	>3 Visits ($)
Noninfectious Uveitis					
All (N = 34,632)	8,450	7,908	8,723	10,016	12,513
Blind (N = 770)	17,846	16,567	15,152	18,972	25,882
Nonblind (N = 33,862)	8,236	7,742	8,554	9,729	11,859
IPP Uveitis					
All (N = 4,708)	12,149	10,900	11,523	15,117	23,976
Blind (N = 229)	23,619	16,758	19,880	30,686	50,207
Nonblind (N = 4,479)	11,607	10,684	10,994	13,907	21,185
Anterior Uveitis					
All (N = 29,924)	7,834	7,412	8,265	9,117	10,523
Blind (N = 541)	15,503	16,498	12,864	12,725	15,213

Conclusions: Uveitis results in a large degree of economic burden, especially for individuals with more severe disease or blindness and for those with repeated uveitis-related medical visits.

The Effect of Health Insurance and Physician Specialty on Quality of Care for SLE. Edward H. Yelin[6], Jinoos Yazdany[6], Laura Trupin[6], Chris Tonner[6], Gabriela Schmajuk[3], Patricia P. Katz[5], Lindsey A. Criswell[4], Laura J. Julian[6], Joann Z. Gillis[2] and Pantelis Panopalis[1]. [1]McGill University, Montreal, QC, Canada, [2]National Jewish Medical Center, Denver, CO, [3]Stanford University, Palo Alto, CA, [4]UCSF-Box 0500, San Francisco, CA, [5]Univ of CA San Francisco, San Francisco, CA, [6]University of California, San Francisco, San Francisco, CA

Background: Quality indicators (QIs) describe the extent to which health care meets minimal standards for quality of care. The authors have recently developed 20 QIs for SLE covering diagnosis, general preventive strategies, osteoporosis prevention and treatment, drug toxicity monitoring, renal disease, and reproductive health.[1] Of the 20 QIs, we deemed 14 amenable to self-report. The present study evaluates the extent to which health care in a community-based sample of persons with SLE (PWSLE), the Lupus Outcomes Study (LOS), adheres to these 14 QIs as a function of the kind of health insurance and specialty of physicians seen for SLE.

Methods: In 2009, 814 PWSLE were in the LOS. Principal data collection is an annual structured telephone interview regarding kind of health insurance, specialty of physicians seen, and health services received, including specific medications. Participants vary in their eligibility for the 14 QIs: all are eligible for the QIs related to counseling about sun avoidance and assessment of cardiovascular risk factors while only 1% are eligible for the QI related to treatment of new-onset proliferative lupus nephritis. We report here the overall pass rate, the % of all QIs for which PWSLE are eligible for which they report requisite health care services, as a function of the kind of health care coverage (HMO vs. non-HMO settings in public and private sectors) and combinations of care for SLE by generalists and rheumatologists. We use logistic regression to estimate the impact of type of health insurance and specialists, with and without adjustment for demographics (age, gender, race/ethnicity, education, and poverty status), disease duration and activity as measured by SLAQ, and number of physician visits on the pass rate. In these estimations, each QI for which PWSLE are eligible represents an observation; we account for the correlation among multiple observations of individuals via generalized estimating equations.

Results: The 814 PWSLE in the LOS were eligible for an average of 5.1 QIs (range 2–12) per person. The overall pass rate was.66 (95% CI.64-.67). The pass rate improved with increasing number of physician visits in the year prior to interview. It was also significantly higher among PWSLE in public sector HMOs than in private sector HMOs or in public and private sector non-HMO settings (Table 1). Those receiving care from generalists and rheumatologists singly or in combination had higher pass rates than those treated by neither. Adjustment had little effect on the results for kind of insurance or specialty of physician.

Conclusions: Pass rates for QIs vary significantly by kind of health insurance coverage and specialties seen by PWSLE and rise with increases in the number of physician visits, suggesting that aspects of health care amenable to policy changes may improve quality of care for PWSLE.

Table 1. Pass Rates (95% CI) for QIs among PWSLE, by Kind of Insurance and Specialties Seen

	Kind of Insurance			
	HMO		Non-HMO	
	Public	Private	Public	Private

The Georgia Lupus Registry: Health Care Utilization Rises during the Transition from Pediatric to Adult Systemic Lupus Erythematosus (SLE) Care. S. Sam Lim[3], Gaobin Bao[1], Larry B. Vogler[4] and Cristina M. Drenkard[2]. [1]Emory University, [2]Emory University, Atlanta, GA, [3]Emory University, Atlanta, GA, [4]Emory University School of Medicine, Atlanta, GA

Background: Some studies have reported childhood onset SLE as being more severe than in adults. Therefore, children with SLE may be at high risk for entering adulthood with disease related morbidity, damage, and disability. Furthermore, medical and psychosocial barriers can complicate the transition from pediatric to adult care. The aim of this study is to describe how health care utilization may change during this transition period.

Methods: The Georgia Lupus Registry is a population-based registry designed to estimate the incidence and prevalence of SLE in Atlanta, Georgia, from 2002 through 2004. Case-finding utilizes multiple sources. As a public health project, trained abstractors are able to document nearly 250 demographic and clinical elements from medical records of potential SLE patients without having to obtain consent. All facilities with potential pediatric SLE patients have been abstracted. All patients met the following case definition:

having either ≥4 ACR criteria or 3 ACR criteria with a diagnosis of SLE by a pediatric rheumatologist at age ≤18 years. The validated SLE patients were matched to the 1999–2004 Georgia Hospital Discharge Database, which captures all emergency room visits (ERV) and hospital admissions (HA) throughout the state and assigns a standardized direct cost to that care.

Results: 37 with childhood-onset SLE turned 19 years old between 1/1/1999 and 12/31/2004. 23 of these recorded at least one ERV or HA during this period (217 total visits) and had an average of 6.3 ACR criteria. The remaining 14 patients did not record an ERV or HA and averaged 5.1 ACR criteria.

	before turning 19 years old (person-years = 104)		after turning 19 years old (person-years = 108)		
	ERV	HA	ERV	HA	P-value*
Visits, total	38		117		<.0001
		21		41	0.01
Visits, Gender					
Male (n = 4)	1		13		0.001
		0		5	–
Female (n = 19)	37		104		<.0001
		21		36	0.047
Visits, Race					
Black (n = 20)	33		103		<.0001
		19		39	0.009
White (n = 3)	5		14		0.039
		2		2	1.00
Cost per Visit, $ Mean	11858		8978		0.37
		13570		13598	0.41
Male (mean)	2528	-	4732	22686	
Female (mean)	12110	13570	9509	12335	
Black (mean)	11709	13269	9884	13936	
White (mean)	12843	16432	2318	6995	
Duration, days					
Median	1		1		0.21
		7		3	0.002
Male (mean)	2.0	-	1.5	7.0	
Female (mean)	4.3	7.1	3.0	3.7	
Black (mean)	4.4	7.2	3.0	4.2	
White (mean)	3.4	7.0	1.5	1.5	

* Based on Wilcoxon Rank-Sum Test

Conclusions: The health care utilization burden of childhood-onset SLE is significant. With nearly equal amount of person-time follow-up before and after turning 19 years old, there is a striking increase in the number of ERV (tripling from 38 to 117) and HA (doubling from 21 to 41). This may signal the need to better coordinate the transfer of care for these patients. Access to care may be a factor as children without resources lose Medicaid coverage when turning 19. Further research is needed to elucidate the modifiable factors driving this change.

791

The Impact of RA Diagnoses on Cost Related Medication Nonadherence in Older Patients: 2004–2007. Leslie R. Harrold[3], Becky A. Briesacher[4], Daniel Peterson[2], Jeanne Madden[1], Jerry H. Gurwitz[2] and Stephen B. Soumerai[1]. [1]Harvard Medical School, Boston, MA, [2]Meyers Primary Care Institute, Worcester, MA, [3]UMass Medical Schl, Worcester, MA, [4]UMass Medical School, Worcester, MA

Introduction: The treatment of rheumatoid arthritis (RA) can involve costly medications. We sought to examine whether cost-related medication nonadherence (CRN) was higher among patients with RA as compared to those without the condition from 2004 through 2007.

Methods: We identified a nationally-representative sample of elderly and disabled patients with rheumatoid arthritis (RA), based on two claims diagnoses (ICD-9 714.XX), and those without RA using the Medicare Current Beneficiary Survey. There were 219 to 241 RA patients and 14279 to14575 non-RA patients annually from 2004–2007 (unweighted n). We compared self-reported CRN (skipping or reducing medication doses or not obtaining prescriptions) among beneficiaries with and without RA. Using logistic regression, we examined whether there were trends over time in the occurrence of CRN among those with and without RA. Then we evaluated whether an RA diagnosis was associated with CRN after controlling for year, demographic characteristics, socioeconomic status, and comorbidities.

Results: The unadjusted annual prevalence of CRN in 2004, 2005, 2006, and 2007 among beneficiaries with RA was 20.7%, 17.5%, 16.7%, and 15.6%, respectively, compared with 15.1%, 14.0%, 11.4%, and 10.6% among beneficiaries without RA (statistically significant differences between RA vs non-RA in 2004 and 2006). In RA patients, the absolute decrease in CRN 2004 to 2007 was 5.1% and relative decrease was 24.6%, while among non-RA patients these were 4.5% and 29.8%, respectively.

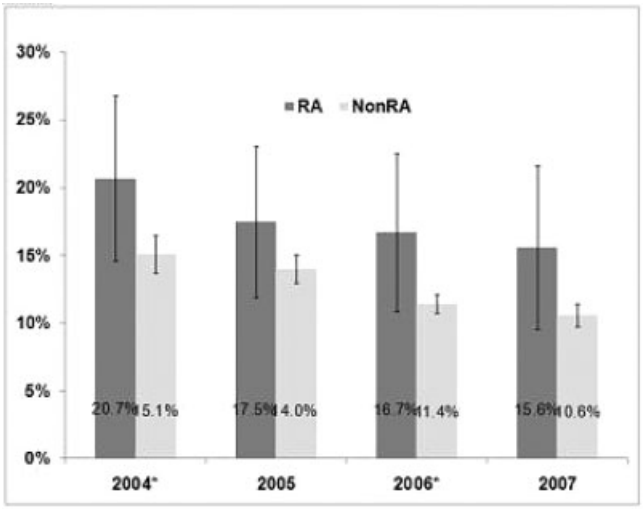

Figure 1. The prevalence of cost-related medication nonadherence among elderly Medicare beneficiaries with a diagnosis of rheumatoid arthritis (RA) versus those without (non-RA), 2004–2007.

The trend in CRN over time was not significant for those with RA ($p=0.23$) but was for those without the condition ($p < 0.0001$). The diagnosis of RA increased the likelihood of CRN (OR 1.27; 95% CI 1.01–1.60) in adjusted analyses.

Conclusions: CRN is a persistent problem for older adults, especially those with RA. While there have been decreases in CRN over time related to the Medicare Replacement Drug Demonstration program and Medicare Part D, substantial numbers of RA patients continue to report problems affording their medications.

The Influence of Immunosuppressive Therapy and Underlying Diseases on Vaccine Responses to Influenza A H1N1/09 Vaccines in Inflammatory Rheumatic Diseases. Cem Gabay, Sara Meier, Danielle Gascon, Karin Posfay-Barbe, Christophe Combesure, M. Bel, Laurent Kaiser, Pierre-Andre Guerne and Claire-Anne Siegrist. Univ Hosp of Geneva, Geneva, Switzerland

Background: Influenza A H1N1 is a new virus that emerged in spring 2009 and rapidly spread around the world causing a pandemic. As patients with inflammatory rheumatic diseases (IRD) exhibit some form of immunodeficiency related to their diseases and the use of immunosuppressive drugs, the Swiss Society of Rheumatology recommended the vaccination of all IRD patients under immunosuppressive agents. However, two important questions remain unresolved: 1) are immunocompromised hosts able to raise successful vaccine responses, 2) is the use of adjuvanted vaccines safe in patients with autoimmune diseases.

Objectives: To determine the efficacy and safety of influenza A H1N1/09 vaccine formulated in a lipid adjuvant (squalene) in patients with IRD.

Patients and Methods: 173 patients with IRD and 138 healthy controls were included from November 2009 to January 2010 in this prospective, open-labeled, single center, parallel-cohorts study. Among IRD patients, there were 82 cases of rheumatoid arthritis (RA), 45 cases of spondylarthropathies (SpA), and 46 cases of connective tissue diseases (18 systemic lupus erythematosus (SLE)) or vasculitis. All received a first vaccine dose and 154 (89%), the second prescheduled vaccine dose. Safety after vaccination was assessed, respectively, in 173 and 149 patients using medical history and clinical indices of disease activity (DAS28, RADAI, and HAQ for RA, BASDAI for axial SpA, SLEDAI for SLE, and BVAS for vasculitis). The kinetic of the vaccine response and antibody titers (using a standardized

in-house hemagglutination inhibition assay) were assessed after the first and the second dose and compared to titers obtained in a control group of healthy individuals vaccinated once. Cellular immune responses to influenza H1N1/09 vaccine will be also determined in a subset of patients and controls.

Results: Disease modifying antirheumatic drugs were used in 85% of RA, 63% of SpA, 94% of SLE patients; oral corticosteroids in 31% of RA, 11% of SpA, and 70 of SLE patients; anti-TNF in 43% of RA and 71% of SpA; and rituximab in 21% of RA and 11% of SLE patients. The different indices of disease activity were not significantly different at baseline and after vaccination. Despite immunosuppression, injection-site tolerability and systemic inflammatory reactions were similar in patients with IRD than in healthy controls. Seroprotection rates (defined by IHA titer >= 1/40) after dose 1 were 129/146 (88.4%) in controls and 103/138 (74.6%) in patients ($P<0.001$). This rate increased to 128/148 (86.5%) after 2 doses. The analysis of the pattern of vaccine immune responses in the different IRD patient groups is in progress and will be presented.

Conclusions: The adjuvanted vaccine against influenza A H1N1/09 is well tolerated and does not induce short-term exacerbation in patients with IRD treated with immunosuppressive agents.

793

The Risk of Myocardial Infarction among Patients with Psoriatic Arthritis. Thorvardur J. Love[1], Daniel Hal Solomon[3] and Elizabeth W. Karlson[2]. [1]Brigham and Women's Hospital, Boston, MA, [2]Brigham and Womens Hosp, Boston, MA, [3]Brigham and Womens Hospital, Boston, MA

Background: Severe psoriasis is associated with an increased risk of myocardial infarction (MI). A recent study found a standardized prevalence ratio of 2.51 for MI among psoriatic arthritis (PsA) patients compared to individuals from a telephone survey of the general population. We examined data from a hospital-based PsA repository, a population based survey, and medical records of patients without PsA to evaluate the risk of MI.

Methods: We performed two matched cohort analyses, using a single group of validated cases of PsA from a psoriatic arthritis patient repository seen at a tertiary care teaching hospital between 1995 and 2008, with each PsA case matched 2:1 on birth year, gender, and race to two separate comparison groups: non-PsA patients drawn from the same hospital population, and participants in the NHANES 2005–2008 population survey. The first documented diagnosis of PsA marked the beginning of follow up. The start of follow up for the hospital non-PsA group was the visit date closest in time to the diagnosis of the matched PsA case. Incident MI was determined by the presence of an ICD9 code in medical records, or self report in the NHANES cohort. Each individual was followed from either the onset of PsA or the matched index date, until they had an MI or follow-up ended. We excluded anyone with less than 12 months of follow up, and those with pre-existing cardiovascular conditions.

Results: We successfully matched 1404 BWH non-PsA patients to 702 PsA cases found in our repository. From NHANES we found two matched controls for each of 734 PsA cases. Cumulative follow up time in the three arms of the study was 21,509 person years. There were 33 incident cases of MI in the PsA-group, 67 in the BWH non-PsA group, and 18 in the NHANES group. The incidence rate (IR) for MI per 10,000 patient years was 72 [50–101], 80 [62–102], and 21 [12–33] per 10,000 patient years at risk in the three groups, respectively. The crude incidence rate ratio for MI in PsA was 0.93 [0.60–1.44] and 3.46 [1.89–6.52] compared to the hospital and NHANES groups. Table 1 shows the results of the multivariate Cox proportional hazards analysis adjusted for age, calendar year, diabetes, hypertension, and hyperlipidemia for the risk of MI.

Table 1. Cox proportional hazard analysis of the risk of MI associated with psoriatic arthritis, adjusted for age, calendar year, diabetes, hypertension, and hyperlipidemia.

	Hospital comparison			NHANES comparison		
	HR	[95% CI]		HR	[95% CI]	
Psoriatic arthritis	**0.99**	**0.94**	**1.04**	**1.18**	**1.08**	**1.28**
Age	1.04	1.02	1.05	1.05	1.03	1.08
Calendar year	1.02	0.95	1.10	1.06	0.94	1.19
Diabetes	1.94	1.28	2.94	2.34	1.29	4.24
Hypertension	4.92	2.51	9.63	3.25	1.49	7.06
Hyperlipidemia	2.82	1.66	4.80	2.14	1.13	4.06

Conclusion: We did not find any difference in the risk of MI in the PsA group when comparing to a non-PsA group drawn from the same hospital based source population. We replicated a previously demonstrated association between PsA and MI when comparing cases of PsA to individuals from the general population. Furthermore, we quantified the risk by estimating the IR, the IRR, and the adjusted HR. This suggests that the choice of control population affects the results of analyses of MI risk in PsA. Studies of PsA cases drawn from the general population are needed to support the hypothesis that PsA increases the risk of MI in the general population.

Validation of a Self-Administered Inflammatory Arthritis Detection Tool for Rheumatology Triage. Mary J. Bell[6], George A. Wells[7], Vivian P. Bykerk[3], Peter Tugwell[1], Ruben Tavares[2], Francis Guillimen[4] and Joel Scarf[5]. [1]Institute of Population Hlth, Ottawa, ON, Canada, [2]MaMaster University, [3]Mt Sinai Hospital, Toronto, ON, Canada, [4]Nancy University, [5]Sunnybrook Health Sciences Ctr, [6]Sunnybrook Health Sciences Ctr, Toronto, ON, Canada, [7]Univ of Ottawa Faculty of Med, Ottawa, ON, Canada

Background: A self-administered tool for the early detection of inflammatory arthritis (IA) has been developed. A systematic review was used to identify stage-one case ascertainment dimensions and constructs amenable to self-assessment. Using a three-round Delphi consensus panel involving 169 arthritis stakeholders, the identified constructs were formulated into lay language items and refined into twelve questions with binary, 'yes'/'no' response options. Studies to validate the tool in various community and clinical settings are ongoing. The objective of the current study was to establish a scoring algorithm for, and validate, the tool for IA triage in the rheumatology wait-list population.

Methods: The tool was self-administered by 143 patients on the waiting lists of two Canadian, academic rheumatologists. At rheumatology presentation, the blinded rheumatologists assigned a clinical diagnosis and categorized each patient as IA or not. Multivariable logistic regression was conducted using IA as an outcome and age, sex, and the twelve tool items as independent variables. Multivariable-adjusted estimates of independent variable effect sizes were used as weights for the tool. Bootstrap AGGregatING (BAGGING) of 200 multivariable models was used to refine estimates of independent variable weights and the tool's performance properties. Receiver operating characteristic (ROC) curves for the models were derived. The predictive performance for the tool was determined from the area under the ROC curve (AUC), and sensitivity and specificity using the optimal model probability cutoff score. The optimal model probability cutoff score was determined from the maximum sum of sensitivity and specificity along the ROC curve. All analyses were performed using SAS/STAT® v. 9.2.

Results: The sample was comprised of a variety of rheumatologic conditions including 30 IA (ankylosing spondylitis, psoriatic arthritis, reactive arthritis, rheumatoid arthritis, and undifferentiated inflammatory arthritis) and 113 non-IA cases (osteoarthritis, pain syndromes, systemic lupus erythematus, and other miscellaneous rheumatologic disorders. Using an equally-weighted, unidirectional scoring scheme, where all 'yes' responses contributed positively towards the detection of IA, a cut-off score of 7 of 12 (0.58) produced an ROC AUC of 0.77, with a sensitivity of 0.87 and specificity of 0.52. Using multivariable logistic regression, a model probability cut-off score of 0.33 produced an ROC AUC of 0.91, with a sensitivity of 0.80 and specificity of 0.89. The model goodness-of-fit was supported by a non-significant Hosmer-Lemeshow test ($p=0.64$). The BAGGING-refined model with a probability cutoff of 0.28 (0.20–0.41) produced an ROC AUC of 0.95 ± 0.02 with a sensitivity of 0.90 (0.85–0.95) and specificity of 0.90 (0.85–0.96).

Conclusions: A scoring algorithm for a self-administered, twelve-item tool was developed and validated for IA detection in the rheumatology wait-list population. Together with its self-assessment mode of administration, the high sensitivity and specificity of the tool render a potential advance in rheumatology triage of IA.

Validation of the SF-6D Utility Measure in Patients with Systemic Lupus Erythematosus (SLE). Mark J. Harrison[5], Nicola Dale[1], Sahena Haque[2], Joanna Shelmerdine[6], Lee-Suan Teh[4], Yasmeen Ahmad[3] and Ian N. Bruce[1]. [1]Arthritis Research UK Epidemiology Unit, The University of Manchester, Manchester, United Kingdom, [2]Arthritis Research UK Epidemiology Unit, The University of Manchester, Manchester, United Kingdom, [3]Betsi Cadwaladr University Health Board-West, Rheumatology, Llandudno, United Kingdom, [4]Department of Rheumatology, Royal Blackburn Hospital, Blackburn, United Kingdom, [5]Health Sciences Research Group, The University of Manchester, Manchester, UK, [6]The Kellgren Centre for Rheumatology, Central Manchester Foundation Trust, Manchester, UK

Purpose: Collection of health-related quality of life (HRQoL) questionnaire with sets of utility values, such as the SF-6D, allow quality-adjusted life years used in cost-utility evaluations to be calculated. However these measures should be evaluated for validity in each setting they are applied. Few studies in systemic lupus erythematosus (SLE) have included a generic HRQoL measure; therefore the validity of these measures for this setting is unclear. This study aims to explore the construct validity and the minimum important difference (MID) of the SF-6D in SLE patients.

Methods: Female patients with SLE (≥4 ACR criteria) were recruited from routine outpatient clinics at 2 time points 5 years apart. At baseline and 5 years patients had a clinical assessment including the SLEDAI 2000 and SLICC damage index. Patients also completed the generic RAND Medical Outcome Study 36-Item Short-Form Survey version 1 (MOS SF-36), which allows the SF-6D to be calculated, at baseline and 5-years and the (disease specific) LupusQoL® was completed at the 5-year time point.

Construct validity was tested by (1) correlation (Pearson) of SF-6D with SLICC (damage), SLEDAI (activity), patient characteristics (age, disease duration, education, smoking, depression, fatigue), and LupusQoL® (at 5-years). The ability to discriminate between groups was tested using the t-test. The minimum important difference (MID) was estimated in two ways: (1) multiplying the SF-6D standard deviation by a small effect size (0.2), and (2) regressing the SF-6D onto SLICC to estimate the change associated with change equivalent to the MID of SLICC.

Results: 181 patients (mean age 48 years, mean disease duration 11 years) had SF-6D scores at baseline; the mean SF-6D score was 0.60 (0.12). The SF-6D correlated more strongly with age (−0.19) and SLICC (−0.24) than disease duration (−0.04), education (0.08) or SLEDAI (−0.06). In 113 patients with an SF-6D calculated score at 5-years, the correlation of the SF-6D with LupusQoL® domains was 0.6–0.8 for all domains apart from intimacy (0.44) and body image (0.36) The SF-6D could distinguish between those who smoked (−0.07, p=0.003), had carotid plaque (−0.05, p=0.027), had depression (−0.09, p<0.001), and reported fatigue (−0.06, p=0.006), from those who did not. The MID was estimated to be 0.024 to 0.028.

Conclusions: The SF-6D is valid for the measurement of HRQoL in patients with SLE; the measure reflects a number of key outcomes of the disease. Low correlation with aspects of intimate relationships and body image represents a concern and reinforces the need for collecting disease-specific measures of HRQoL alongside generic measures. The MID for the SF-6D is 0.024–0.028, smaller than estimates for other rheumatic disease such as rheumatoid arthritis.

Working Status in Patients with Early Inflammatory Polyarthritis: Results from the Norfolk Arthritis Register (NOAR). S. M. M. Verstappen[1], M. Lunt[1], T. Marshall[2], D. K. Bunn[2], J. Chipping[2] and D. P. M. Symmons[1]. [1]Arthritis Research UK Epidemiology Unit, The University of Manchester, Manchester, United Kingdom, [2]Norfolk Arthritis Register, Norfolk and Norwich University Hospital, Norwich, United Kingdom, United Kingdom

Background: Loss of paid work is one of the major consequences in patients with inflammatory polyarthritis (IP) and its subset rheumatoid arthritis. The objectives of this study were to (i) describe the change in working status over 10 yrs and (ii) to identify possible predictors for loss of work due to ill-health in working patients with early IP.

Methods: Consecutive patients with early IP (≥ 2 swollen joints for ≥ 4 weeks) from a primary-care based inception cohort (NOAR), recruited between 1990 and 1994, aged <63 yrs at symptom onset were included in this study. Data about working status since symptom onset until 10 yrs after registration in the NOAR cohort were available for this study population. Job titles were coded and used to differentiate between manual and non-manual jobs. At registration (baseline), clinical assessments included the DAS28 and the HAQ-score. Blood was collected to determine CRP, RF and ACPA. The association of baseline disease characteristics and loss of paid work 10 yrs after inclusion was assessed using logistic regression analysis, adjusting for age at registration and gender (OR, 95%CI). These analyses were restricted to patients for whom 10 year follow-up employment status was available and who were working, temporarily on sick leave or temporarily unemployed at registration. Loss of paid work was defined as being retired due to ill-health or receiving incapacity benefits at 10 yrs. In paid work was defined as working or temporarily on sick leave. Patients who retired (early) not due to ill-health or became a houseperson were excluded from the regression analysis.

Results: The preliminary results of this study show that, of the 329 patients working at symptom onset, 38 (11.6%) had already stopped working due to ill-health before registration in the register. Data from 225 patients could be used to assess the association between baseline characteristics and loss of paid work at 10 yrs. The mean age at registration of these 225 patients was 43 (SD 10) yrs and 63% were women. At registration, 183 were working, 37 were temporarily on sick leave, and 5 were temporarily unemployed. At 10 yrs, 56/225 (25%) had lost their job due to ill-health. Women were less likely to stop working due to ill-health (OR 0.53, 95%CI 0.29, 0.98). Older age at registration was also associated with an increased risk of stopping work due to ill-health (OR 1.09, 95%CI 1.05, 1.13). Although a trend for an association was found for RF, none of the clinical variables measured at baseline were significantly associated with the loss of work when adjusting for age and gender, i.e.: DAS28 (OR 0.93, 95%CI 0.71, 1.21), HAQ (OR 1.11, 95%CI 0.64, 1.94), RF positive (OR 1.99, 95%CI 0.98, 4.07), ACPA positive (OR 1.90, 95%CI 0.87, 4.16). Furthermore, having a manual job was also not associated with the loss of work due to ill-health (OR 1.43, 95%CI 0.74, 2.77).

Conclusion: In this study we found that many patients with early IP had already stopped working within the first couple of months after symptom onset and before starting DMARDs. In this small study population, we could not confirm any of the associations between clinical and job related variables, which have been found in previous RA studies, with loss of work due to ill-health.

A Randomized Attention-Controlled Study of Motivational Interviewing To Encourage Exercise in Fibromyalgia: Week 12 Interim Analysis. Dennis C. Ang[3], Anthony S. Kaleth[1], Sylvia M. Bigatti[2], Steven A. Mazzuca[3], Chandan K. Saha[2] and Robert W. Bandy[2]. [1]Indiana Univ Purdue Univ Indianapolis, [2]Indiana University, [3]Indiana University, Indianapolis, IN

Background: Aerobic exercise is an important treatment option for the management of fibromyalgia (FM). Unfortunately, the early benefits of structured, supervised exercise programs are often compromised by declining adherence as the exercise regimen transitions to an unsupervised, often home-based, program. Individuals who are able to maintain adherence almost always prolong the symptomatic benefits of exercise. We sought to determine the efficacy of motivational interviewing (MI) to maintain long-term adherence and extend the health benefits of exercise for FM patients.

Methods: Subjects met ACR diagnostic criteria for FM and had moderate pain severity at baseline (Brief Pain Inventory (BPI) ≥ 4). Subjects were randomized to MI or attention control (AC) conditions. All were advised to adopt a standard regimen of aerobic exercise and received two supervised training sessions. Subjects assigned to MI (n=107) participated in six counseling by telephone over the next 12 weeks. Subjects assigned to AC (n=109) participated in an identical schedule of telephone discussions about topics relevant to FM self-management (e.g., pain, fatigue, sleep). Clinical outcomes (BPI and Fibromyalgia Impact Questionnaire (FIQ)) were assessed at baseline and weeks 12, 24 and 36.

Results: Most of the sample was female (96%), white (88%), married

(61%), and employed (54%). Mean body mass index (BMI) was 31.4 kg/m^2. Baseline distributions for FIQ Total and BPI (mean ± SD = 67.0 ± 12.7 and 6.0 ± 1.3, respectively) suggested moderate-to-severe FM severity. The average self-reported total of physical activity (PA) of moderate or greater intensity (CHAMPS) was only 1.7 hours/wk. Treatment groups were similar at baseline with respect to demographic and clinical characteristics and retention rates at week 12 (MI: 91% vs. AC: 94%). Mean change (±SD) over 12 weeks in exercise adherence and clinical outcome measures are tabled below.

Outcome	MI (N = 96)	AC (N = 101)	*P*-value¶
Hours/wk of ≥moderate intensity physical activity*	2.8 ± 5.1	1.0 ± 3.6	0.007
Pain severity†	−1.3 ± 1.5	−0.9 ± 1.8	0.069
Symptom severity‡	−14.2 ± 14.7	−10.4 ± 17.4	0.105

*Community Health Activities Model Program for Seniors (CHAMPS)
†BPI (range; 0–10); Negative change represents improved pain
‡FIQ Total (range: 0–100): negative change represents improved symptoms
¶From ANCOVA, adjusted for baseline score and disease duration

Conclusion: MI is a directive, client-centered counseling style that focuses on enhancing motivation to change by helping clients explore and resolve ambivalence about a target behavior (e.g., exercise). Compared to AC, participants in the MI group reported greater improvement in both physical activity and clinical measures. Pending long-term efficacy data, exercise-based MI appears to be a promising tool to encourage increased PA and improve clinical symptoms in patients with FM.

Correlation between Bone Mineral Density and Urine Carboxyl Terminal of Collagen Type (CTX) in Premenopausal Fibromyalgia Patients. Alaa Alsalawy[3], Mohammed M. Kamel[2] and Ibrahim Eweis[1]. [1]AlAzhar University, Cairo, Egypt, [2]ALAzhar University, Alkhobar, Saudi Arabia, [3]Tanta University, Tanta, Egypt

Objective: The aim of the study was to compare Bone mineral Density (BMD), Serum Osteocalcin (OC), and Urine Carboxyl terminal of collagen type I(CTX) of premenopausal patients suffering from fibromyalgia(FMS), to that of healthy premenopausal females. Then to determine the relationship between (BMD), urine(CTX), and the development of rapid bone loss and early osteoporosis among premenopausal fibromyalgic patients.

Subjects and Method: Thirty-one premenopausal patients with fibromyalgia and thirty age matched healthy females subjects as a control group were included in this study. Serum osteocalcin and urine CTX were measured using ELISA technique (Enzyme Linked Immune Sorbent assay) in all cases, BMD was measured in femoral neck and lumber spine by using X- ray absorptiometry. Statistical analysis were done using SPSS virgin 15. Student's unpaired (t)test and pearson's correlation analysis were performed to assess the correlation between BMD and urine CTX.

Results: BMD of lumber and femoral neck were significantly lower in fibromyalgic patients compared to the healthy females ($p<0.001$). Serum Osteocalcin were lower in fibromyalgic patients with no significant difference compared to healthy females. There were a significant negative correlation between urine CTX and BMD of lumber spine and femoral neck in fibromyalgic patients.

Conclusion: The results of this study indicate that the fibromyalgic premenopausal patients are highly susceptible to develop osteopenia and early osteoporosis comapred to normal healthy subjects. We recommend to measure BMD of all fibromyalgia patients especially those with high level of urine CTX.

Cyclobenzaprine (CBP) Is a Potent Antagonist of Serotonin Receptor 2a (5-HT2a) and α-2 Adrenergic Receptors: Mechanistic Implications for Promoting Restorative Sleep in Fibromyalgia Syndrome (FMS). Herbert W. Harris[1] and Seth Lederman[2]. [1]Krele Pharmaceuticals, Saddle Brook, NJ, [2]Krele Pharmaceuticals, New York, NY

Background: Cyclobenzaprine (CBP) at very low dosages (VLD)(≤ 4 mg q.h.s.) is being investigated to improve sleep quality, reset circadian rhythm and treat daytime symptoms of fibromyalgia syndrome (FMS) (ref 1). The mechanism of action of cyclobenzaprine remains obscure. Indirect evidence from pharmacological studies implicates antagonism of either Serotonin Type 2a (5-HT2a) receptors (ref 2, 3) or α-2 adrenergic receptors (ref 4, 5). In these studies cyclobenzaprine was shown to block the biological effects of known 5-HT2a receptor agonists, or α-2 adrenoreceptor agonists in tissue slices or spinal cord sections. The objective of the present studies was to provide more direct evidence of the mechanism of action of CBP treatment by determining the binding affinities for relevant receptors.

Methods: Affinities (pK_i values) of CBP were determined for the 5-HT2(a, c) receptors, the histamine H1 receptor, and the α-2(a,b,c) adrenoreceptor family. Binding assays were are carried out in 50 mM Tris-HCl (pH 7.4) containing 1mM EDTA. Ligands used included: 5-HT2a, [^{3}H] Ketanserin (60–80 Ci/mmol); 5-HT2c, [^{3}H] Mesilulergine (60–80 Ci/mmol); α-2 adrenoreceptors, [^{3}H]MK-912 (60–80 Ci/mmol); H1, [^{3}H]-Pyrilamine (60–80 Ci/mmol). Receptor sources used included: 5-HT2a, rat cortical membranes; 5-HT2c, pig choroid plexus membranes; α-2 adrenoreceptors, human recombinant receptors expressed in SF9 cell lines; H1, bovine cerebellar membranes.

Results: CBP showed nanomolar affinity (9.0 nM) for the 5-HT2a receptor. In addition, CBP showed high affinity for members of the α-2 adrenoreceptor family (α-2a, 110 nM; α-2b, 9.9 nM; α-2c, 66 nM). CBP showed no measurable affinity (>5,000 nM) for histamine H1 or 5-HT2c receptors.

Conclusions: CBP binds with high affinity at the 5-HT2a receptor and members of the α-2 adrenoreceptor family, antagonizes the binding of known agonists and has been shown previously to block agonist activity *in vivo*. 5-HT2a binding is a property of trazodone, which is FDA approved as an antidepressant but which is prescribed off-label to promote sleep and as such, is the second most commonly prescribed treatment for insomnia in the US (ref 6). Published findings suggest a role for 5-HT2a receptors in the regulation of deep non-REM sleep reviewed in (ref 7). The combination of 5-HT2a and α-2 adrenoreceptor antagonism is associated with the antidepressants mianserin and mirtazepine (but mirtazepine also has significant H1 blockade.) CBP's absence of measurable affinity for the histamine H1 receptor may be associated with low potential for weight gain. Together, the functional antagonism of 5-HT2a and α-2 adrenoreceptors may underlie the ability of bedtime CBP to improve sleep quality in FMS.

Developing an Improved PROMIS Fatigue Short-Form for Use in Patients with Fibromyalgia. Stephen Schilling[5], Steven I. Blum[1], Stavros Tourkodimitris[2], Andy Stankus[3] and David A. Williams[4]. [1]Forest Research Institute, Jersey City, NJ, [2]Forest Research Institute, [3]KantarHealth, [4]Univ of MI Hlth System-Lobby M, Ann Arbor, MI, [5]University of Michigan

Purpose: The NIH roadmap project "Patient-Reported Outcomes Measurement Information System (PROMIS)" has developed calibrated item banks for a variety of domains relevant to chronic illnesses, including fatigue, which can be used to administer computer adaptive testing or to develop static questionnaires and short forms. PROMIS has developed a 7-item Short-Form for general use in fatigue, but it is unclear how well this short-form performs in measuring the fatigue of individuals with Fibromyalgia (FM). This study sought to develop and test an improved fatigue short-form for use in FM patients, constructed from the PROMIS fatigue item bank using calibrations derived from individuals with FM.

Methods: An Item Response Theory (IRT) analysis was conducted using data collected from an internet-based survey of 1207 self-identified individuals (88.9% Female; 90.5% Caucasian) currently suffering from FM. Participants had to be ≥ 18 years at the time of response and have been previously diagnosed with FM by a physician. In order to reduce response burden,

respondents were randomized into one of 3 cohorts, each of which completed one-third of the 95 items from the entire PROMIS v1.0 Fatigue Item Bank (www.nihpromis.org). Items were balanced between cohorts so that there was no overlap of questions. IRT analysis was conducted using Samejima's Graded Response Model (GRM) to fit the data using MULTILOG 7. The relative contribution of items measuring the latent trait was assessed by the item information function (IIF). Polyserial Correlations and the average of the IIF for all items from the full item bank were compared with those items included in the PROMIS Fatigue-Short Form to identify candidate items for an alternative scale. Cronbach's alpha was used to assess the reliability of the existing and proposed alternative scales.

Results: The current 7-item PROMIS Fatigue Short-Form contains 3 Fatigue Experience items and 4 Fatigue Impact Items. The Fatigue Experience items had a Cronbach's alpha reliability score of 0.77. The Fatigue Impact items had a reliability score of 0.81; including one item [IMP40: *How often did you have enough energy to exercise strenuously?*] which had the lowest information function (IIF=0.11) in the full item-bank. By contrast, the items with the highest IIF from both Fatigue Experience [EXP40: *How fatigued were you on average?* (IIF=6.22)] and Fatigue Impact [IMP51: *To what degree did you have trouble finishing things?* (IIF=2.94)] are not included in the current PROMIS Short-Form. A proposed short-form containing items with high average IIFs for Fatigue Experience and Fatigue Impact, each containing 5 items achieved reliability scores of 0.95 and 0.92 respectively. It is likely that the concept of fatigue for individuals with FM differs to some degree from other clinical populations; this is reflected in the identification of a new set of items showing greater discriminative ability for measuring fatigue in FM patients.

Conclusions: A new Short-Form can provide improved precision in measurement of the fatigue associated with fibromyalgia compared with the current 7-item PROMIS Fatigue Short-Form. Further testing and validation of the alternative short-form is needed.

Evaluation of Drug-Drug Interactions of Sodium Oxybate: Results from Pharmacokinetic/Pharmacodynamic Studies with Duloxetine, Lorazepam, and Tramadol. Mark Eller, Whitney Halladay and Annette Madrid. Jazz Pharmaceuticals, Inc.

Background: Clinical trials have demonstrated the efficacy and tolerability of sodium oxybate (SXB) for fibromyalgia treatment. Since polypharmacy is common in fibromyalgia, we evaluated SXB for interactions with three drugs commonly used by fibromyalgia patients.

Methods: Three phase 1 studies characterized the pharmacokinetics (PK) and pharmacodynamics (PD) of SXB (2.25 g single dose) with duloxetine (60 mg/day for 4 days; N=24), lorazepam (2 mg single dose; N=18), and extended release tramadol (100 mg/day for 5 days; N=19) in healthy volunteers. Drugs were administered individually and in combination with SXB in a double-blind, placebo-controlled, crossover design. Blood sampling at pre-defined time points enabled estimation of PK parameters for drugs administered alone and combined with SXB. Assessment of PD interactions at pre-defined time points included subject self-assessment of sleepiness/alertness (100 mm visual analogue scale [VAS]; 0=very alert to 100=very sleepy) and the Digit Symbol Substitution Test (DSST) for cognition and attention. Tolerability was evaluated based on the occurrence of adverse events (AEs), physical examination including vital signs, laboratory, and clinical tests including 12-lead electrocardiograms.

Results: Subjects were Caucasian (≥95%), mean age was similar across studies (31–33 years); the proportion of females varied (duloxetine, 54%; tramadol, 47%; lorazepam, 39%). The PK of each drug was consistent with established profiles; no statistically or clinically significant PK effects were observed for any of the drugs when administered in combination with SXB. The PD paralleled the PK profile of individual drugs. SXB+duloxetine and SXB+tramadol resulted in increases in sleepiness VAS scores that were similar to SXB alone. Sleepiness VAS scores with SXB+lorazepam were higher than when each drug was administered individually ($p<0.05$) and had a later and more prolonged peak than SXB alone. SXB alone peaked earlier (1.5 hours) than lorazepam alone (4 hours), and declined more rapidly. Compared to administration of the single agents, decreases in DSST scores with co-administration were only consistently seen with SXB+duloxetine (generally significant across time points vs duloxetine alone, and significant vs SXB alone at 1.5 hours only; $p<0.05$). All AEs were mild to moderate. One discontinuation, due to ventricular extrasystole in a patient administered tramadol, was not related to study medication.

Conclusions: The PK, PD, and tolerability profiles suggest that the combination of SXB with duloxetine or tramadol are not likely to result in clinically relevant effects. Sleepiness ratings increased when SXB and lorazepam were combined.

Fibromyalgia Patients with High Global Disease Severity, Depression, Anxiety or Cognitive Dysfunction Are Likely To Benefit from Cognitive Behavioral Therapy. Chad S. Boomershine[1], Cara L. Hammonds[1], Jennifer Y. Hong[2] and Kenneth A. Wallston[2]. [1]Vanderbilt University, Nashville, TN, [2]Vanderbilt University

Background: Cognitive behavioral therapy (CBT) is recommended for treating fibromyalgia (FM) patients. However, due to cost and limited availability, a system for identifying patients most likely to benefit from CBT is needed. Because CBT works by increasing two aspects of cognitive adaptability (CA), perceived competence (PC) and dispositional optimism (DO), FM patients with low CA are likely to benefit from CBT. We studied CA levels in FM patients to identify characteristics that could be used to guide patient selection for CBT.

Methods: Data from FM patients (n=99) referred to a rheumatology clinic were analyzed. FM diagnosis was made on clinical grounds by an experienced rheumatologist (CSB). CA was measured using the 8-item CA Index (CAI),[1] with higher CAI scores reflecting greater PC and DO. Severity of FM symptoms were assessed using the Fibromyalgia Impact Questionnaire (FIQ) for global disease severity, the fatigue severity scale (FSS) for fatigue, the Everyday Cognition Scale 20 (ECog20) for cognitive dysfunction, the Athens Insomnia Scale (AIS) for sleep quality, the Physician Health Questionnaire 9 (PHQ9) for depression, the Generalized Anxiety Disorder 7 (GAD7) for anxiety and a pain visual analogue scale (VAS pain) for pain. The Regional Pain Scale (RPS) and tender point count (TPC) were both used to quantify number of painful body areas. Spearman rank correlations and Mann-Whitney U testing compared questionnaire scores (PASW Statistics 17). Data is reported as median (interquartile range).

Results: CA level negatively correlated with global FM disease severity (CAI vs FIQ global $\rho=-0.53$, $p<0.001$) and the severity of mental symptoms including fatigue (CAI vs FSS score $\rho=-0.36$, $p<0.0001$), cognitive dysfunction (CAI vs ECog20 $\rho=-0.46$, $p<0.0001$), sleep quality (CAI vs AIS $\rho=-0.33$, $p=0.001$), depression (CAI vs PHQ9 score $\rho=-0.70$, $p<0.0001$), and anxiety (CAI vs GAD7 score $\rho=-0.59$, $p<0.0001$). CA level did not correlate with the severity of physical symptoms including pain severity (CAI vs VAS pain score $\rho=-0.08$, $p=0.458$) or number of painful body areas (CAI vs RPS $\rho=-0.20$, $p=0.053$; CAI vs TPC $\rho=0.03$, $p=0.842$). To determine characteristics that best identified patients with low CA, patients were divided into two groups: those with normal (CAI ≥36) versus below-normal (CAI <36) CA levels. Median scores on questionnaires that significantly correlated with CAI scores were compared between the CA level groups. FM patients with low CA were best identified as those with high levels of global disease severity [FIQ global 72.3 (63.9,79.8) vs 60.6 (45.8,63.7), $p<0.0001$], depression [PHQ9 16 (12,19.25) vs 7.86 (4.25,10.75), $p<0.0001$], anxiety [GAD7 13.5 (8,19) vs 3 (2,10), $p<0.0001$] or cognitive dysfunction [ECog20 41 (32,47) vs 28 (22,36), $p<0.0001$].

Conclusions: CA level negatively correlates with the severity of mental symptoms of fatigue, cognitive dysfunction, sleep quality, depression and anxiety but not physical symptoms of pain or number of painful body areas in FM patients. FM patients with high global disease severity, depression, anxiety or cognitive dysfunction are most likely to benefit from cognitive behavioral therapy.

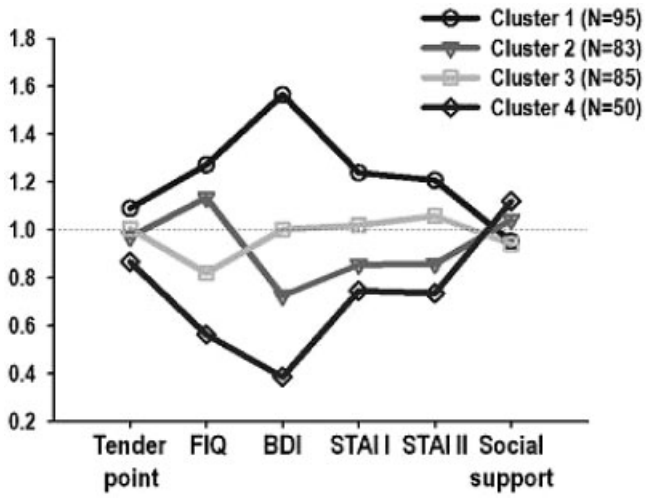
803

Identifying Fibromyalgia Subgroups Using Cluster Analysis: Relationships with Clinical Variables. Shin-Seok Lee[3], Seong-Ho Kim[6], Seong-Su Nah[11], Ji Hyun Lee[8], Seong-Kyu Kim[2], Yeon-Ah Lee[10], Seung-Jae Hong[10], Hyun-Sook Kim[4], Hye-Soon Lee[5], Hyoun Ah Kim[1], Chung-Il Joung[7] and Sang-Hyon Kim[9]. [1]Ajou University Hospital, Ajou University School of Medicine, [2]Catholic University of Daegu, School of Medicine, [3]Chonnam Natl Univ Med School, Gwangju, Korea, Republic of, [4]College of Medicine, Chosun University, [5]Hanyang University College of Medicine, [6]Inje University Haeundae Paik Hospital, [7]Konyang University Medical School, [8]Maryknoll Medical Center, [9]School of Medicine, Keimyung University, [10]School of Medicine, Kyung Hee University, [11]Soonchunhyang University, College of Medicine

Purpose: Patients with fibromyalgia (FM) do not form a homogenous group and have different clinical symptoms, physical, social, and psychological functions, and therapeutic responses. This study determined whether FM patients could be distinguished based on pain and physical, social, and psychological variables, and if so, whether the identified subgroups differ with respect to clinical features and treatment patterns.

Methods: 313 FM patients were interviewed using a structured questionnaire that included sociodemograhpic data, current or past FM symptoms, and current use of relevant medications. A k-means cluster analysis was conducted using variables reflecting tender points, the Fibromyalgia Impact Questionnaire, Beck Depression Inventory, State-Trait Anxiety Inventory, and Social Support Scale. Cluster subgroups were compared with chi-square tests for categorical variables and analysis of variance for continuous variables.

Results: Four distinct clusters were identified in these patients. Group 1 was characterized by high pain levels, severe physical and mental impairment, and low social support. Group 2 had moderate pain and physical impairment, mild mental impairment, and moderate social support. Group 3 had moderate pain, low physical and moderate mental impairment, and low social support. Group 4 had low pain levels, nearly normal physical and mental function, and high social support. Group 1 was more often a current or past smoker, more likely to have a variety of symptoms, including swelling, cognitive dysfunction, dizziness, syncope, esophageal dysmotility, dyspepsia, irritable bladder, vulvodynia, and restless leg syndrome, and less often a current non-steroidal anti-inflammatory drug user.



Conclusion: We identified four subgroups of FM patients based on pain and physical, social, and psychological function. These subgroups had different clinical symptoms and medication profiles, suggesting that the management of FM patients should be tailored to the individual patients' characteristics.

Lack of Detection of Xenotropic Murine Leukemia Virus-Related Virus (XMRV) in Patients with Fibromyalgia. Jorge J. Gonzalez Martin[1], Gabriel Herrero-Beaumont[2] and Rafael Delgado[3]. [1]Reumatología, IIS-Fundación Jiménez Díaz, 28040, [2]Reumatología, IIS-Fundación Jimenez Díaz, 28040, [3]Servicio de Microbiología, Imas12, Hospital Universitario 12 de Octubre

Xenotropic murine leukemia virus-related virus (XMRV) is a recently described human retrovirus that has been associated with prostate cancer. Recently, XMRV sequences and specific immune responses have been detected in 67% of patients with the diagnosis of Chronic Fatigue Syndrome (CFS) in North America. Based in the common features between CFS and Fibromyalgia (FM), we decide to study the presence of XMRV in a group of 15 patients previously diagnosed with FM. DNA was extracted from whole blood and analyzed by nested PCR using 3 sets of primers corresponding to the *gag* and *env* regions of XMRV. Primers for human beta-globin (hBG) were used as positive control of human DNA amplification. The sensitivity of the nested PCR procedure, estimated by spiking the XMRV molecular clone VP62 into negative samples, was 1–10 copies per sample. We did not found any evidence of this new agent in any patient with FM studied and XMRV does not appear to be related with FM. With this relative small population we cannot absolutely exclude an association of XMRV with FM, however it would be highly unlikely a proportion of FM cases with XMRV greater than 22% (3 of 15 cases, 95% confidence interval), which is clearly insufficient to support a significant association between XMRV and FM.

Disclosure: J. J. Gonzalez Martin: None; **G. Herrero-Beaumont:** None; **R. Delgado:** None.

Milnacipran Improves Pain and Global Status Independent of Changes in Depressive Symptoms in Patients with Fibromyalgia. Lesley M. Arnold[5], R. Michael Gendreau[1], Judy Gendreau[2], Allan Spera[3] and Wei Chen[4]. [1]Cypress Bioscience, Inc., San Diego, CA, [2]Cypress Bioscience, Inc., [3]Forest Research Institute, Jersey City, NJ, [4]Forest Research Institute, [5]University of Cincinnati, Cincinnati, OH

Purpose: Milnacipran is effective in improving multiple symptom domains in fibromyalgia (FM), including pain, physical function, and depressive symptomatology. This post hoc analysis was conducted to elucidate the relationship between changes in pain and patient global status and changes in depressive symptomatology.

Method: In this phase 3 trial, FM patients were randomized to milnacipran 100 mg/day (n=516) or placebo (n=509) for 12 weeks of stable-dose treatment. Patients with current major depressive episodes (assessed by MINI) or Beck Depression Inventory (BDI) scores >25 were excluded from the trial; however, 30% of patients had a history of depression at screening and in many cases had some evidence of depressive symptomatology. Outcome measures included a pain responder assessment (≥30% improvement from baseline in pain VAS scores), Patient Global Impression of Change (PGIC) responder analysis (rating of "very much improved" or "much improved"), and a 2-measure composite responder analysis (individual patients were required to meet both pain and PGIC responder criteria) at the end of the 12-week stable-dose treatment period. Changes in depressive symptoms were assessed with the BDI. Path analysis was used to describe the association between improvements in depressive symptoms and pain relief. The analysis was based on a regression model that partitioned the overall treatment effect into direct and indirect components.

Results: Patients treated with milnacipran had a small but statistically significant decrease in BDI scores relative to placebo (−2.12 vs −1.24; $P=.008$); these changes were significantly correlated with improvements in pain VAS ($r=0.210$) and PGIC ($r=0.309$) scores (both $P<.001$). Pain, PGIC, and 2-measure composite responder rates were the highest in patients with the largest improvements in BDI scores and the lowest in patients with no improvement or worsening of BDI scores. However, even in patients with no improvement or worsening in BDI scores, milnacipran treatment resulted in significantly higher responder rates than placebo on pain, PGIC, and 2-measure composite responder analyses ($P<.05$, all measures). Path analysis demonstrated that 12.8% (90% CI: 4.8%, 23.5%) of the milnacipran treatment effect on pain relief at endpoint can be explained by improvements in depressive symptoms, and the remaining 87.2% (90% CI: 76.3%, 95.2%) was unexplained by improvements in depressive symptomatology.

Conclusion: In patients with FM, treatment with milnacipran 100 mg/day significantly improves multiple domains, including pain, global status, and depressive symptoms. Much of the improvement in pain and global status with milnacipran is independent of improvements in depressive symptoms.

Milnacipran Reduces the Overall Severity of Fibromyalgia Symptoms in Patients with Fibromyalgia. Robert H. Palmer[2], Robert M. Bennett[4], Yong Wang[3] and R. Michael Gendreau[1]. [1]Cypress Bioscience, Inc., San Diego, CA, [2]Forest Research Institute, Jersey City, NJ, [3]Forest Research Institute, [4]Oregon Health & Science Univ, Portland, OR

Purpose: Fibromyalgia (FM) is a disorder characterized by chronic widespread pain, fatigue, and impaired physical and global function. Patients with FM often have a multitude of other symptoms that include stiffness, poor sleep quality, and cognitive dysfunction. The Fibromyalgia Impact Questionnaire (FIQ) is a validated instrument that measures the spectrum of these FM-related symptoms and can identify patient responses to therapy. Milnacipran, approved in the US for the management of FM, has shown efficacy in treating multiple symptoms in FM patients. This post hoc analysis examines the effect of milnacipran on patients' FM severity.

Method: Data from a randomized, double-blind, placebo-controlled trial were analyzed. Patients with FM received milnacipran 100 mg/day (n=516) or placebo (n=509) for 4 to 6 weeks of flexible dose escalation followed by 12 weeks of stable-dose treatment. The FIQ was administered to patients at baseline and at each study visit. Patients were classified into 3 severity categories based on their FIQ total scores at baseline: <39 (mild impairment); ≥39 to <59 (moderate impairment); ≥59 (severe impairment). Improvements in FM severity were determined by the percentage of patients at endpoint shifting from the severe to the moderate or mild categories, or from the moderate to the mild category. Odds ratios (OR) for milnacipran were calculated for shifts in each severity category and are expressed relative to placebo treatment. Analysis was based on LOCF.

Results: FM severity based on the total FIQ score at baseline was mild (8.1%), moderate (48.5%), and severe (43.4%). At all study visits, patients treated with milnacipran had significantly larger decreases from baseline in FIQ total scores than placebo ($P<.001$ vs placebo). Of patients with severe FM at baseline, 61.1% of patients treated with milnacipran improved by at least one category of severity (32.2% to moderate and 28.9% to mild) compared with 46.1% of patients treated with placebo (26.5% to moderate and 19.6% to mild) (OR, 1.8; $P=.002$; number needed to treat, 7). Of patients with moderate or severe FM at baseline, 52.2% of milnacipran patients improved by at least one category, compared with 42.0% of placebo patients (OR, 1.5; $P=.002$; number needed to treat, 10).

Conclusion: These results represent an assessment of efficacy that indicate that milnacipran 100 mg/day is effective for treating the overall symptoms of FM, as measured by improvements in FIQ total scores. Patients with moderate or severe impairment at baseline were more likely to improve their FM severity with milnacipran than with placebo.

National Fibromyalgia Association Survey on Children with Fibromyalgia: Preliminary Results. Sanjida Ali[1] and Rae Marie Gleason[2]. [1]Forest Research Institute, Jersey City, NJ, [2]National Fibromyalgia Association

Purpose: Juvenile fibromyalgia (FM) is a musculoskeletal pain condition that can impact the functional status and psychosocial development of children and adolescents. Currently, there is limited information on the prevalence of juvenile FM in the U.S. The National Fibromyalgia Association (NFA), in collaboration with Forest Research Institute, is conducting an internet survey to gather information on juvenile FM. One aim of the survey is to collect data that will help researchers and clinicians to better understand the nature and prevalence of FM in children. This report presents preliminary findings from the NFA survey.

Methods: The survey was completed by parents or guardians of children who have "fibromyalgia symptoms such as body-wide chronic pain, fatigue, stiffness, sleep problems, headache, irritable bowel and restless legs." For each child, respondents selected responses for the following items: age, gender, symptom severity, FM diagnosis, treatment information (ie, treating physician, medications, nonpharmacologic therapies), and lifestyle information. Responses from surveys submitted by parents or guardians of children (<18 years) from 12/05/2009 to 06/02/2010 were analyzed.

Results: Completed surveys were submitted for 284 children with symptoms of juvenile FM, >85% of whom were from the U.S. Results show that 76.4% of the children were female and 23.2% were male (0.4%, no response). Mean age was 13.6 years, with 17.6% ages ≤10 years, 33.5% ages 11–14 years, and 48.9% ages 15–17 years. 44.3% of the children were being treated by a healthcare professional, 26.4% by a rheumatologist and 10.6% by a primary care/family physician. 121 children (42.6%) had received a confirmed FM diagnosis; 60.3% were diagnosed by a rheumatologist and 23.1% by a primary care/family physician. Among children with a confirmed FM diagnosis, the most frequent symptoms (>90%) were widespread pain, pain influenced by stressors, fatigue, stiffness, sleep problems, headaches, foggy thinking, and anxiety. The frequency at which these symptoms were rated moderate or severe was 62.0% to 91.7%. Since developing FM symptoms, >50% of the diagnosed children had moderately or substantially decreased their involvement in strenuous physical activities or socializing with peers; 47.9% had changed schooling as a result of their FM symptoms. Current treatment with prescribed medications (i.e. serotonin-norepinephrine reuptake inhibitor, antiepileptic, tricyclic antidepressant, sedative-hypnotic, selective serotonin reuptake inhibitor, muscle relaxant, dopamine agonist) was reported in ≤12.4% of diagnosed children. Rates of previous use of these medications ranged from 0% to 21.5%. Nonpharmacologic therapies were more common, with >30% of diagnosed children currently using hot baths, exercise, and/or supplements to manage FM symptoms.

Conclusions: Results from the NFA's internet survey suggest children with FM present with higher rates of many of the classical symptoms of FM than observed in adults with FM. Also, less than half of the children with symptoms suggestive of FM had received a confirmed diagnosis, suggesting a possibility of underdiagnosis of FM in the pediatric population.

Nocturnal Heart Rate Variability Parameters. A Potential Fibromyalgia Biomarker. Claudia Lerma, Aline Martinez, Natllely Ruiz, Angelica Vargas, Oscar Infante and Manuel Martinez-Lavin. National Institute of Cardiology, Mexico

Background: Researchers strive to identify biomarkers for fibromyalgia (FM). Heart rate variability (HRV) analyses provide a quantitative marker of autonomic nervous system activity. Several HRV studies in FM have described changes consistent with relentless sympathetic hyperactivity. Sleep is modulated by autonomic activity. Sleeping problems are prominent in FM.

Objective: To explore different HRV parameters measured during sleeping hours as potential FM biomarkers.

Patients and Methods: We studied 21 women with FM according to the 1990 ACR criteria and 21 age-matched healthy women. None of the participants was on any medication that could affect autonomic activity. All participants used a Holter monitor while sleeping at home. Calculations were done from 00.00 to 06.00 hours. The following time-domain HRV parameters were studied: mean NN interval (mean NN), standard deviation of the NN intervals (SDNN), mean standard deviation of the average NN intervals calculated over 5 minutes (SDANN), and finally a HRV parameter developed by one of the authors (CL); transient heart rate acceleration episodes (THRAE).

Statistical analysis: Student T test compared parameters from both groups. The best cut-off point for each parameter was determined from ROC curves. Sensitivity, specificity, positive predictive value, negative predictive value and odds ratio were estimated for each parameter.

Results: Are shown in tables 1 and 2. Both groups have similar demographic characteristics. HRV values clearly differentiated patients from controls. Nocturnal SDNN had the greatest odds ratio (12, with confidence intervals 95% = 3.2–44.9) followed by SDANN (8.5, CI 95%, 2.2–31.8)

Table 1. Demographic data and HRV analyses from 00.00 to 06.00 hr.

	FM n = 21	Controls n = 21	p
Age (years) ± SD	32.7 ± 8.0	30.5 ± 7.6	0.37
Body mass index	24.5 ± 4.6	25.2 ± 3.2	0.56
NN mean (ms)	857 ± 92	937 ± 132	0.02
SDNN (ms)	91 ± 22	122 ± 33	< 0.01
SDANN (ms)	58 ± 22	78 ± 28	0.03
THRAE	23 ± 14	41 ± 31	0.01

Table 2. Predictive values of the potential HRV biomarkers.

	Cutoff point	AUC	Sensitivity (%)	Specificity (%)	PPV (%)	NPV (%)	OR (CI 95%)
NN mean at night (ms)	888.1	0.67	71	67	68	70	5 (1.3–18.7)
SDNN (ms)	113.1	0.79	86	67	72	82	12 3.2–44.9)
SDANN (ms)	68.8	0.71	81	67	71	78	8.5 (2.2–31.8)
THRAE	28.5	0.65	76	52	62	69	3.5 (0.9–13.1)

AUC = area under ROC curve, PPV = positive predictive value, NPV = negative predictive value, OR = odds ratio.

Conclusions: We identify 4 nocturnal HRV parameters that differentiate FM patients from healthy individuals. Multivariate analysis of these values could possibly yield more discriminative information. The specificity of these findings for FM when compared to other painful rheumatic syndromes remains to be established.

Orthostatic Stress Reverses Sympathetic but Not Parasympathetic Abnormalities of Fibromyalgia Patients. Florence Luong[2], Donald D. Price[2], Michael E. Robinson[2] and Roland Staud[1]. [1]Univ of Florida JHMHC, Gainesville, FL, [2]University of Florida

Fibromyalgia syndrome (FM) is characterized by widespread chronic pain and tenderness. Previous studies have shown alterations of the central nervous system functions in FM including increased sensitivity to painful and non-painful stimuli and dysfunctional autonomic nervous system (ANS) responses. Dysfunctional ANS responses in FM patients include orthostatic hypotension, diminished microcirculatory vasoconstriction, and sympathetic hyporeactivity. The ANS can be assessed using heart rate variability (HRV) analysis which can provide important information on sympathetic and parasympathetic functions in FM.

Methods: We sought to determine the autonomic adaptability of FM patients using a mild orthostatic stressor. Whereas VLF and LF bands of HRV represent sympathetic ANS function, HF band variability correlates with parasympathetic function. We performed HRV spectral analysis of 55 FM and 44 normal control subjects (NC) during 15 min of rest followed by 5 min of standing. Heart and respiratory rate as well as blood pressure were monitored.

Results: Frequency analysis of FM subjects showed significantly lower variability in VLF, LF, and HF bands compared to NC during rest ($p < .05$) indicating sympathetic ANS dysfunction.

Table 1. Average (SD) of HRV during rest in NC and FM subjects

	VLF	LF	HF	VHF
NC	849.7 (998.4)	1412.2 (1778.4)	2096.1 (3593.6)	166.6 (335.5)
FM	442.4 (457.0)	597.7743 (777.9)	618.5089 (932.1)	56.8811 (71.0)
P value	.049	.01	.03	>.05

During 5 min of standing heart and respiratory rates as well as blood pressure of FM subjects were similar to NC (all $p > .05$). Whereas variability of VLF and LF normalized HF of FM subjects remained abnormal.

Table 2. Average (SD) of HRV during standing in NC and FM subjects

	VLF	LF	HF	VHF
NC	1368.3 (1622.5)	1306.7 (1301.1)	1357.5 (2504.3)	145.5 (195.1)
FM	1076.2 (2235.5)	1013.2 (1216.4)	388.8 (402.3)	60.0 (60.5)
P value	>.05	>.05	.03	.01

Conclusion: FM patients demonstrate sympathetic dysfunction that normalizes during standing. In contrast, parasympathetic function of FM patients is abnormal not only at rest but also during mild orthostatic stress.

Disclosure: F. Luong: None; **D. D. Price:** None; **M. E. Robinson:** None; **R. Staud:** None.

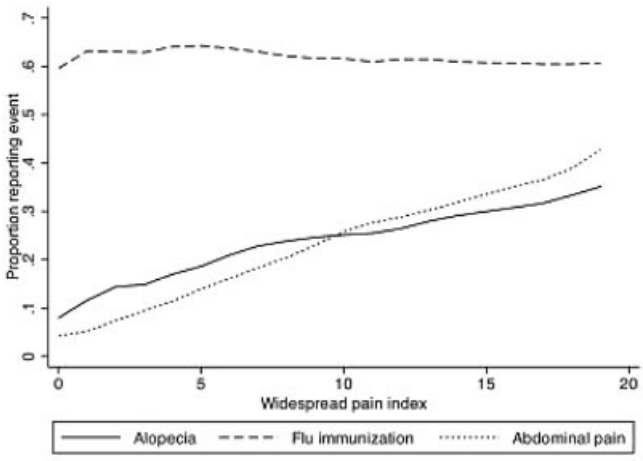
Over-Reporting Is a Central Determinant of Pain and Symptom Reporting in Fibromyalgia. Frederick Wolfe. National Data Bank for Rheumatic Diseases, Wichita, KS

Purpose: Central sensitization (CS) and global sensory augmentation (GSA) have been demonstrated in laboratory experiments, and have been proposed as major mechanisms to explain increased pain and sensory reporting in fibromyalgia (FM) and chronic widespread pain (CWP). However, there are other possible mechanisms in clinical FM, including over-reporting (OR), which might be considered to be related to increased concern about symptoms and non-symptom events. It is possible that the CS and GCA as well as OR could be operating at the same time. In this study we investigated the presence of GCA and OR as a function of widespread pain (WP), a measure related to pain threshold.

Methods: We studied 3 sets of variables to determine if their probability increased with increasing WP. We hypothesized that influenza immunization (FI) would not increase with increasing WP, as it was not a matter of personal concern to patients; that abdominal pain (AP) and other symptom variables would increase, observations that are consistent with the CS and GSA hypotheses. Finally we tested whether non-symptom events such as hair loss or alopecia (AL) and hearing loss (HL) would increase, According to the GSA hypothesis, these events would not increase; but they might increase if OR was present.

To be certain that the presence of patients diagnosed with FM would not distort the analyses, we excluded them from analysis, and studied 10,228 patients with rheumatoid arthritis or osteoarthritis. By self-report, we determined the presence of FI in the last 12 months, and symptom events (AP) and non-symptom events (AL, HL) present in the last 6 months. WP was determined using the Widespread Pain Index (WPI).

Results: Adjusted for age, sex and education level, FI was not significantly associated with WPI, $p=0.839$ ROC AUC = 0.618. AP was strongly associated with WPI, $p<0.001$, ROC AUC =0.732; and AL was also associated with WPI, $p<0.001$, ROC AUC = 0.659. The association are shown graphically in Figure 1.



To determine the associations of VAS pain (0–10) with these variables, we noted that there was 0.0 pain level difference for FI+ vs. FI- (3.6 vs. 3.6), but there was a 1.3 unit difference comparing AP+ with AP- patients (4.7, 3.4) and a 0.9 difference for AL+ vs. AL- patients (4.3, 3.4). A similar pattern was found in analyses of fatigue. Similar results were obtained with FM patients added, and for HL substituted for AL.

Conclusions: These data show that events that are not of personal concern are unrelated to WPI and pain. However, events such as AL that are not symptoms but may be of personal concern to patients are associated with increased WPI and pain, suggesting that OR influences WPI, pain, symptoms

and non-symptoms in the clinic. CS and GSA are not sufficient to explain observed pain and symptoms in FM. The degree to which CS/GSA and OR each contribute to WPI, FM and CWP in the clinic is a central question that should be the subject of future research.

Disclosure: F. Wolfe: None.

Proteomic Mass Spectra Classification in Fibromyalgic Patients. Camillo Giacomelli[3], Laura Bazzichi[3], Federica Ciregia[2], Chiara Baldini[3], Francesca Sernissi[2], Pasquale Pepe[1], Laura Giusti[2], Antonio Lucacchini[2] and Stefano Bombardieri[3]. [1]Department of Clinical Pharmacology, University of Pisa, Pisa, Italy, [2]Department of Psychiatry, Neurobiology, Pharmacology and Biotechnology. University of Pisa, Pisa, Italy, [3]Rheumatology Unit. Department of Internal Medicine. University of Pisa, Pisa, Italy

Background: Fibromyalgia (FM) is a chronic non inflammatory musculoskeletal disorder characterised by widespread pain and by the presence of at least 11 out of 18 specific tender points on physical examination. Currently no validated laboratory biomarkers are available for FM and the diagnosis of the disease remains exclusively clinical. The aim of the present study was to perform a proteomic analysis of FM patients' saliva with surface-enhanced laser desorption/ionization time-of-flight/mass spectrometry (SELDI-TOF/MS).

Methods: For this study, we enrolled 66 patients, all female (mean age 43.60±11.30 yrs, Mean±SD), all fulfilling the ACR criteria and 50 healthy controls matched for age and sex.

Whole saliva samples are centrifuged to remove undissolved material. Aliquots of resulting supernatants are analysed by SELDI-TOF/MS. Saliva is applied to the spots of Protein Chip Arrays (CM10, Q10, H50). After an incubation period, unbound proteins and other contaminants are washed off the spots using buffers as required by the array chemistry; only proteins interacting with the chemistry of the array surface are retained for analysis. Finally matrix (sinapinic acid-SPA) is applied to each spot to facilitate laser desorption and ionization. The datasets are obtained from biological samples collected from different patients classified in different classes (e.g. disease versus control). Univariate and multivariate Logistic analysis was performed.

Summary of Results: Univariate analysis identified 22 peaks differently expressed in FM in comparison to healthy controls in a range of m/z between 2618 and 29533. One of these well overlap with molecular weight of Phosphoglycerate mutase-1 (MW 29 KDa) found alterated in our previous work (1). Multivariate analysis showed as best independent predictors for FM three peaks between m/z range from 2500 to 12000 which were able to classify FM patients with a percentage error of 24%.

Conclusion: These preliminary results showed the possibility to identify a salivary biomarker through salivary proteomic analysis with SELDI-TOF in FM patients. The next step will be the identification of the alterated proteins by purification by purification with chromatography and immunoprecipitation techniques.

Sexual Dysfunction in Female Fibromyalgia Patients. Jacob N. Ablin[4], Inna Gurevitz[3], Hagit Cohen[1] and Dan Buskila[2]. [1]Ben-Gurion University of the Negev, Beer Sheva, Israel, [2]Soroka Medical Center, Beer Sheva, Israel, [3]Soroka Medical Center, Beer - Sheva, Israel, [4]Tel Aviv Sourasky Medical Center, Tel Aviv, Israel

Background or Statement of Purpose: Fibromyalgia, the prototypical central pain syndrome, is characterized by widespread pain, tenderness and fatigue.

Fibromyalgia causes significant impairment in general well-being and quality of life, often inflicted on young, predominantly female, patients. Sexual functioning is considered an important parameter determining quality of life and is often negatively affected by rheumatological disorders. Impaired sexual function has negative effects on intimacy, on self – esteem and on the ability to maintain a long-term relationship.

In Fibromyalgia, various factors may impact on sexuality, including contact—avoidant behavior due to tenderness, depression, fatigue and the effect of medications.

The purpose of the current study was to evaluate sexual dysfunction among fibromyalgia patients.

Methods: Subjects: Fifty female subjects were recruited. Participants were asked to complete a questionnaire regarding sexual functioning.

Inclusion criteria included age over 18 and fulfillment of the ACR 1990 criteria for classification of fibromyalgia. Patients were consecutively recruited from the Rheumatology clinic. Exclusion criteria included conditions deemed to preclude informed consent.

The control group included fifty-five healthy volunteers, who were matched for age and gender.

The study was approved by the local Institutional Review Board of the hospital.

Demographic data regarding age, education, marital status and past medical history were collected. Participants underwent physical examination and tender point assessment was performed using manual palpation. All participants filled out the Arizona Sexual Experience Scale, which evaluates five areas of sexual functioning: sexual drive, sexual arousal, vaginal wetting, orgasm and sexual satisfaction.

Statistics: demographic parameters were compared using the Chi squared method. Sexual function parameters were compared using analysis of variance (ANOVA) for each parameter. Linear regression coefficients were calculated to describe the association between sexual function parameters and variables of age and pain intensity.

Summary of the Results: Table 1 presents the results of the Arizona sexual experience scale among fibromyalgia patients and controls.

Table. sexual function parameters among fibromyalgia patients and healthy controls.

	FM patients N = 50 Mean (Std.Dev)	Healthy Controls N = 55 Mean (Std. Dev)	ANOVA
Arizona Sexual Experience			
Sexual drive	4.8 (1.1)	3.2 (1.0)	F (1,13)=52.9, p<0.0001
Sexual arousal	4.6 (1.2)	2.8 (0.8)	F (1,13)=79.0, p<0.0001
vagina wetting	4.2 (1.0)	2.9 (0.7)	F (1,13)=59.3, p<0.0001
Orgasm	4.4 (1.3)	2.8 (1.0)	F (1,13)=47.1, p<0.0001
Sexual satisfaction	4.1 (1.5)	2.5 (1.0)	F (1,13)=41.0, p<0.0001
Total score	22.0 (5.4)	14.3 (4.0)	F (1,13)=68.9, p<0.0001

Conclusions: The results of the current study indicate a multi – factorial sexual dysfunction among female fibromyalgia patients. All stages of sexual functioning, evaluated were significantly disturbed in comparison with healthy controls. Physicians treating fibromyalgia patients should be aware of, and actively inquire about sexual dysfunction as part of a multi-disciplinary evaluation of female fibromyalgia patients.

Simplifying Fibromyalgia Assessment: The VASFIQ Brief Symptom Scale. Chad S. Boomershine, Gergana Zlateva, Yi Wang, Ed Whalen and Birol Emir. Vanderbilt University, Nashville, TN

Background: Fibromyalgia (FM) is a complex disorder of chronic widespread pain and tenderness associated with symptoms of fatigue, poor sleep, depression, and anxiety. Due to its complexity, identifying clinically significant symptoms and monitoring treatment response in FM is difficult. While the Fibromyalgia Impact Questionnaire (FIQ) can quantify global disease severity, scoring complexity, length and the inability to identify patients with significant symptoms limit its clinical utility. We hypothesized a more clinically useful FM scale could be formed from the 7 FIQ visual analogue scales (the VASFIQ), with the sum of VASFIQ scores providing a global disease severity measure and cut-off scores for individual VASs derived to identify clinically significant symptoms of fatigue, poor sleep, depression and anxiety.

Methods: Data from 2229 patients enrolled in 3 pregabalin FM treatment

trials (LIFT[1], RELIEF[2] and 1100[3]) were analyzed including scores from the FIQ, the Hospital Anxiety and Depression Scale (HADS), the Medical Outcomes Study (MOS) Sleep Problems Index 9 (SLP) and the Multidimensional Assessment of Fatigue Global Fatigue Index (MAF). Spearman rank correlations compared scores. Receiver operating characteristic (ROC) analysis identified cut-off scores on individual FIQ VASs with corresponding validated questionnaires used to define cases.

Results: VASFIQ global scores correlated with FIQ global scores at baseline (ρ=0.94, p<0.0001) and study endpoints (ρ=0.97, p<0.0001). Change in VASFIQ and FIQ global scores at study endpoints correlated (ρ=0.96, p<0.0001). Individual FIQ VAS scores correlated with all corresponding validated questionnaire scores at baseline (VASfatigue with MAF ρ=0.67; VASsleep with SLP ρ=0.50; VASdepressed with HADS-D ρ=0.57; VASanxiety with HADS-A ρ=0.64, all with p<0.0001) and study endpoints (VASfatigue with MAF ρ=0.76; VASsleep with SLP ρ=0.67; VASdepressed with HADS-D ρ=0.62; VASanxiety with HADS-A ρ=0.67, all with p<0.0001). Change in individual FIQ VAS scores correlated with change in corresponding validated questionnaire scores at study endpoints (VASfatigue with MAF ρ=0.64; VASsleep with SLP ρ=0.57; VASdepressed with HADS-D ρ=0.43; VASanxiety with HADS-A ρ=0.47, all with p<0.0001). ROC analyses showed a VASfatigue score of ≥7.5 was 76.0% sensitive and 82.2% specific for fatigue defined as a ≥30 score on the MAF [ROC area 0.87, 95% confidence interval (CI) 0.85–0.89], a VASsleep score of ≥7.9 was 68.7% sensitive and 71.2% specific for poor sleep defined as a ≥50 score on the SLP (ROC area 0.76, 95% CI 0.74–0.79), a VASdepression score of ≥5.8 was 71.3% sensitive and 72.6% specific for depression defined as a ≥11 score on the HADS-D (ROC area 0.80, 95% CI 0.77, 0.82) and a VASanxiety score of ≥6 was 71.2% sensitive and 77.7% specific for anxiety defined as a ≥11 score on the HADS-A (ROC area 0.83, 95% CI 0.81, 0.84).

Conclusions: The VASFIQ is a brief FM scale to assess global disease severity and identify patients with clinically significant symptoms of fatigue, poor sleep, depression and anxiety.

Sodium Oxybate Improves Pain, Function, and PGIC in Patients with Fibromyalgia: A Pooled Analysis of 2 Pivotal Clinical Trials. I. Jon Russell[5], Robert M. Bennett[3], Cayetano Alegre[1], John B. Winfield[4], Chinglin Lai[2], Y. Grace Wang[2] and Beverly Benson[2]. [1]Hospital de la Vall d'Hebron, Alella, Spain, [2]Jazz Pharmaceuticals, Inc., [3]Oregon Health and Science University, Portland, OR, [4]University of North Carolina, Chapel Hill, NC, [5]University of Texas Health Science Center, San Antonio, TX

Background: In addition to chronic pain, fibromyalgia (FM) patients exhibit fatigue, sleep disturbances, and functional impairment. Sodium oxybate (SXB) demonstrated efficacy and tolerability for the treatment of FM in two pivotal phase 3 clinical trials. The current analysis further evaluates the effects of SXB on pain, function, and global status using pooled data from the two trials.

Methods: The trials were of similar design (randomized, double-blind, placebo-controlled), length (14 weeks), and dosing regimens (placebo, SXB 4.5 g and 6 g dosing equally divided between bedtime and 2.5 to 4 hours later). The primary outcome variable for both studies was the proportion of patients who achieved a 30% reduction in pain on a 0–100 mm visual analog scale (PVAS). Other measured variables included quantitative changes in PVAS, changes in daily function assessed as the proportion of subjects with ≥30% reduction in Fibromyalgia Impact Questionnaire (FIQ) score, changes in patient-reported health status (Patient Global Impression of Change [PGIC]), and two composite endpoints: a "Pain Composite" with two measures (PGIC of "very much better" or "much better" + ≥30% reduction in PVAS) and an "FM Composite" with three measures (PGIC of "very much better" or "much better" + ≥30% reduction in PVAS + ≥30% reduction in FIQ). Last observation carried forward was used for missing data.

Results: A total of 1121 subjects were randomized (placebo n=371; SXB 4.5 g n=377; SXB 6 g n=373). The demographic characteristics of the patients in the pooled trials were comparable (overall, 90.4% female; 91.2% white; median age 48.0 years). The proportion of patients with ≥30% pain reduction was significantly greater with SXB; 47.8% and 54.8% for 4.5 g and 6 g, respectively, relative to placebo (30.9%; p<0.001). Pain reduction ≥50% was reported by 36.0% of SXB 4.5 g patients and 40.4% of SXB 6 g patients compared with 18.9% on placebo (both p<0.001). Least squares mean changes from baseline showed greater PVAS reductions with both SXB doses relative to placebo, beginning at Week 1 and maintained through Week 14 (p<0.001). Greater proportions of patients treated with SXB 4.5 g (52.6%) and 6 g (55.6%) achieved ≥30% reduction in FIQ total score relative to placebo (34.3%; p<0.001). Improvements in pain and function were paralleled by greater proportions of SXB patients reporting PGIC scores of "much better" or "very much better" (p<0.001 for both doses). The proportion of patients at Week 14 meeting the Pain Composite criteria and those achieving the FM Composite criteria were significantly greater with both SXB doses compared with placebo (p<0.001). The most common adverse events with an incidence greater than 5% in either SXB treatment group and twice the placebo rate were nausea, dizziness, vomiting, anxiety, and fatigue.

Conclusions: This pooled analysis supports the results of the individual trials in demonstrating that SXB provides statistically and clinically significant improvements in FM pain, function, and global health status relative to placebo.

Sodium Oxybate Improves Sleep and Fatigue in Patients with Fibromyalgia: Pooled Analysis from 2 Pivotal Clinical Trials. Stuart L. Silverman[3], Andrew J. Holman[4], Beverly Benson[1], Sarah Alvarez-Horine[1], Y. Grace Wang[1] and Piercarlo Sarzi-Puttini[2]. [1]Jazz Pharmaceuticals, Inc., [2]L. Sacco University Hospital, Milano, Italy, [3]Osteoporosis Medical Center, Beverly Hills, CA, [4]Pacific Rheumatology Associates, Inc., Renton, WA

Background: Fibromyalgia (FM) is characterized by chronic widespread pain as well as sleep disturbance and fatigue. Two pivotal clinical trials of sodium oxybate (SXB) demonstrated that SXB significantly reduced pain and fatigue, and improved sleep relative to placebo. This analysis further evaluates the effects of SXB on sleep and fatigue using pooled data from the two trials.

Methods: Both trials were of similar design (randomized, double-blind, placebo-controlled), length (14 weeks), and dosing regimens (placebo, SXB 4.5 g and 6 g equally divided between a dose at bedtime and another one 2.5 to 4 hours later). Baseline assessments were made after a washout period (up to 30 days) and prior to treatment initiation. Data from each treatment group were pooled (n=371 placebo; n=377 SXB 4.5 g; n=373 SXB 6 g) to evaluate the efficacy of SXB for pain (0–100 visual analogue scale [VAS]), fatigue (0–100 VAS), sleep disturbances (Jenkins Sleep Scale [JSS]; a validated, 4-item, self-report questionnaire for sleep disturbances), and effects of excessive daytime sleepiness on daily functioning (Functional Outcomes of Sleep Questionnaire [FOSQ]; a patient-report questionnaire); last observation carried forward was used for missing data.

Results: Demographics of the pooled patients are consistent with the FM population (90.4% female, and 91.2% white, median age 48.0 years). Mean baseline pain, fatigue, sleep disturbance, and FOSQ scores were also similar to the individual studies and consistent with significant impairment. The proportions of patients who achieved 30% and 50% reductions in pain were significantly greater with SXB than placebo (p<0.001). Least squares mean changes from baseline in fatigue VAS showed significant reductions with both SXB doses beginning at Week 1 that were maintained over the duration of treatment and were significantly greater than placebo at each weekly assessment (p<0.001). At 14 weeks, changes from baseline in fatigue VAS were −25.3 and −28.0 for SXB 4.5 g and 6 g, respectively, compared with −15.5 for placebo. SXB resulted in reduction in sleep disturbances at Week 14 as indicated by a significant overall treatment effect (p<0.001) and pairwise comparisons with placebo (p<0.001 for both SXB groups) on the JSS total score; least squares mean changes at Week 14 were −5.4 and −6.0 for the SXB 4.5 g and 6 g groups, respectively, compared with −2.9 for placebo. Similarly, treatment effects on functioning related to daytime sleepiness and tiredness at Week 14 were observed for the FOSQ, with least squares mean changes (improvement) from baseline of 2.2 for both SXB groups compared with 1.3 for placebo (both p≤0.001). The most common adverse event was headache, 22.9%, 18.4%, and 15.1% in the pooled SXB

6 g, SXB 4.5 g, and placebo groups, respectively. Adverse events with an incidence >5% in all SXB treated patients and twice the rate in placebo were nausea, dizziness, vomiting, and anxiety.

Conclusions: This pooled analysis of two pivotal clinical trials supports the efficacy of SXB. SXB significantly reduced pain and fatigue, improved sleep, and lessened the impact of daytime sleepiness on daily functioning.

SPECT Imaging of the Brain: Regional Cerebral Blood Flow before and after Treatment of Patients with Primary Fibromyalgia. Manal Osman[3], Osama Hajji[3], Ola Abdul Nasser[3], Ahmad Khodair[2] and Nashwa Al Sarraf[1]. [1]Internal Medicine Department, Faculty of Medicine, Cairo University, Cairo, Egypt, [2]Radiology Department, Faculty of Medicine, Ain Shams University, Cairo, Egypt, [3]Rheumatology and Rehabilitation Department, Faculty of Medicine, Ain Shams University, Cairo, Egypt

Objective: Whether regional cerebral blood flow (rCBF) is affected by Duloxitine Hcl in Egyptian women with primary fibromyalgia (FM) and if it correlates with clinical findings.

Methodology: Thirty untreated women with FM were subjected to full history taking and thorough clinical examination(headache, anxiety, fatigue, sleep disturbances, wide spread pain, tender points). The patients (group I) and ten apparently healthy controls (group II) were studied with single photon emission computed tomography of the brain (brain SPECT) after IVI of Tc-99^{m} HMP[lrm]AO as a cerebral perfusion agent. The resting state (rCBF) was measured for the deep structures (thalamus and caudate nucleus) and cerebral cortices (anterior, lateral, posterior) of both sides. Fifteen patients(group Ia) received the conventional therapy of fibromyalgia and the other fifteen (group Ib) received Duloxitine Hcl (a potent serotonin and norepinephrine reuptake inhibitor which is approved by FDA) 60 mg daily for 3 months followed by measuring rCBF.

Results: There was a statistically highly significant lower (rCBF) in the thalamus and caudate nucleus in patients as compared to controls but no such difference in the anterior, lateral and posterior cerebral cortices. No significant difference clinically or radiologically was found comparing group Ia results before and after 12 weeks. There was a highly significant difference with fatigue and a significant difference as regard neck pain, headache, generalized body ache and morning stiffness when comparing group Ib results before and after 12 weeks. The rCBF to thalamus and caudate nucleus showed a high significant increase in group Ib after 3 months. There was a significant difference in number of tender points, the duration of morning stiffness as well as thalamic and caudate nucleus blood flow comparing the change in Ia and Ib groups.

Conclusions: The decrease of regional cerebral blood flow to thalamus and caudate nucleus in patients with primary FM may be the cause of their symptoms. Improvement of the symptoms by administration of duloxitine Hcl may be due to increase of blood flow to the thalamus and caudate nucleus.

The Prevalence of Fibromyalgia in Patients with Chronic Hepatitis C Infection. Ausaf Mohammad[1], John J. Carey[4], Eoin R. Storan[2], Margaret Scarry[2], Mary B. Keane[2], Angela Moore[2], Ann Lyons[2], Maureen O' Grady[2], Catriona Minihan[2] and John M. Lee[3]. [1]Department of Hepatology and Rheumatology, Galway University Hospital, Ireland, [2]Galway University Hospital, [3]Hepatology Galway University Hospital, [4]Rheumatology Merlin Park University Hospital

Purpose: Chronic HCV infection is associated with rheumatologic conditions including arthritis and vasculitis. Previous studies have not specifically addressed the presence of fibromyalgia syndrome (FMS) in this population. In this study we assessed the prevalence of fibromyalgia in a cohort of subjects with chronic HCV and its relationship to subject demographics, viral characteristics and quality of life.

Methods: Cross-sectional study of a cohort of HCV infected individuals at our university hospital. Study was approved by local I.R.B. and all subjects gave written informed consent prior to participation. Patients with decompensated liver disease, concomitant autoimmune liver disease, arthritis, vasculitis, co-infection with hepatitis B or D, or HIV, end-stage renal failure, organ transplantation, cancer and those patients who were currently receiving anti-viral treatment were excluded. All subjects underwent a single interview including a fibromyalgia impact questionnaire, pain assessment measured on a 100-mm visual analogue scale (VAS) and the Stanford Health Assessment Questionnaire 20-Item Disability Scale (HAQ-DI). All patients underwent clinical examination including a standard assessment for fibromyalgia tender points. Additional details were recorded from the medical record including information about their HCV infection and its treatment, laboratory data including antibody profiles, other illnesses and medications.

Results: 185 patients attending the hepatology unit consented to participate. 110 (59%) were females with a mean age of 46.7 years. 106 (57%) subjects met criteria for the presence of FMS. Widespread pain and ≥11 tender points were present in all of the subjects with fibromyalgia, fatigue in 98 (92%), depression in 60 (57%), and arthralgia/ joint stiffness in 16 (15%). Among those with FMS mean pain score was 70 ± 11.78 and 36% reported some functional impairment on HAQ-DI (>0), with 17% reporting moderate-severe functional impairment (HAQ-DI ≥1.5). Compared to subjects who did not meet criteria for fibromyalgia, patients with fibromyalgia were more likely to be older, females, living alone, smokers, have a history of depression, had acquired HCV via a blood transfusion, and had HCV genotype-1(table 1, $p < 0.005$ for all categories).

Table 1. Comparing HCV infected subjects with and without FMS

	Chronic HCV patients with FMS (n = 106)	Chronic HCV patients without FMS (n = 79)	*t, p* value
Female	82 (77%)	28 (35%)	17.6; 0.001
age ≥ 45 years	80 (73%)	26 (33%)	17.9; 0.001
Wide spread pain	106 (100%)	20 (25%)	25.7; 0.001
Depression	60 (57%)	20 (25%)	15.3; 0.001
HCV acquisition via blood transfusion	65 (61%)	26 (33%)	15.0; 0.001
Genotype 1	82 (77%)	20 (25%)	20.4; 0.001

Conclusions: The prevalence of FMS was very high (57%) among subjects with HCV infection, one third of whom reported some degree of functional impairment. Further research is needed to better understand FMS in patients with HCV.

The Prevalence of Fibromyalgia in Patients with Hereditary Hemochromatosis. Ausaf Mohammad[1], John J. Carey[4], Eoin R. Storan[2], Margaret Scarry[2], Mary B. Keane[2], Angela Moore[2], Ann Lyons[2], Maureen O' Grady[2], Catriona Minihan[2] and John M. Lee[3]. [1]Department of Hepatology and Rheumatology Galway University Hospital, Ireland, [2]Galway University Hospital, [3]Hepatology Galway University Hospital, [4]Rheumatology Merlin Park University Hospital

Introduction: Hereditary hemochromatosis (HH) is a well-defined syndrome characterized by the toxic accumulation of iron in parenchymal cells of liver, heart, and endocrine glands and is associated with inflammatory arthritis. Although studies have reported arthralgia and fatigue as common symptoms of this disorder little data exist of the presence of fibromyalgia syndrome (FMS) in this population.

Purpose: In this study we assessed the prevalence of fibromyalgia in a cohort of subjects with HH and it's relationship to subject demographics, HH status, and quality of life.

Methods: Cross-sectional study of a cohort of individuals with HH at our university hospital. Study was approved by local I.R.B. and all subjects gave informed consent. Patients with decompensated or concomitant autoimmune liver disease, arthritis, and vasculitis were excluded. All subjects underwent a single interview which included a fibromyalgia impact questionnaire, pain assessment measured on a 100-mm visual analogue scale (VAS) and disability assessment measured on the Stanford Health Assessment Questionnaire 20-Item Disability Scale (HAQ-DI) [10]. All patients underwent clinical examination by a trained physician which included assessment for arthritis and fibromyalgia tender points. Demographic data, details of HH and

laboratory data including autoantibody profiles and iron studies were recorded from the patients' medical record.

Results: 350 patients with HH attending the hepatology unit consented to participate, 230 (66%) of whom were males with a mean age of 43 years (range 27–70). 170 (41%) subjects met criteria for the presence of FMS. In subjects with fibromyalgia, fatigue and ≥11 tender points were present in all of the subjects, wide spread pain in 150 (88%), depression and arthralgia/joint stiffness in 70 (41%). Among those with FMS mean pain score was 69 ± 10.25 and 33% reported some functional impairment on HAQ-DI (>0), with 10% reporting moderate-severe functional impairment (HAQ-DI ≥1.5). Patients with fibromyalgia were more likely to be older, males with wide spread pain and history of depression, and had C282Y homozygosity in the HFE gene (table 1, $p < 0.005$ for all categories).

Table 1. Comparing HH subjects with and without FMS

	Patients with FMS (n = 170)	Patients without FMS (n = 180)	*p* value
Male	140 (82%)	90 (50%)	0.001
age ≥ 45 years	90 (53%)	50 (28%)	0.001
Wide spread pain	150 (88%)	40 (22%)	0.001
Depression	70 (41%)	30 (16%)	0.001
C282Y Homozygous Genotype	160 (94%)	110 (61%)	0.001

Conclusions: There is a high prevalence of FMS (41%) among subjects with HH, one third of whom showed some degree of functional impairment.

Use of Path Analysis To Evaluate the Effects of Sodium Oxybate on Pain Reduction in Patients with Fibromyalgia. Fowzia Ibrahim[2], Chinglin Lai[1] and Ernest Choy[3]. [1]Jazz Pharmaceuticals, Inc., [2]King's College London, [3]Kings College Hospital, London, United Kingdom

Background: Although chronic widespread pain is the hallmark symptom of fibromyalgia (FM), sleep disturbances are also a characteristic of patients with FM. In clinical trials, sodium oxybate (SXB) has been shown to reduce pain and improve sleep. This study explores the relationship of the effects of SXB on these two outcomes.

Methods: All randomized patients in two placebo-controlled phase 3 clinical trials of SXB for the treatment of FM were included in the analyses. Ordinal linear regression models were used initially to explore the association between reduction in pain and other covariates. In addition, we perform path analysis to examine the direct and indirect treatment effect of SXB on reduction of pain and sleep disturbances. Pain reduction was based on changes from baseline in pain visual analogue scale (VAS) scores, and sleep improvement was based on changes from baseline in the Jenkins Sleep Scale (JSS) total score, with question 4 of the JSS, and the sleep question of the Fibromyalgia Impact Questionnaire (FIQ) used in sensitivity analyses.

Results: The analysis included 1,121 subjects with mean age of 46.8 (SD: 11.0) years. Ninety percent were female and 91% were White. Mean change in JSS score: [−2.76 (SD: 5.32); −5.44 (5.75); −6.05 (5.88)] and change in pain reduction: [−9.02 (21.75); −14.53(21.33); −18.37 (23.16)] for placebo, SXB 4.5 g and SXB 6 g, respectively. Multivariate linear regression shows that change in JSS score was associated with reduction in pain [Coefficient 95% CI: 1.50 (1.27, 1.72); p<0.001]. However, when the effects of other factors (tired upon awakening, stiffness, and fatigue) were adjusted for, the change in JSS score was not statically significant (0.01(−0.14, 0.17); p=0.86).

The path analysis showed the standardized direct (unmediated) effect of JSS score on pain reduction was 0.40, 95% CI (0.38, 0.48), indicating when JSS score changes by 1 standard deviation, pain intensity changes by 0.4 standard deviations in the same direction. In addition, change in fatigue is strongly associated with change in pain. The standardized direct effect of fatigue on pain was 0.84 (0.77, 0.85) and the indirect effect of JSS score mediated by fatigue is 0.35 ((0.31, 0.39); p=0.001). Since fatigue is highly correlated with stiffness (0.59) and tiredness upon awakening (0.67), adding these effects to the model showed the mediation effect of fatigue was reduced to 0.023 ((0.01, 0.04) p=0.002).

Conclusions: The results show that SXB reduces pain and improves sleep. However, the reduction in pain cannot solely be explained by improvement in sleep as measured by JSS, suggesting there is direct effect of SXB on pain reduction. For the component of reduction in pain mediated through improvement in sleep, it is mediated by reducing fatigue, tiredness upon awakening, and stiffness. This suggests that for SXB improvement in quality of sleep is associated with improvement in fatigue, tiredness upon awakening, and stiffness.

Very Low Dosage (VLD) Bedtime Cyclobenzaprine (CBP) Reduces Cyclic Alternating Pattern (CAP) Rate Indices of EEG Sleep Instability and Improves Pre-Sleep Fatigue in Fibromyalgia Syndrome (FMS). Harvey Moldofsky[1], Herbert W. Harris[2], Tad Archambault[4], Terence Kwong[1] and Seth Lederman[3]. [1]Centre for Sleep & Chronobiology, Toronto, ON, Canada, [2]Krele Pharmaceuticals, Saddle Brook, NJ, [3]Krele Pharmaceuticals, New York, NY, [4]VirtuStat Ltd, North Wales, PA

Background: The importance of nonrestorative sleep in the pathophysiology of FMS suggests new treatments that improve sleep quality may improve daytime symptoms of fibromyalgia (FMS). We previously reported a randomized double-blind placebo-controlled 8 week study of very low dose (VLD) (≤4 mg) cyclobenzaprine (CBP) h.s. in 36 patients with FMS, which showed that bedtime CBP treatment (Tx) was associated with significant improvements in pre-sleep/p.m. fatigue, pain, and pain sensitivity (dolorimetry) with increased Stage 2 non-REM sleep (ref 1). Previous EEG sleep studies in FMS identified increased Cyclic Alternating Patterns (CAP) A2 & A3 in non-REM sleep, measures of sleep instability related to the symptoms of FMS (ref 2 & 3). We now report the effect of CBP Tx on nocturnal sleep EEG CAP and daytime fatigue in FMS.

Methods: CAP A2 & A3 rates are objective EEG sleep measures of sleep instability whereas CAP A1 rate is associated with sleep stability. To investigate whether the CAP A2 & A3 rates are decreased by Tx that target unrefreshing sleep in FMS patients, we retrospectively analyzed the polysomnography (PSG) data from a study in which bedtime CBP improved fatigue, pain and subjective sleep in a 8 week dose-escalating, double-blind, placebo-controlled randomized trial involving 36 FMS subjects. Each subject had screening and baseline PSGs (combined 2 pre-Tx PSGs) and 3 single nights of PSG during Tx after 2, 4 and 8 weeks. We analyzed whether subjects had an increased number of nights with decreased CAP(A2+A3) after the initiation of Tx by classifying the subjects nightly into responders and non-responders based on a CAP(A2+A3) rates normalized for the total CAP rate (A1+A2 +A3). Three placebo-Tx subjects, but no CBP-Tx subjects, withdrew from the study after initiation of Tx and without any nights of PSG. Consequently, the LOCF analysis imputed no improvement for these subjects.

Results: Initially we analyzed the study data for CAP(A2+A3)/(A1+A2+A3) over a range (10–50%) to identify cut-offs for responders by LOCF and OC (for ≥ 1 night improvement) and found that defining responders as ≤30% or ≤33% had the greatest difference between CBP and placebo-Tx and the smallest p-value (p<0.05). CAP response of ≥1 night of sleep EEG analyses that compared 2 pre-Tx drug free nights to 3 post-Tx PSG nights (defined by CAP(A2+A3)/(A1+A2+A3) ≤33% was analyzed for correlations with clinical improvement measures of patient-reported fatigue (pre-sleep/p.m. and post-sleep/a.m.); pain (p.m. and a.m.) and dolorimetry. Reduction in p.m. fatigue in CBP-Tx subjects is significantly correlated with CAP response (p = 0.0064), whereas p.m. fatigue was neither decreased nor correlated with responder status in placebo-Tx subjects.

Conclusions: 1. Normalized CAP A2 & A3 rates are novel physiological sleep EEG indices of nonrestorative sleep in FMS.

2. Very low dose CBP at bedtime decreases CAP A2 & A3 sleep EEG measures of nonrestorative sleep which correlates strongly with improvement in p.m. fatigue in FMS patients.

Vibrotactile Analgesia Is Not Abnormal in Fibromyalgia Patients. Casey T. Goldman[2], Donald D. Price[2], Michael E. Robinson[2] and Roland Staud[1]. [1]Univ of Florida JHMHC, Gainesville, FL, [2]University of Florida

Vibrotactile analgesia formerly known as Gate-Control analgesia is dependent on input from myelinated A-beta nerve fibers during noxious stimuli. This type of analgesia can be elicited by vibrotactile stimulation either homotopically or heterotopically to a pain stimulus. Because multiple analgesic mechanisms including diffuse noxious inhibitory controls (DNIC) and spatial summation have been found to be abnormal in fibromyalgia (FM) patients and may contribute to the clinical pain of this chronic pain population, we hypothesized that another analgesic mechanism i.e. vibrotactile analgesia would also be deficient in FM patients.

Methods: 28 normal control (NC) and 29 FM subjects were enrolled into this protocol. Mean age was 30 (10.7) and 39 (11.1) years for NC and FM subjects, respectively. The overall clinical pain of FM subjects was 4.2 (2.1) VAS units. The NC were pain-free. A bio-thesiometer was used for application of 25 mA vibratory stimuli to the forearms. Sensitivity adjusted 10 sec heat stimuli (MEDOC) between 42 and 50 deg C were used to elicit heat pain ratings of 3.5 ± 0.5 VAS units (0–10) at the forearms of all subjects.

Results: When vibrotactile and noxious stimuli were simultaneously applied to the forearms NC and FM subjects experienced a 46% and 35% reduction in experimental pain intensity, respectively. These pain reductions were similar for homotopic and heterotopic stimulation. Vibrotactile analgesia was not statistically different between NC and FM subjects.

Conclusion: Vibrotactile stimulation of the skin resulted in substantial experimental pain reductions of FM patients. Thus not all types of endogenous analgesic mechanisms seem to be dysfunctional in FM patients. Furthermore, vibrotactile analgesia may represent a clinically relevant method of pain reduction for FM patients.

A Putative Functional Variant within the Ubiquitin-Associated Domain-Containing Protein 2 Gene (UBAC2) Is Associated with Increased Risk of Behcet's Disease. Amr H. Sawalha[7], Travis Hughes[6], Ajay Nadig[6], Vuslat Yilmaz[2], Kenan Aksu[1], Gokhan Keser[1], Ayse Cefle[3], Ayten Yazici[3], Andac Ergen[5], Haner Direskeneli[4] and Güher Saruhan-Direskeneli[2]. [1]Ege University, [2]Istanbul University, [3]Kocaeli University, [4]Marmara University, Istanbul, Turkey, [5]Okmeydani Research and Education Hospital, [6]OMRF, [7]University of Oklahoma, OMRF, VAMC, Oklahoma City, OK

Purpose: Using a genome-wide association scan and DNA pooling, we previously identified 5 novel genetic susceptibility loci for Behcet's disease. Herein, we fine-map the genetic effect within the UBAC2 gene, replicate this genetic association in an independent cohort of Behcet's disease patients and controls, and identify a functional polymorphism in this locus.

Methods: Two independent cohorts of Behcet's disease patients and controls from Turkey were studied. The discovery and replication cohorts included 152 patients and 172 controls, and 376 patients and 369 controls, respectively. Genotyping of 14 SNPs within and around UBAC2 was performed using TaqMan SNP genotyping assays.

Results: The genetic association between Behcet's disease and UBAC2 was established and confirmed in two independent cohorts of patients and controls (Meta-analysis OR= 2.05, meta-analysis P= $1.75\times10-7$). Haplotype analysis identified both a disease risk and a protective haplotype (P= 0.00014 and 0.0075, respectively). Using conditional haplotype analysis we identified that the SNP rs7999348 (A/G) within UBAC2 is the most likely SNP to explain the genetic effect in this locus. Indeed, we demonstrate that rs7999348 is a putative functional SNP that results in increased mRNA expression of a UBAC2 transcript variant in PBMCs of individuals homozygous for the Behcet's disease-associated "G" allele.

Conclusion: We establish and confirm the genetic association between UBAC2 and Behcet's disease in two independent cohorts of patients and controls. Fine mapping of this genetic effect and conditional analysis followed by functional studies identified the minor allele in rs7999348 as a disease-risk allele that alters UBAC2 expression.

A Role for PACE4 in Pain in Mice and Humans: Pain Phenotype of a PACE4 Null Mutant and Genetic Association with Knee Osteoarthritis Pain. Anne-Marie M. Malfait[6], Albert B. Seymour[5], Ana M. Valdes[4], Linda S. Wood[5], Kathryn Durham[5], Micky Tortorella[3], Nigel K. Arden[8], Frances L. Vaughn[7], Paul E. Leaverton[7], Deborah J. Hart[4], Robert E. Sorge[1], Susana G. Sotocinal[2], Ara Schorscher-Petcu[1] and Jeffrey S. Mogil[1]. [1]Dept of Psychology and Alan Edwards Centre for Research on Pain, McGill University, Montreal, QC, Canada, [2]Dept of Psychology and Alan Edwards Centre for Research on Pain, McGill University, [3]Guangzhou Institute of Biomedical Health, Guangzhou, China, [4]King's College London, London, United Kingdom, [5]Pfizer Global Research and Development, Cambridge, MA, [6]Rush University Medical Center, Chicago, IL, [7]The Arthritis Research Institute of America, Clearwater, FL, [8]University of Oxford, Oxford, United Kingdom

Background: PACE4 is a member of the proprotein convertase family of serine proteases essential for the proteolytic maturation of a wide variety of proteins, including growth factors, hormones, and zymogens. We recently reported that PACE4 activates the aggrecanases, ADAMTS-4 and ADAMTS-5, in human osteoarthritic (OA) cartilage. The aim of the current study was to assess if genetic variants in the PACE4 gene are implicated in the risk for knee OA.

Methods and Subjects: The rs900414 single nucleotide polymorphism (SNP) in the PACE4 gene (*PCSK6*) was genotyped in three independent cohorts ("Discovery": 508 symptomatic knee OA cases, 159 asymptomatic knee OA, and 276 controls; "Clearwater": 85 symptomatic and 92 asymptomatic knee OA cases; and "Chingford" 62 symptomatic, 157 asymptomatic knee OA cases, and 527 controls). In follow-up to the human findings, PACE4 KO mice and wildtype littermates (C57BL/6) were tested on a battery of algesiometric assays, including mechanical and thermal hypersensitivity in response to intraplantar administration of substance P (SP) (2.5–20 μg), and for pain behavior in response to intrathecal SP (5–45 ng) or in response to intraperitoneal injection of 0.6% acetic acid.

Results: The minor allele at rs900414 (allele frequency 32%) was found to be significantly associated with symptomatic OA in the discovery samples and to be consistently increased among asymptomatic OA cases compared to symptomatic knee OA in all three cohorts. A fixed-effects meta-analysis yielded OR=1.34 (95% CI 1.09 –1.64) p=0.005 (Figure 1) and no between-study hetereogeneity was observed (I^2=0%). PACE4 KO mice displayed normal baseline sensitivity to thermal and mechanical stimuli as assessed by paw withdrawal, von Frey, tail-clip, hot-plate and tail-withdrawal tests. However, PACE4 KO mice developed significantly less thermal and mechanical hypersensitivity in response to intraplantar injection of SP. In addition, intrathecal injection of substance P resulted in a dose-dependent induction of pain behaviors (scratching, biting and licking) in wildtype but not in PACE4 KO mice. Moreover, compared to wildtypes, PACE4 KO mice showed >50% less pain behavior in the acetic acid writhing test.

Conclusions: These results suggest that the rs900414 SNP in the human PACE4 gene is strongly associated with protection against pain in knee OA. Studies in PACE4 KO mice further implicate PACE4 in pain.

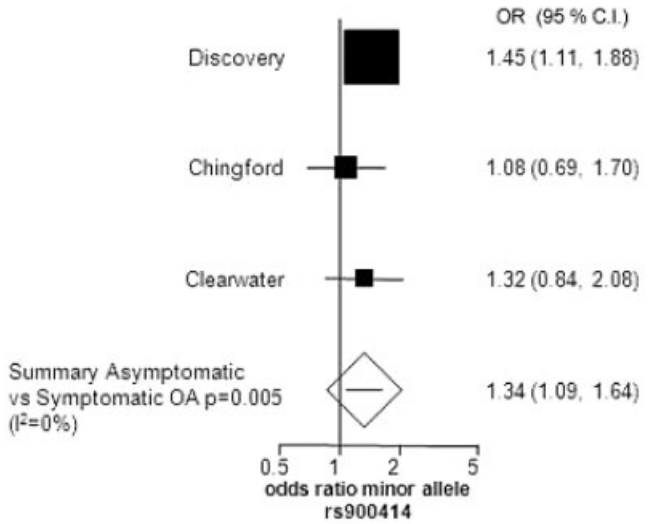

Figure 1. Forest plot showing study specific effect size estimates and summary odds ratio for the association between the PACE4 SNP rs900414 and risk of asymptomatic OA vs symptomatic OA.

Objective: Two functional single nucleotide polymorphisms (SNPs) in the PTPN22 gene (R620W, C1858T, rs24746601; and R263Q, G788A, rs33996649) have been previously associated with autoimmune diseases. The aim of the present study was to investigate the role of the R263Q SNP for the first time and to re-evaluate the role of the R620W PTPN22 polymorphism in the genetic predisposition to systemic sclerosis (SSc) susceptibility and clinical phenotypes.

Methods: A total of 3422 SSc patients (2020 with limited cutaneous SSc (lcSSc) and 1208 with diffuse cutaneous SSc (dcSSc)) and 3638 healthy controls from an initial case-control set of Spanish Caucasian ancestry, as well as seven independent replication cohorts of Caucasian ancestry (from Belgium, England, Germany, Italy, the Netherlands, USA and Sweden), were included in our study. Genotyping was performed using the TaqMan allelic discrimination assay for both the rs33996649 and the rs2476601 PTPN22 polymorphisms. A meta-analysis was then performed to test the overall effect of these PTPN22 gene polymorphisms in SSc.

Results: We observed evidence of association of the rs2476601 T allele with SSc susceptibility in the meta-analysis results (P=0.01 pooled, OR=1.15, 95% CI 1.03–1.28). Moreover, the rs2476601 T allele is significantly associated with anti-centromere (ACA) positive status (P=0.01 pooled, OR=1.22, 95% CI 1.05–1.42). Although we found that the rs33996649 A allele was significantly associated with SSc in the Spanish population (P=0.02, OR=0.58, 95% CI 0.36–0.92), this association was not confirmed in the meta-analysis (P=0.36 pooled, OR=0.89, 95% CI 0.72–1.1).

Conclusion: Our study suggests that the PTPN22 R620W polymorphism influences SSc genetic susceptibility but that the novel R263Q genetic variant does not. Moreover, our data strengthen the evidence that the R620W mutation is a common risk factor in autoimmune diseases.

BLK Is Expressed in Human Peripheral T Cells and Thymocytes and Regulates CD4+ T Cell Numbers in Cord Blood. Kim R. Simpfendorfer[1], Lina Olsson[2], Nataly Manjarraz-Orduno[2], Houman Khalili[2], Annette T. Lee[2] and Peter K. Gregersen[1]. [1]Feinstein Institute for Medical Research, Manhasset, NY, [2]Feinstein Institute for Medical Research

Background: B-lymphocyte kinase (BLK) is an intracellular tyrosine kinase previously presumed to exert its major funtion in B cells. SNP variants in the 5′UTR/ promoter region of *Blk* lie on a common haplotype that is associated with both rheumatoid arthritis and lupus. In humans the functional affect of *Blk* risk alleles to disease susceptibility is yet to be elucidated. The risk haplotype has been associated with lowered mRNA expression of *Blk* in human B cell lines. In mice, *Blk* expression is reportedly restricted to B cells, yet *Blk* knockout animals fail to exhibit a phenotype. Interestingly, both naïve and memory B cells fail to show allelic imbalance for *Blk* in humans, and while B cell activation lowers the expression of *Blk*, the risk allele shows no difference in rates of downregulation. Therefore, it is possible that in humans the influence of BLK on autoimmunity may be mediated at a particular stage of B cell differentiation, or by a non-B cell compartment. Recently, our laboratory demonstrated allelic imbalance of *Blk* in peripheral blood $CD4^+$ T cells.

Analytical procedures and results: We examined the influence of *Blk* genotypes on BLK expression and the distribution of T and B cell populations in human umbilical cord blood, peripheral blood and thymus. Western blot and quantitative RT-PCR was used to examine BLK expression and flow cytometry was performed to compare immune cell populations.

Results: We found that BLK is expressed in thymocytes and purified CD4+ T cells in humans at both the mRNA and protein level, with higher expression in the thymus than in mature peripheral blood T cells. Furthermore, similar to human B cell lines, the *Blk* risk haplotype exhibits evidence of lower expression in both T cells and human thymus. In healthy individuals homozygous for the *Blk* risk allele (A/A) there is a significantly greater

proportion of CD4+ T cells than in individuals homzygous for the protective allele (T/T).

Conclusions: These data suggest that the causative *Blk* allele may play a role in disease pathogenesis by its action in CD4+ T cells as opposed to, or in addition to, B cells. Future studies will examine mRNA expression of Blk, FoxP3 and cytokine expression in CD4+ T cells and phosphorylation of signalling molecules in UCB and thymus samples to further dissect the role of BLK in CD4+ T cell numbers and function.

Epigenetic Studies Characteristic of Muscle Biopsies (MBx) from Untreated Children with Juvenile Myositis (JM). Lauren M. Pachman, Min Wang, Hehuang Xie, Peter Hendrickson, Sheela Shrestha and Gabrielle Morgan. Children's Memorial Research Center, Chicago, IL

Background: Previous Affymetrix array-based gene expression studies of muscle biopsies (MBx) from children with definite/probable juvenile dermatomyositis (JDM) showed that, despite a florid display of IFN-α induced genes, patients with a longer duration of untreated disease (DUD) >2 months had a marked upregulation of genes related to vascular remodeling compared with muscle from JDM with a DUD of 2 months or less (Chen Y-W, Duration of chronic inflammation alters gene expression in muscle from untreated girls with juvenile dermatomyositis, BMC Immunol. 2008 Jul 31;9:43).

Objective: To profile the methylation patterns in a cohort of children with JDM in order to determine: 1) the impact of methylation alterations in JDM, and 2) the association of methylation profiles with the chronicity of the inflammatory response as determined by DUD.

Materials and Methods: DNA from diagnostic MBx from 20 white girls and boys (mean age = 6.4 ± 3.5 yrs) with definite/probable JDM were used for this study: five with DUD ≤2 mos; 15 with DUD >2 mos at MBx were compared with four age-, gender- and race-matched controls. The DNA was tested using the Illumina Methylation27 BeadChip for genome-wide methylation profiling and further analyzed with GenomeStudio Data Analysis Software. Bisulfite pyrosequencing confirmed DNA methylation from 10 matched controls and 71 children with a spectrum of juvenile myositis (56 JDM, 7 overlap, 5 juvenile polymyositis [JPM], and 3 other). The patient population (50/71 girls, mean age 7.6 ± 4.1 yrs) included 41 white, 14 Hispanic and 16 others. Among the 71 patients, 54 of them had DUD ≥2 mos untreated symptoms.

Results: In the first part of this study, 20 untreated JDMs displayed distinct methylation profiles from the four age-, gender-, and race-matched controls. Twenty-two genes showed significant differential methylation, including WT1 and the transcriptional regulation genes HOXC11, HOXD4, and EMX2. Specific pyrosequencing studies confirmed the Illumina methylation profiles for both hypo and hypermethylation responses respectively. Further investigation of WT1 methylation status in 71 JDM muscle samples showed no significant difference in methylation within JDM samples with respect to the specific JDM diagnosis vs other forms of JM, DUD, race, age at MBx, TNF-α-308 A allele, or treatment status at MBx.

Conclusions: Epigenetic studies of untreated JDM muscle showed specific patterns of methylation alteration, including WT1, which targets Bcl2, a critical factor in apoptosis. Unlike the gene expression and microRNA expression studies of JDM diagnostic muscle biopsies, disease chronicity, as measured by DUD, does not appear to alter the DNA methylation profiles.

Speculation: We speculate that further epigenetic studies will be highly informative, suggesting new concepts concerning the pathophysiology of JDM.

Supported by NIH/NIAMS R01 AR48289 and Cure JM Foundation (LMP).

Functional Change of 5-Aminoimidazole-4-Carboxamide Ribonucleotide Formyltransferase in Dermal Fibroblasts from Methotrexate-Sensitive and Resistant Mice. Xin You[2], Bruce N. Cronstein[2], Adrienne Williams[2] and Thierry Dervieux[1]. [1]Cypress Pharmaceuticals, [2]NYU

Background: Methotrexate (MTX) has been widely used in the treatment of RA but it is effective in only 60% of patients and its mechanism is complex. To date, the adenosine-mediated anti-inflammatory effect of MTX is best supported by the in vitro, in vivo, and clinical data. Pharmacogenetic studies indicate that genetic polymorphisms in adenosine pathway enzymes are associated with good response to MTX therapy in RA and animal experiments showed that MTX suppressed inflammation in air pouches of C57Bl/6 and BALBc, but not DBA/1J mice. To investigate the mechanism for genetically based resistance to the anti-inflammatory effects of MTX, functional change of a critical enzyme in MTX metabolism and the adenosine pathway, 5-aminoimidazole-4-carboxamide ribonucleotide formyltransferase (AICAR TF) was measured.

Methods: Dermal Fibroblasts (DF) from BALBc and DBA/1J mice were cultured from skin. Following MTX incubation with DFs, AICAR TF activity before and after MTX treatment was analyzed after preparation of (6*R*,6*S*)-10-formyltetrahydrofolate from 5,10-Methenyltetrahydrofolate. Protein concentration was determined by the Bradford protein assay. AICARFT activity was monitored by the formation of FHat *A* for 4 min using a Perkin-Elmer Lambda2 spectrophotometer. In addition, MTX polyglumate (pg) concentration was measured and AICAR TF mRNA was quantited by real time (RT) PCR.

Results: *In silico* analysis of the sequence of folyl polyglutamate synthase and AICAR TF indicate differing haplotypes of the enzymes in BALB/c and DBA1J mice. MTX treatment inhibited AICAR TF activity in DF from BALBc mouse in a dose-dependent manner (2.61 nmole/μg.min, 1.00 nmole/μg.min, and 0.9 nmole/μg.min at the dose of MTX 0, 10-7M, and 10-6M, respectively). Seventy percent decrease was observed at MTX 10-6M. AICAR TF activity was not reduced in DF from DBA1J mouse by MTX, and even increased after hydrogen peroxide stimulation with MTX (1.98 nmol/μg.min, 2.78 nmol/μg.min, and 3.83 nmol/μg.min at the dose of MTX 0, 10-7M, and 10-6M, respectively). The cellular concentration of MTXPG in BALBc fibroblasts is more than 2-fold greater than that observed in DBA1J fibroblasts at MTX 10-6M. There is no significant difference in AICAR TF mRNA in DFs between BALBc and DBA1J mice.

Conclusions: Genetic polymorphisms of the critical enzymes involved in MTX metabolism and the adenosine pathway contribute to the different responses to MTX in the treatment of Rheumatoid Arthritis.

Functional Polymorphisms in the Inhibitory FCGR2B Associate with Efficacy of IVIG Treatment Response among Patients with Kawasaki Disease. Sadeep Shrestha[2], Howard W. Wiener[1], Aditi Shendre[1], Richard A. Kaslow[1], Aaron K. Olson[3], Mary Beth Lee[3], Jeffrey C. Edberg[4] and Michael Portman[3]. [1]Department of Epidemiology, University of Alabama at Birmingham, [2]Department of Epidemiology, University of Alabama at Birmingham, Birmingham, AL, [3]Department of Pediatrics, University of Washington, Seattle Children's Hospital, [4]Division of Clinical Immunology and Rheumatology, Department of Medicine, University of Alabama at Birmingham

Background: Intravenous immunoglobulin (IVIG) is the principal treatment for Kawasaki disease (KD). Approximately 20% of KD patients in US are refractory to IVIG, and display higher coronary artery disease and aneurysm rates than those non-refractory. Studies in animal model systems have demonstrated a requirement for expression of the inhibitory Fcγ receptor FCGR2B in IVIG therapeutic responses. We hypothesized that naturally occurring functional SNP variants in the human FCGR2B gene would influence efficacy of IVIG treatment in patients with KD.

Methods: We examined three well-characterized and functionally relevant SNPs in the inhibitory FCGR2B gene among 197 patients (104 European-American (EA), 47 Asians, 46 Other) with KD (based on criteria recommended by the American Heart Association) that had been treated with IVIG as standard of care. Among these patients, 56 were defined as non-responders (persistent fever (temperature >38°C) at >36 hours from the initiation of IVIG infusion or recurrent fever at >36 hours after completion of the initial IVIG infusion) and 141 as responders. SNPs chosen for study are 2 promoter variants at −120 and −386 that alter transcription factor binding and quantitative gene expression and a non-synonymous SNP in the transmembrane region of the protein that alters lipid domain association and quantitative inhibitory potential. Genotyping was performed by Pyrosequenc-

ing. Race and ethnicity were genetically determined using Principle component analysis with 162 ancestry informative markers.

Results: Significant association between all of the functional FCGR2B variants and IVIG response were observed in EA patients. Both the more active promoter variants (−120A/−386C, OR = 4.46 [1.30–15.3], p=0.01/ OR=4.38 [1.28–15.1], p=0.01 respectively) and the more functionally active non-synonymous variant in the transmembrane domain (+775T, OR = 2.38 [1.00–5.88], p=0.05) were positively associated with IVIG response. The 2 promoter variants are in complete linkage disequilibrium and are not independent effects. Because of lower allele frequency and smaller sample size in the other populations, we did not have sufficient power to demonstrate associations between FCGR2B variants and IVIG responses.

Conclusions: Our data are the first to demonstrate a genetic basis in humans for IVIG responses in KD. The known functional consequences of the variants in FCGR2B that associate with IVIG response result in high receptor expression and function and thus are biological plausible and consistent with murine model studies demonstrating a requirement for FCGR2B in IVIG efficacy. Replication of these findings could suggest a role for screening of patients for FCGR2B genotypes prior to treatment.

Systemic sclerosis (SSc) is a rare autoimmune disorder, characterized by severe vasculopathy and fibrosis of the skin and internal organs. The most severe complication is pulmonary artery hypertension (PAH). Several variants in immune regulatory genes have already been implicated in SSc. The *PBEF* gene plays an important role in immune modulation, and two polymorphisms in the promoterregion, namely *PBEF −1001T>G* (rs9770242) and *PBEF −1543C>T* influence the predisposition to pulmonary disease. For this reason we investigated the role of these two polymorphisms in the genetic predisposition to systemic sclerosis (SSc) and clinical phenotype susceptibility in 2737 SSc patients and 1913 healthy controls. In two separate populations and in a meta-analysis, the combined *PBEF −1543CC −1001TT genotype*, was found associated with SSc susceptibility (P=0.009 OR 1.20 (95%CI: 1.05–1.37). In addition, these subjects showed an increased decline in forced vital capacity (FVC) over 15 years (P=0.02) (RR 1.64, 95% CI: 1.02–2.64) and a higher PBEF serum concentration (P<0.01), compared to carriers of the minor alleles. On the other hand, patients with genotype *PBEF -1001TT* were at lower risk for PAH development compared to the carriers with genotypes *PBEF −1001GG* and *PBEF −1001TG* (P<0.001) (RR 3.29, 95% CI: 1.52–7.12). These results reveal an important role for PBEF in the genetic predisposition to SSc and its clinical hallmark PAH.

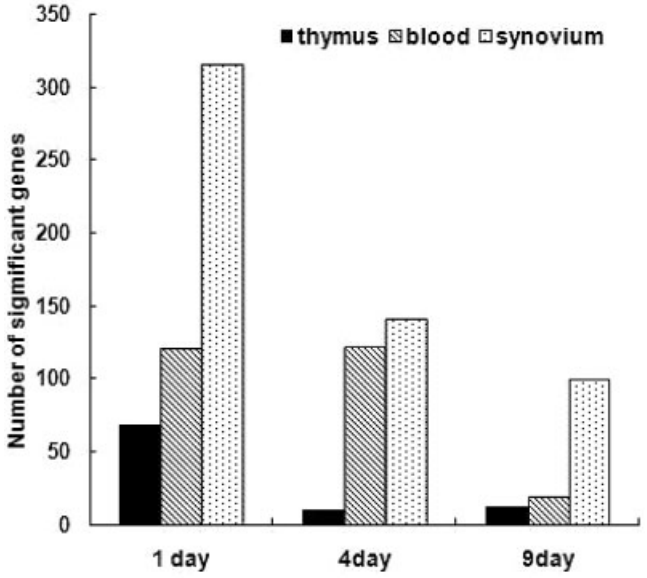
Gene Expression Profile at the Initial Phase of Collagen-Induced Arthritis in the Synovium, Peripheral Blood and Thymus. Seung-Cheol Shim[2], Mi-Kyung Lim[1] and Dong-Hyuk Sheen[1]. [1]Eulji University, Daejeon, Korea, Republic of, [2]Eulji University, Daeejon, Korea, Republic of

Background: Current management strategies aim to detect rheumatoid arthritis (RA) at an early stage. Transcription profiling is applied in the search for biomarkers for detecting early stage disease. Peripheral blood T cells in RA show incomplete activation which is unclear whether this process occurs in the peripheral or central lymphoid organs. Eventhough gene profilings in several RA animal models have been reported previously, most of these studies were performed after active arthritis developed and only in the peripheral organs.

Objective: To explore gene expressions at the initial phase of collagen induced arthritis (CIA) before the arthritic features develop in the synovium, peripheral blood and thymus.

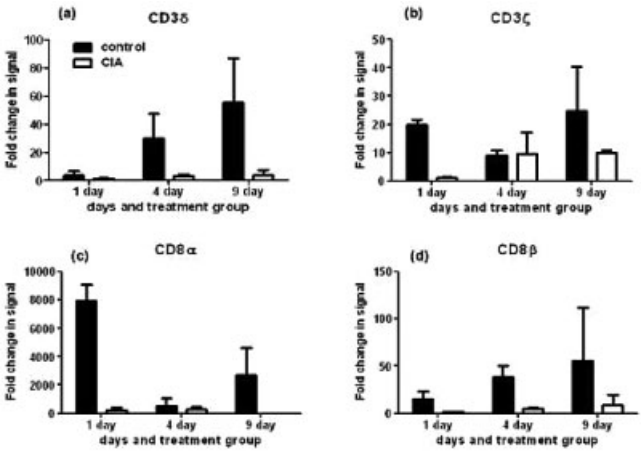
Methods: For gene expression analysis using cDNA microarray technology, samples of thymus, blood, and synovium were collected from CIA and control rats on days 0, 1, 4 and 9 after the first immunization. Labeled cRNA samples were hybridized to each Rat-12 expression bead array for 16–18 h at 58°C, according to the manufacturer's instructions (Illumina, Inc., San Diego, USA). Detection of array signal was carried out using Amersham fluorolink streptavidin-Cy3 (GE Healthcare Bio-Sciences, Little Chalfont, UK) following the bead array manual. Arrays were scanned with an Illumina bead array Reader confocal scanner according to the manufacturer's instructions. Array data export processing and analysis was performed using Illumina BeadStudio. We also performed real-time RT-PCR to validate our microarray findings.

Results: Of the 22,517 genes on the array, 1,243 genes were differentially expressed at least 2 fold in various organs of CIA compared to controls. Even on day 1, over 300 genes were differentially expressed in the synovium of CIA.



10% of the genes expressed differentially were immune-related genes in synovium and thymus, and 25% in blood. Among 20 genes related with T-cell mediated immunity, 9 genes were significantly down-regulated in the synovium of CIA compared to controls, which include cd3ζ, cd3δ, cd8α, cd8β. However, the expression levels of those genes showed no difference in the thymus and blood between CIA and controls.

The differential expressions of cd3ζ, cd3δ, cd8α, cd8β in CIA, as revealed by real-time RT-PCR, agreed well with the microarray data.



Conclusions: This study provides evidence that the most genes start to express differentially on day 1 after the first immunization in CIA. And the downregulation of cd3ζ, cd3δ, cd8α, cd8β occurs just in the synovium at the initial phase of CIA, which might play a role in the pathogenesis of CIA.

Genetic Variants Associated with Susceptibility to Knee Osteoarthritis: The Johnston County Osteoarthritis Project. Xiaodong Wu[3], Venkateswarlu Kondragunta[4], Jordan B. Renner[2], Gordon W. Duff[5], Kenneth S. Kornman[4] and Joanne M. Jordan[1]. [1]Chapel Hill, NC, [2]Department of Radiology and Thurston Arthritis Research Center, University of North Carolina at Chapel Hill, [3]Interleukin Genetics, Inc., Waltham, MA, [4]Interleukin Genetics, Inc., [5]School of Medicine, University of Sheffield

Purpose: Factors that differentiate individuals who develop osteoarthritis (OA) from those who do not may be valuable in developing prevention strategies. Although several genetic variants have been associated with susceptibility to OA, most have not been replicated in adequately sized cohorts. We therefore sought to validate genetic variants predictive of OA susceptibility in a Caucasian patient sample in the United States, in a population-based study.

Method: Caucasian participants (N=1,173; 38% men; mean age=60 years) in the Johnston County OA Project were examined for susceptibility to radiographic knee OA in a cross-sectional analysis. Anterior-posterior standing knee radiographs were obtained with footmat positioning and read by a single musculoskeletal radiologist for Kellgren-Lawrence grade (K-L, 0–4). OA cases were defined as having KL>=2 in at least one knee. Non-OA controls were defined as having KL=0 in both knees. Genotypes of 37 single nucleotide polymorphisms (SNPs) in 16 genes, including gene variants previously shown to be associated with OA and variants in genes that are functionally implicated in OA, such as the proinflammatory IL-1 gene family, were determined using the single-nucleotide primer extension method. Logistic regression with adjustment for age, gender and body mass index was used to determine associations between gene polymorphisms and susceptibility to radiographic knee OA. Since this was not an exploratory analysis, we analyzed the data without correction for multiple comparisons, but also report the results of a permutation test for multiple comparisons. An association was considered a positive validation if the p-value after adjustment for age, gender and BMI <0.05 for the risk allele, genotype or haplotype previously reported to be associated with OA.

Results: Out of 16 genes tested, 6 were significantly associated with susceptibility to radiographic knee OA. These included ABCG2, GDF5, IL1R1, IL1RN, IL6 and VDR genes (table 1). VDR rs731236 also showed significance after correction for multiple comparisons.

Table 1. Genetic variants associated with susceptibility to radiographic knee OA.

Gene	SNP	Allele/ genotype	OR	95% CI (L)	95% CI (U)	P
GDF5	rs143383	C/C	0.57	0.36	0.91	0.018
VDR	rs1544410	T/*	1.51	1.07	2.13	0.020
IL6	rs1800797	A	1.38	1.09	1.74	0.008
ABCG2	rs2231142	A/*	0.64	0.42	0.97	0.036
IL1R1	rs2287047	T	0.74	0.56	0.97	0.029
IL1RN	rs380092	T/T	0.56	0.33	0.96	0.034
VDR	rs731236	C/*	1.69	1.19	2.39	0.003

Conclusion: This study validated several genetic markers for association with susceptibility to radiographic knee OA in a population-based study of Caucasians.

HLA-DRB1*04 Is a Novel Fetal Susceptibility Allele in Congenital Heart Block. Therese Östberg[2], Stina Salomonsson[2], Bo Ding[4], Håkan Eliasson[4], Lars Alfredsson[4], Lars Klareskog[5], Anders Hamsten[2], Tomas Olsson[4], Leonid Padyukov[2], Tomas Axelsson[6], Swedish Congenital Heart Block Study Group[7], Fredrik Gadler[2], Anders Jonzon[6], Sven-Erik Sonesson[3], Ingrid Kockum[4] and Marie Wahren-Herlenius[1]. [1]Department of Medicine, Karolinska Institutet, Stockholm, [2]Department of Medicine, Karolinska Institutet, [3]Department of Women and Child Health, Karolinska Instituet, [4]Karolinska Institutet, [5]Karolinska University Hospital, Stockholm, Sweden, [6]Uppsala University, [7]www.combinesweden.se

Objective: Congenital heart block may develop in the fetus of Ro52 autoantibody positive women. The reported recurrence rate for autoantibody associated congenital heart block is however only 10–25%, indicating that other factors than maternal autoantibodies influence the disease development and fetal outcome. The most potent genetic influence on susceptibility to autoimmune diseases is the HLA locus, and as there is a strong and well-known HLA-DR*03 allele association with SLE, Sjögren's syndrome and production of Ro/SSA autoantibodies, we hypothesized that specific alleles of the HLA locus may render the fetus susceptible to congenital heart block induced by maternal autoantibodies.

Methods: Genotyping was performed for 561,490 SNPs in DNA from 348 individuals of 88 Swedish Caucasian families with a Ro/SSA autoantibody positive mother and with at least one case of congenital heart block (83 mothers and 72 fathers, 92 index cases and 101 unaffected siblings). Full HLA-A, -C and HLA-DRB1 allele typing was performed by SSP-PCR in 60 families with complete trios. Swedish Caucasian population-based healthy controls from the EIRA (n=1056) and PROCARDIS (n=654) studies were used in case-control association analysis. Genetic linkage was analyzed by transmission disequilibrium test (TDT).

Results: A case-control analysis between the index cases and population-based controls revealed an association of congenital heart block with 6 SNPs in the 6p21 MHC locus at a genome-wide significance of $p<5\times10-8$ (OR 2.57–3.12). In family-based TDT analysis of distinct MHC class I and II alleles we observed an association of the HLA-DR*04 allele with congenital heart block, and that this variant was significantly more often transmitted to children that developed congenital heart block (p=0.01). No difference in the transmission frequency of the DRB1*04 allele from mothers (maternal DRB1*04 allele frequency 7.6%) compared with fathers (paternal DRB1*04 allele frequency 20.8%) was observed. No other HLA-DRB1, -A or -C association with congenital heart block was found. The previously described HLA-DRB1*03 association in the mothers compared with controls was observed also in our cohort, and 79.7% of the mothers carried DRB1*03.

Conclusions: Our study identifies HLA-DRB1*04 as a novel fetal genetic variant that confers susceptibility to develop congenital heart block in response to exposure to Ro/SSA autoantibodies, and indicates equal maternal and paternal genetic influence on fetal susceptibility to maternal autoantibody exposure.

IL13 Is a Risk Locus for Psoriatic Arthritis but Not Psoriasis Vulgaris. John Bowes[1], Pauline Ho[2], Salma Salah[1], Richard B. Warren[5], Eleanor Korendowych[7], Neil McHugh[7], Oliver FitzGerald[4], Jonathon Packham[3], Ann W. Morgan[6], Christopher E. M. Griffiths[5], Ian N. Bruce[2], Jane Worthington[1] and Anne Barton[2]. [1]Arthritis Research UK Epidemiology Unit, The University of Manchester, UK, [2]Arthritis Research UK Epidemiology Unit, The University of Manchester, UK; The Kellgren Centre for Rheumatology, Manchester, UK, [3]Arthritis Research UK, National Primary Care Centre, Keele University UK, [4]Department of Rheumatology, University College Dublin, Ireland, [5]Dermatological Sciences, The University of Manchester, UK., [6]NIHR-Leeds Musculoskeletal Biomedical Research Unit, University of Leeds, UK, [7]Royal National Hospital for Rheumatic Diseases

Background: Psoriasis vulgaris (PsV) is a chronic inflammatory skin disease in which up to 30% of subjects have additional joint involvement. This has led to psoriatic arthritis (PsA) being recognised clinically as a distinct entity. Both conditions are complex diseases influenced by environmental and genetic factors. All the currently known genetic risk factors are shared between the two conditions. The identification of genetic risk factors that could differentiate the two diseases would allow a better understanding of why some patients with PsV develop arthritis. Two recent PsV genome-wide association studies, both containing a significant proportion of PsA cases, identified an association to the Interleukin 13 (*IL13*) gene as a susceptibility risk factor. However further investigation of this effect in one study found it to be primarily restricted to those individuals with PsA, thus suggesting the discovery of a potential specific genetic risk factor for PsA. Given this intriguing evidence we have investigated association to this gene in large sample collections of PsA and PsV patient samples compared to a common set of healthy controls.

Methods: Two SNPs (rs20541 and rs1800925) mapping to the *IL13* gene were genotyped in 1057 PsA patients and 1136 PsV patients using the Sequenom genotyping platform. Control data for 5575 healthy individuals was available from the WTCCC2 genotyped on the Illumina Human 1M-Duo platform. Association tests, Hardy-Weinberg equilibrium (HWE), and linkage disequilibrium (LD) were performed using the PLINK software package. Additional analyses were performed in phenotypic subgroups of PsA (Type I or II psoriasis and seronegative for rheumatoid factor).

Results: Both SNPs were in HWE and found to be highly associated with susceptibility to PsA (rs1800925 ptrend = 6.1×10^{-5} OR = 1.33 CI 1.16:1.53, rs20541 ptrend = 8.0×10^{-4} OR = 1.27 CI 1.10:1.45), but neither was associated with PsV. LD between the SNPs, calculated in the control samples, was found to be low ($r^2 = 0.23$). Sub-phenotype analysis revealed that the two SNPs remained associated with PsA in patients with both type I and type II psoriasis.

Conclusions: This study confirms that the effect of *IL13* risk locus is specific for PsA, thus highlighting the first key biological pathway that differentiates PsA from PsV. The identification of markers that differentiate the two diseases raises the possibility in the future of allowing screening of PsV patients to identify those at risk of developing PsA.

Major Differences among Proteomes of Macro-Vascular and Micro-Vascular Endothelial Cells: 2D-DIGE Approach. Hanadi Dib[1], Philippe Chafey[3], Guilhem Clary[3], Morgane Le Gall[3], Cedric Broussard[4], Luc Camoin[4], Christian Federici[3], Veronique Witko-Sarsat[3], Mathieu C. Tamby[3] and Luc Mouthon[2]. [1]INSERM 1016, Cochin Institute, Paris Descartes University, Paris, France, [2]INSERM 1016, Cochin Institute, Paris Descartes University, Paris, France, [3]INSERM 1016, Cochin Institute, Paris, France, [4]Proteomics Platform of Paris Descartes, Paris, France

Rationale: Progress on the isolation and culture of various endothelial cells (EC) has allowed comparison of their biochemical and physiologic properties. However, very few studies compared the proteomes of EC from different sources.

Objective: To compare proteomes of macro-vascular and micro-vascular EC.

Methods: Proteomes of human umbilical vein EC (HUVEC) and 2 sources of micro-vascular EC, human pulmonary (HMVEC-P) and dermal micro-vascular EC (HMVEC-D) from healthy Caucasian donors (4 in each group) were compared using two-dimension differential in gel electrophoresis (2D-DIGE) at pH ranges of 3–11 and 4–7 and mass spectrometry.

Results: Among the 2167+/−50 protein spots detected in pH 4–7 gels, 100 were differentially expressed between HUVEC and micro-vascular EC with a ratio ≥ 2 and a T-test ≤ 0.01. Sixty-three proteins were identified including fatty acid binding protein 4 and retinal dehydrogenase 1 that were over-expressed in micro-vascular EC at 235.7 and 5.8 average ratio, respectively. Ingenuity software analysis interestingly showed that numerous proteins over-expressed in micro-vascular EC are implicated in the retinoic acid pathway. Sixteen protein spots were differentially expressed between HMVEC-D and HMVEC-P with a ratio ≥ 2 and a T-test ≤ 0.01 in pH 4–7 gels and 9 were identified. In pH 3–11 gels, 41 protein spots were differentially expressed between HUVEC and HMVEC-D and HMVEC-P with a ratio ≥ 2 and for a T-test ≤ 0.01. Among these protein spots, 33 were identified. Four protein spots were differentially expressed between HMVEC-D and HMVEC-P with an average ratio ≥ 2 and for a T-test ≤ 0.01 and were identified, corresponding to cytoskeleton proteins or enzymes implicated in glycolysis.

Conclusion: Major differences were observed between proteomes of macro-vascular and micro-vascular EC. Some of the differentially expressed proteins might be of great importance in the homeostasis and pathophysiology of EC.

mtDNA Haplogroups Define Two Phenotypes of Osteoarthritis (OA). Ignacio Rego-Pérez[4], Mercedes Fernández-Moreno[5], M. Deberg[1], Sonia Pértega[3], Carlos Fernández-López[5], Natividad Oreiro[5], Manuel Acasuso[2], Victoria Bonome-González[2], Y. Henrotin[1] and Francisco J. Blanco[5]. [1]Bone and Cartilage Res. Unit. Univ. of Liege, Liege, Belgium, [2]Centro de Salud Matogrande - SERGAS, A Coruña, Spain, [3]Epidemiology Unit. INIBIC-Complejo Hosp. Univ. A Coruna, A Coruna, Spain, [4]Osteoarticular and Aging Res. Lab. Rheumatology Div, INIBIC-Complejo Hosp, Univ. A Coruña, Coruña, Spain, [5]Osteoarticular and Aging Res. Lab. Rheumatology Div, INIBIC-Complejo Hosp, Univ. A Coruña, A Coruña, Spain

Background: Recent findings evidence that mitochondria mediate in the pathogenesis of the osteoarthritis (OA). Biomarkers are a promising tool to detect patients with OA preferably in an early stage of the disease. In this work we aim to assess a mitochondria-related phenotype in patients with OA.

Methods: We analyzed the determinations of serum levels of 12 OA-related biomarkers: MMP-1, MMP-3, MMP-13, MPO, Coll2-1 Coll2-1NO_2, C2C, CPII, hyaluronic acid, YKL-40, COMP and cathepsin K, in 48 OA patients and 52 healthy controls carrying the haplogroups H and J, to perform logistic regression models and receiver operating characteristic (ROC) curves that permit us to predict diagnosis of OA. This models also included clinical variables such as gender, age and smoking status.

Results: The MMP-13 was the only biomarker significantly increased in OA patients, when compared with healthy controls, in both mtDNA haplogroups H and J ($p<0.001$). Type II collagen biomarkers Coll2-1, Coll2-1NO_2, Coll2 ratio, C2C, CPII and C2C:CPII ratio were significantly increased in OA patients that carry the mtDNA haplogroup H when compared with OA carriers of the mtDNA haplogroup J ($p<0.01$ in all cases). The logistic regression model for diagnosis for carriers of the mtDNA haplogroup H showed that those biomarkers significantly associated with OA were hyaluronic acid and C2C:CPII; the area under the curve (AUC) of the ROC curve for this model was 0.926 (95% CI=0.857–0.995) and the optimal probability cutoff for discriminate between OA and healthy controls was 0.269, with a sensitivity of 96%, a specificity of 78%, and a positive likelihood ratio of 4.3. For carriers of the mtDNA haplogroup J, the logistic regresion model for diagnosis showed that those biomarkers significantly associated with OA were MMP-13, MMP-3 and C2C; the AUC for this model was 0.880 (95% CI=0.782–0.978), and the optimal probability cutoff for discriminate between OA patients and healthy controls was 0.271, with a sensitivity of 96%, a specificity of 68%, and a positive likelihood ratio of 3.

Conclusions: MMP-13 appears to be a good candidate biomarker for diagnosing OA. Some of the OA-related biomarkers clearly show a different profile depending on the mtDNA haplogroup. This permitted us to perform two models of haplogroup-based diagnoses of OA.

Neurotransmitter Receptor Gene Polymorphisms Are Associated with Widespread Pain: Findings from the First Genome-Wide Association Study of Musculoskeletal Pain. Kate L. Holliday[3], Tuhina Neogi[2], David Felson[2], Ke Wang[1], Wendy Thomson[4] and John McBeth[4]. [1]Boston University School of Public Health, [2]Boston University School of Medicine, [3]University of Manchester, Manchester, United Kingdom, [4]University of Manchester

Background: Musculoskeletal pain disorders are prevalent with 10% of the general population reporting widespread pain. Heritability estimates for widespread pain are around 50% although the susceptibility loci have yet to be identified. The purpose of this study was to identify susceptibility loci by conducting the first genome-wide association study (GWAS) of widespread pain.

Methods: As part of the Framingham SHARe project, subjects from 3 generations were genotyped using Affymetrix 500k and 50k gene-focused SNP chips. Genotypes were called using the BRLMM algorithm. Samples were excluded for low call rate (<95%), excess heterozygosity and mendelian errors. SNPs were excluded for deviation from HWE ($p<10^{-6}$), low call rate (<97%), MAF<0.01 and mendelian errors (>100). Whole genome imputation was carried out using HapMap CEU data and MACH v1.0.15. Data on musculoskeletal pain was available for a subset of these subjects (n=3850) from 2 generations. The reporting of painful regions on a homunculus was used to classify cases with widespread pain (reporting pain in contra-lateral body quadrants above and below the waist and in the axial skeleton) and controls (reporting no pain). Generalised estimating equation regression analysis was used to perform a case-control GWAS analysis under an additive genetic model on autosomal SNPs with a MAF>0.03, while accounting for relatedness between subjects and using genomic control to adjust for population stratification in R.

Results: Imputation was conducted on 378,163 SNPs meeting quality control criteria providing 2,321,937 SNPs for analysis in 572 cases and 1587 controls. The genomic inflation factor was 1.02. Using a p-value cut off of 1×10^{-5}, we identified 52 SNPs in association with widespread pain which comprise 8 individual loci, many of which are strong candidate loci for susceptibility to widespread pain. In particular, an intronic SNP in the neurotransmitter receptor gene GABA B receptor 2 (*GABBR2*) was associated with an increased risk of having widespread pain (OR=1.37 (1.24, 1.51) $p=6.7 \times 10^{-6}$). A SNP 100 Kb downstream of another neurotransmitter receptor, glutamate receptor 2 (*GRIA2*), was also associated with an increased risk of having widespread pain (OR=1.54 (1.35, 1.73) $p=8.96 \times 10^{-6}$).

Conclusion: This study, the first GWAS of widespread pain, implicates a number of biologically relevant loci in neurotransmitter genes that are directly linked to pain pathways. Validation of these findings is now required in independent cohorts to ascertain the true impact of these loci on widespread pain susceptibility and is currently underway.

Pathogenesis of Idiopathic Recurrent Pericarditis and Role of the *TNFRSF1A* Gene Mutations. Luca Cantarini, Orso Maria Lucherini, Maria Giuseppina Brizi and Mauro Galeazzi. Unit of Rheumatology, University of Siena, Siena, Italy

Background: Recurrences develop in up to 20–50% of patients with acute pericarditis. Although many causes of pericarditis are well known, the etiology remains obscure in about 85% patients and it is therefore labelled as idiopathic. Recurrent pericarditis is common in familial Mediterranean fever (FMF), due to mutations in the *MEFV* gene, and tumor necrosis factor receptor-associated periodic syndrome (TRAPS), due to mutations in the *TNFRSF1A* gene, but it rarely occurs alone. Colchicine is the standard treatment for FMF, while patients with TRAPS do not respond to colchicine therapy. Basing on its efficacy in preventing polyserositis in FMF, colchicine has been also proposed for the treatment of recurrent pericarditis and demonstrated to decrease the recurrence rate.

Objective: Our aim was to investigate the possible involvement of *TNFRSF1A* mutations in a group of patients with idiopathic recurrent pericarditis who were refractory to colchicine treatment.

Methods: 102 patients characterized by a poor response to colchicine were enrolled. Mutations of *TNFRSF1A* were searched for by amplifying, using polymerase chain reaction (PCR), genomic DNA, and direct sequencing.

Results: *TNFRSF1A* mutations were found in 7 of 92 patients. Two of the 7 patients had a family history of recurrent pericarditis (they were siblings). One of the 7 patients carried a novel heterozygous deletion (ΔY103-R104), 5 patients carried a heterozygous low-penetrance R92Q mutation and 1 patient carried a rare V95M mutation.

Conclusions: Our data suggest that TRAPS should be kept in mind in the differential diagnosis of recurrent pericarditis and mutation analysis of the *TNFRSF1A* gene should be considered in patients of Mediterranean origin. A poor response to colchicine treatment, and a positive family history, recently reported in up to 10% of recurrent pericarditis patients, may indicate the need to investigate mutations in the TNFRSF1A gene in recurrent pericarditis patients. However, to date, further studies are needed in order to better determine additional criteria for identifying the few subjects who might carry such mutations.

Radiographic Kellgren-Lawrence (KL) Grade 1 Is Genetically Distinct from KL 0: Implications for Genetic Studies of Knee Osteoarthritis (OA). Venkateswarlu Kondragunta[3], Xiaodong Wu[3], Jordan B. Renner[2], Gordon W. Duff[4], Kenneth S. Kornman[3] and Joanne M. Jordan[1]. [1]Chapel Hill, NC, [2]Department of Radiology and Thurston Arthritis Research Center, University of North Carolina at Chapel Hill, [3]Interleukin Genetics, Inc., [4]School of Medicine, University of Sheffield

Purpose: The Kellgren-Lawrence (KL) radiographic grading system is widely used in studies of osteoarthritis (OA). Although KL grades 1 and 0 together often form the control group in epidemiologic studies, Hart and Spector (2003) showed different knee OA progression rates for KL1 and KL0, suggesting distinct phenotypes. We explored whether KL grades 1 and 0 are genetically distinct by comparing frequencies of genetic markers between subjects with the two KL grades.

Method: Caucasian participants (N=1,173; 38% men; mean age=60 years) in the Johnston County OA Project with 4–11 year follow-up data were examined. Anterior-posterior standing knee radiographs were obtained with footmat positioning at both time points and read by a single musculoskeletal radiologist for K-L grades (0–4). Genotypes of 37 single nucleotide polymorphisms (SNPs) in 16 genes reported to be associated with OA were determined using the single-nucleotide primer extension method. Incidence of OA was defined by an increase in KL grade at follow up, in those with KL 0 bilaterally at baseline. Differences in genotype or allele frequencies between KL1 and KL0 and between subjects with incident OA and those without incident OA were determined by Chi-Square test or logistic regression with adjustment for age, gender and body mass index (BMI). Since all SNPs had been previously associated with OA, we present the data both with (permutation test) and without correction for multiple comparisons. An association was considered positive if the adjusted p-value was <0.05 for the risk allele, genotype or haplotype.

Results: Compared to subjects with KL0 (n=407), those with KL1 (n=383) were older (65.4 yrs vs. 63.0 yrs) and heavier (BMI 29.2 kg/m^2 vs. 28.4). Frequencies of alleles or genotypes in 4 genes, including IL1RN, IL6, ABCG2, and DVWA, were significantly different between KL0 and KL1 subjects (table 1). After adjusting for multiple comparisons, genotype T/T of IL1RN rs579543 was still significantly associated with KL1. Among these genetic markers, four variants in 2 genes, IL1RN (rs419598, p=0.039; rs579543, p=0.008; and rs9005, p=0.03) and IL6 (rs1800797, p=0.014), were also associated with incidence of radiographic knee OA. In addition, compared to KL0 subjects, KL1 subjects were more likely to progress to KL>=2 (33.5% vs 8.5%) as previously reported. No population genetic substructure was detected in this Caucasian population.

Table 1. Distribution of genetic markers between KL0 and KL1.

Gene	SNP	Allele/ genotype	KL-1	KL-0	P
ABCG2	rs2231142	A/*	0.17	0.23	0.043
DVWA	rs11718863	T	0.15	0.19	0.026
IL 1 RN	rs419598	C/C	0.08	0.04	0.022
IL 1 RN	rs579543	T/T	0.09	0.04	0.008
IL 1 RN	rs9005	A/A	0.10	0.06	0.042
IL6	rs1800797	A	0.47	0.40	0.017

Conclusion: This study provides genetic evidence to support differentiating KL1 and KL0 subjects in radiographic knee OA studies.

Salivary Proteomic Profile in Behçet's Disease. Rosaria Talarico, Chiara Baldini, Laura Giusti, Ylenia Da Valle, Camillo Giacomelli, Elena Donadio, Francesca Sernissi, Anna d'Ascanio, Laura Bazzichi, Antonio Lucacchini and Stefano Bombardieri. Rheumatology Unit, Department of Internal Medicine, University of Pisa, Pisa, Italy

Background: Behcet's disease (BD) is a chronic, systemic vasculitis characterized by recurrent oral and genital ulcers, skin lesions and ocular involvement. In the recent years proteomics has provided new insights for biomarker research in many autoimmune diseases. We have previously described some qualitative and quantitative differences in the composition of saliva in a limited number of BD patients with respect to healthy controls. No data are available on differences in the salivary proteomic profile between active and inactive subsets of disease.

Aim: Following our preliminary results, the primary aim of this study was to analyse the expression of proteomic biomarkers in a larger group of BD patients. The secondary aim was to search for biomarkers of disease activity in BD, by comparing the proteomic profile of active and inactive BD patients.

Methods: Twenty-seven BD consecutive patients (Mean age at disease onset 25±4 years; male/female:19/8; mean disease duration: 11±5 yrs) all fulfilling the ISG criteria for BD and the same number of healthy controls with similar demographic characteristics were enrolled in this study. Clinical manifestations of BD patients at the time of sample collection were recorded. Saliva samples were collected under standard conditions. Aliquots from the individual salivary samples were pooled into various groups for analyses by 2-dimensional-electrophoresis (2DE). The first set of 2DE gels compared a group of pooled healthy volunteers with a group containing all BD samples. The second analysis was performed comparing the group of active BD patients with inactive disease.

Results: Out of 27 BD patients, 11 were active (ocular involvement: 5; CNS involvement: 2; mucocutaneous: 4) and 16 were under remission. The analysis of the obtained protein profiles allowed us to observe significant differences in the expression of 37 spots; eight out of 37 collapsed into 5 separate proteins, and specifically: lipocalin, calgranulin B, prolactin inhibitor precursor (PIP), carbonate anhydrase VI, Cystatine SN precursor. In addition 29 differently expressed spots were cut out for digestion with trypsin and addressed to the MALDI-TOF-MS in order to be identify. When BD active patients were compared to those inactive, 30 spots significantly different were observed; in particular, a >2 fold decrease of PIP, PLUNC 2 and Cystatine SN precursor and a >2 fold increase of calgranulin B differentiated the profile of active from inactive BD patients. Again 10 non identified spots were addressed to the MALDI-TOF-MS to complete the identification.

Conclusions: The results of this study allow us to identify a number of proteins differently expressed in BD with respect to healthy subjects. Some of them, particularly Calgranulin B, appeared to be able not only to distinguish BD patients from controls, but also to differentiate active from inactive BD patients. This seems to be of particular interest since Calgranulin B is a S100 calcium-binding protein known to promote phagocyte migration and infiltration of granulocytes and might be implicated in the pathogenetic background of BD.

Study of the Chondrogenic Differentiation Process by Metabolic Labeling of Mesenchymal Stem Cells. Beatriz Rocha[1], Valentina Calamia[2], Patricia Fernández-Puente[2], Jesús Mateos[2], Cristina Ruiz-Romero[2] and Francisco J. Blanco[2]. [1]Osteoarticular and Aging Research Lab, Proteomics Unit, Nodo Asociado de ProteoRed. INIBIC-Complejo Hospitalario Universitario A Coruña, A Coruña, Coruña, Spain, [2]Osteoarticular and Aging Research Lab, Proteomics Unit, Nodo Asociado de ProteoRed. INIBIC-Complejo Hospitalario Universitario A Coruña, A Coruña, Spain

Background: Osteoarthritis (OA) is the most common degenerative joint disease, mainly characterized by articular cartilage degradation. Today, there is a growing interest in treating this articular failure with mesenchymal stem cells (MSCs), which are thought to be capable of differentiating into chondrocytes and repair injured joints.

The aim of this study is to standardize the stable isotope labeling by amino acids in cell culture technique (SILAC) with human bone marrow MSCs, and to apply this quantitative proteomic approach for the identification of those molecular mechanisms that participate in chondrogenesis.

Methods: Bone marrow cells were plated in DMEM medium for SILAC, lacking lysine and arginine. Light media was supplemented with standard amino acids, while isotope-labelled L-lys and L-arg were employed in the heavy media. Then, chondrogenic differentiation was induced by micromass culture under control conditions (DMEM), or with two different chondrogenic media: a home-made (HMCM) medium containing 10 ng/mL TGF-β3 and other factors, and a commercial medium from Pierce Biotechnology (CCM). Evaluation of a proper chondrogenesis was performed by histological and genetic means on the micromasses at 7 and 14 days of culture, in order to analyze the expression of chondrocyte phenotype such as SOX9, type II collagen and proteoglycans. For the proteomic analyses, heavy (H) and light (L) samples were mixed 1:1, and separation and analysis of the resulting mixtures was performed by nanoscale LC-MALDI-MS/MS. The identification and quantification of proteins was carried out with Protein Pilot 2.0 software.

Results: To determine the feasibility of this approach and the optimal time points of study during the differentiation process, we first performed a pilot study with metabolic labelling of undifferentiated cells and on various days of differentiation. We assessed the chondrogenic capacity of these cells when cultured in SILAC media, and evaluated their differentiation to chondrocytes under the two diverse chondrogenic media and the control medium.

Finally, we were able to identify 190 MSCs intracellular proteins. Most of these proteins could be quantified, and we found 20 that were altered during the differentiation process with statistical significance ($p<0.05$). Among them, a relevant increase in several histones was detected using both media, pointing out their role in the chromatin remodelling processes that are driven by the chondrogenic factors. Moreover, glycolytic enzymes decreased at 14 days of chondrogenesis only with the commercial medium, suggesting a decrease in the activity of this pathway. We also found that fibronectin levels decline during the induction of chondrogenesis with the commercial medium, confirming previously published results.

Conclusions: We have standardized the SILAC technique with human bone marrow MSCs in culture for the study of their differentiation to chondrocytes (chondrogenesis). Most of the differences that we have found are specific of the chondrogenic media employed. The analysis of those proteins secreted from the micromasses (secretomes) will also be essential for the evaluation of changes in ECM synthesis.

The *FAAH* Gene Is Involved in Risk of Symptomatic Osteoarthritis of the Knee and in Pain in Osteoarthritis. Ana M. Valdes[1], Anne-Marie Malfait[3], Sally Doherty[5], Rosalina Das[4], Margaret Wheeler[5], Deborah Hart[2], Tim D. Spector[2], Cyrus Cooper[6], Michael Doherty[5] and Nigel K. Arden[6]. [1]King's College London, London, United Kingdom, [2]King's College London, [3]Rush University Medical Center, Chicago, IL, [4]Rush University Medical Center, [5]University of Nottingham, United Kingdom, [6]University of Southampton - University of Oxford, United Kingdom

Objective: Osteoarthritis (OA) is the most common large joint (hip or knee) pathology in older people and the main cause for large joint pain and disability in this age-group. FAAH (fatty acid amide hydrolase) is an enzyme that degrades the endocannabinoid anandamide. In animal models genetic or pharmacological inactivation of FAAH produces analgesic, anti-inflammatory, anxiolytic, and antidepressant phenotypes and human genetic variants have been associated with increased cold perception. Our aim was to assess if a genetic variant in the *FAAH* gene previously implicated in peripheral pain sensitivity is involved in risk for large joint OA.

Methods and Subjects: The rs4141964 SNP in the *FAAH* gene was typed in 1847 knee OA cases, 1199 hip OA cases and 2036 controls from three independent UK cohorts (Nottingham, Chingford and Hertfordshire). Expression of the *faah* gene was tested in the dorsal root ganglia (DRG) of naive and medial meniscus destabilized (DMM) C57BL/6 mice. DMM

operated mice were tested for mechanical allodynia at 4, 8, and 16 weeks after surgery, using von Frey fibers. At each of these time points, the DRG L2-L5 were harvested and mRNA was extracted for RT-PCR analysis.

Results: The minor allele (A) at rs4141964 –previously implicated in higher pain sensitivity - was found to be consistently increased among OA cases compared to controls in all three cohorts. A fixed effects meta-analysis for knee OA yielded OR= 1.17 95% CI 1.05 –1.29; p=0.003 (Figure 1) and OR= 1.15 95% CI 1.01 –1.30; p=0.034 for hip OA. No significant between-study heterogeneity was observed (I^2=0%).

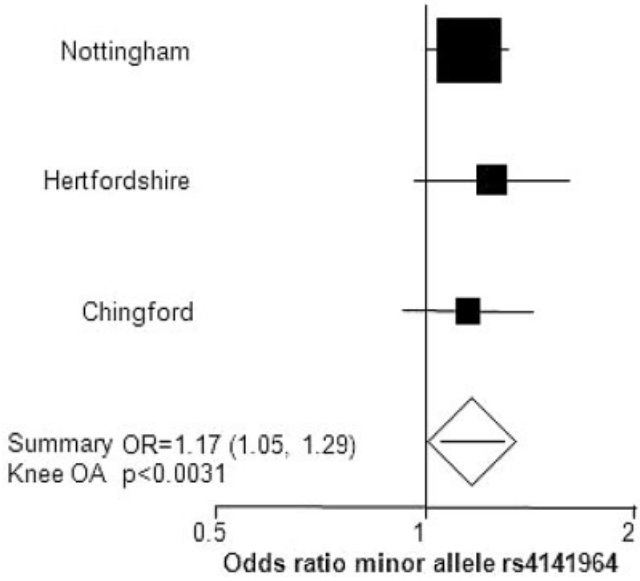

Figure 1. Genetic association between the *FAAH* polymorphism rs4141964 and knee OA in three UK cohorts. Forest plot showing the study specific estimates and the fixed effects meta-analysis estimate.

In the Hertfordshire cohort study the AA genotype was increased among OA patients with knee pain compared with those with asymptomatic OA (p<0.06). In the murine DMM model, progressive mechanical allodynia was apparent in the operated hind limb, 4–8 weeks post surgery, and then resolved 8–16 weeks after surgery. FAAH mRNA levels in the innervating DRG correlated with the mechanical allodynia, and FAAH mRNA was over-expressed relative to naive mice at 8 weeks, but not at 4 or 16 weeks post-surgery.

Conclusions: The *FAAH* gene appears to be implicated in large joint OA and OA pain.

The Profile of miRNA Expression during the Differentiation of Murine Osteoclast. Inhye E. Ahn[1], Ji Hyeon Ju[2] and Jin Sil Park[3]. [1]Department of Internal Medicine, The Methodist Hospital, Houston, TX, [2]Division of Rheumatology, Department of Internal Medicine, Catholic University of Korea, Seoul, Korea, Republic of, [3]Rheumatology Research Center, Catholic University of Korea, Seoul, Korea, Republic of

Objectives: By identifying chronological patterns of miRNA expression during the differentiation of murine osteoclast, this study aimed to reveal clusters of non-coding genes involved in the regulation of bone metabolism.

Methods: Murine bone marrow-derived monocytes were stimulated with M-CSF only or with the combination of RANKL. Cultured cells were harvested at the designated time points critical for osteoclastogenesis, which ranged from the 24-hour after the monocyte culture, at the point of precursor cells (day 3), when cell-to-cell fusion occurred (day 5), and when mature osteoclasts were formed (day 7). Isolated miRNA underwent microarray analysis. Types and patterns of miRNA expression were compared between two stimulation groups and also between chronological points within each stimulation group.

Results: At the point of cell fusion, six miRNAs were identified to be expressed significantly higher in monocytes stimulated with both M-CSF and RANKL than in those with M-CSF only (p<0.05). This number of differentially expressed genes between two stimulation groups increased to 35 as osteoclast matured. Patterns of miRNA expression in M-CSF plus RANKL-stimulated monocytes were categorized into nine clusters by K-mean clustering analysis.

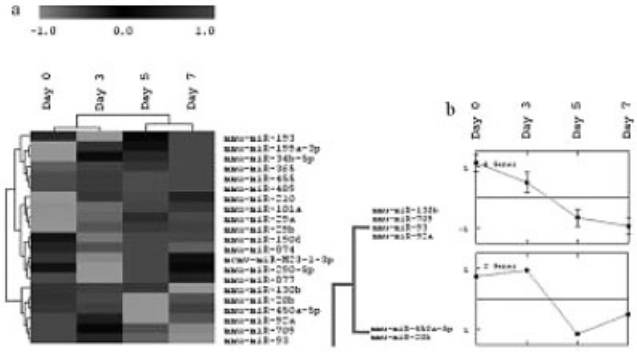

Figure 1. Patterns of gene expression patterns during the differentiation of osteoclast stimulated with M-CSF plus RANKL. Critical time points for osteoclastogenesis were designated for analysis, which ranged from the 24-hour after the monocyte culture (day 0), at the point of precursor cells (day 3), when cell-to-cell fusion occurred (day 5), and when mature osteoclasts were formed (day 7).

In all clusters, the most distinctive change of differential gene expression was observed during cell fusion. Two clusters showed declining patterns throughout the differentiation which included miR-20b, 92a, 93, 130b, 450a and 709.

Conclusion: The number of differentially expressed genes in murine osteoclastogenesis increased as cell maturation progressed. The most critical time point with marked changes in miRNA expression was when cell fusion occurred.

Towards Allele-Specific Dynamic Proteomics: Measuring Protein Synthesis and Turnover Using Heavy Water Labelling and Peptide Mass Spectrometry. Michael J. Deery[1], Alessandra De Riva[2], Claudia Prevosto[2], Sarah McDonald[2] and Robert Busch[2]. [1]Centre for Proteomics, University of Cambridge, [2]Dept of Medicine, University of Cambridge

Background: Genome-wide association studies have uncovered structural and promoter polymorphisms associated with autoimmune disease and confirmed long-established associations with major histocompatibility complex (MHC) alleles. The underlying mechanisms often remain unclear; allelic differences in protein synthesis, folding, maturation, and turnover are of interest. Numerous techniques exist for measuring protein synthesis and turnover, but they suffer drawbacks when studying allelic effects in biologically relevant systems. Here, we have combined stable isotope labelling using heavy water (^2H_2O) with peptide mass spectrometry to devise a biosynthetic labelling approach suitable for allele-specific dynamic proteomics.

Methods: MHC proteins were studied as a model system with disease-relevant isotypic and allelic variation. Antigen-presenting cells (APCs), such as B-lymphoblastoid cell lines, murine splenocytes, or short-term cultures derived from peripheral blood, were subjected to continuous labelling with ^2H_2O. MHC proteins were isolated by immunoprecipitation and SDS-PAGE, fragmented with trypsin, and peptides identified using LC/MS/MS. Selected peptides were analysed for ^2H incorporation by LC/MS. Labelling patterns were interpreted using mass isotopomer distribution analysis and used to calculate fractional protein synthesis as a function of labelling time.

Results: Analysis of tryptic peptides from murine or human MHC class I or class II proteins enabled protein identification and measurement of biosynthetic label incorporation, using small samples of a variety of APC types. Measured peptide mass isotopomer distributions were consistent with ^2H label incorporation from ^2H_2O at a fixed number of effective labelling sites and allowed calculation of fractional synthesis rates. Protein turnover was

quantifiable after accounting for cell growth or turnover and changes in protein levels. Estimates of fractional protein synthesis from analysis of different peptide mass isotopomers, and from different peptides derived from the same protein, were internally consistent and congruent with literature estimates based on other methods. Well-labelled peptides were identified that distinguished selected MHC class I and class II isotypes or alleles, enabling allele-specific measurements of protein synthesis and turnover. Analysis of multiple peptides indicated that multiple amino acids contributed to label incorporation from ^2H_2O; algorithms for predicting labelling patterns from sequence are being refined.

Conclusions: The safety, simplicity, and versatility of ^2H_2O labelling combine with the sensitivity, precision, and specificity of LC/MS to enable allele-specific measurements of MHC protein synthesis and turnover. The approach is readily extended to other proteins and can be applied to primary cells and *in vivo*. These capabilities will aid studies of protein dynamics as a link between genetic polymorphisms and mechanisms of pathogenesis. The ability of the technique to accommodate complex samples suggests potential for proteome-wide studies of protein dynamics.

β2 Integrins Control the Pro-Inflammatory Phenotype of Type 1 Macrophages and Dendritic Cells. Kim C. M. Santegoets[2], Mark H. Wenink[2], Richard Huijbens[2], Lenny van Bon[2], Alessandra Cambi[2], Piet L. Van Riel[3], Wim B. Van Den Berg[1] and Timothy R. D. J. Radstake[2]. [1]Radboud Univ Nijmegen Med Cntr, Nijmegen, The Netherlands, [2]Radboud University Nijmegen Medical Center, [3]University Hosp Nijmegen, Nijmegen, The Netherlands

Background: Initially in inflammation pro-inflammatory macrophages are necessary to initiate a full inflammatory response thereby facilitating the control of a possible threat (e.g. tissue damage or pathogens). However, at a certain point this pro-inflammatory program should switch off to prevent chronic inflammation. We hypothesized that the accumulation of monocytes at a site of inflammation induces a shift from an initially pro-inflammatory macrophage phenotype to a phenotype aimed at suppressing the initiated immune response.

Methods: To investigate this we cultured monocytes with GM-CSF or M-CSF into pro-inflammatory type 1 or anti-inflammatory type 2 macrophages, respectively, in different cell densities. After differentiation the macrophages were harvested and replated in a fixed concentration before stimulation with single TLR ligands or heat-killed M. tuberculosis. Dendritic cells (DCs) were also cultured in increasing cell densities to determine the effect on T cell proliferation and differentiation. FACS analysis was performed on the expression of a wide range of markers including TLRs. Quantitative-PCR was used to determine the expression of TLR signaling inhibitors. Furthermore, various integrins were selectively blocked during culture with blocking antibodies.

Results: Differentiation of type 1 macrophages in increasing cell densities dramatically lowered their TNFa, IL-1β and IL-6 release and increased the production of IL-10 and VEGF upon TLR stimulation with single ligands or M. tuberculosis. Increasing cell density had no effect on the cytokine production by type 2 macrophages. The shift towards a more anti-inflammatory type 1 macrophage depended on cell-cell contact via β2 integrins and was due to a soluble factor. TGFβ, IFNβ and IL-6 were excluded as playing roles in this phenotypical shift. However, TGFβ was capable of reversing the anti-inflammatory phenotype induced by cell-cell contact through β2 integrins, resulting in highly inflammatory type 1 macrophages. The pro-inflammatory phenotype of DCs was also restricted by cell-cell contact leading to a high production of IL-10 while the release of IL-12p70 was potently reduced. Correspondingly, DCs cultured in low density were strong inducers of T cell differentiation into IFNγ producing cells upon TLR7/8 stimulation while this capability was potently suppressed when DCs were cultured in high cellular density.

Conclusions: These data show for the first time that cell-cell communication via β2 integrins on type 1 macrophages and DCs alters their differentiation, suppressing their pro-inflammatory phenotype. In many chronic inflammatory diseases high levels of TGFβ are present. This appears to prevent the shift towards more anti-inflammatory macrophages. Concluding, β2 integrin activation during macrophage differentiation is likely to be crucial in the suppression of ongoing immune responses thereby preventing chronic inflammation and possibly tolerance breakthrough, which might be impaired by the excessive presence of TGFβ.

"Alarmins" S100A8 and A9 Are Expressed in Synovium of Early OA Patients and Regulate Synovial Activation and Joint Destruction during Experimental Osteoarthritis. Peter van Lent[1], Arjen Blom[1], Rik Schelbergen[1], Annet Sloetjes[1], Thomas Vogl[2], Johannes Roth[2] and Wim van den Berg[1]. [1]Dep of Rheumatology University Hospital Nijmegen Medical Centre, Nijmegen, Gelderland, The Netherlands, [2]Institute of Immunology Muenster, Muenster, Germany

Purpose: Prominent proteins released by activated macrophages are the "alarmins" S100 A8 and A9. There is increasing belief that synovial tissue activation contributes to OA cartilage pathology The aim is to evaluate the presence of S100A8/S100A9 in synovia of patients with early OA and to explore active involvement of S100A8/A9 in cartilage destruction in experimental osteoarthritis models that differ in degree of synovial activation.

Methods: Arthroscopic biopsies were taken from 30 early OA patients. mRNA levels (RT-PCR) and immunolocalisation was determined and related to joint destruction (Kellgren Lawrence score). Experimental OA was either induced by transection of the medial anterior meniscotibial ligament which leads to destabilisation of the medial meniscus (DMM) or by injection of collagenase into murine knee joints, which causes overall ligament damage and broad instability. Collagenase-induced-osteoarthritis involves chronic synovial activation in contrast to DMM. Synovial expression of S100A8 and S100A9 was measured using immunolocalisation. Both models were induced in $S100A9^{-/-}$ deficient mice (myeloid cells also lack S100A8 at the protein level). Primary chondrocytes were stimulated with S100A8 and A9 and MMP levels were measured using RT-PCR

Results: mRNA and protein levels of S100A8 and A9 were significantly higher in synovial biopsies of early OA patients when compared to control joints. S100A8 and A9 was predominantly found in synovial macrophages. Of great interest, high levels correlated to increased joint destruction (KL score). The function of S100A8 and S100A9 was further studied in experimental OA models. Kinetic studies show that in surgically induced DMM model, S100A8 and A9 was marginally expressed within the synovium, only evident at day 7 after induction and consistent with limited synovial thickening. The degree of OA cartilage pathology in the knee joint was similar in $S100A9^{-/-}$ and WT mice at day 42 after induction of DMM.

In contrast, during the course of collagenase-induced osteoarthritis, S100A8 and S100A9 was strongly upregulated in synovium at day 7 and remained high at days 14, 28 and 42. Expression of these proteins nicely correlated with thickening of the synovial lining layer comprising activated macrophages. When collagenase-induced-osteoarthritis was elicited in $S100A9^{-/-}$ mice, significantly lower synovial activation was observed when compared to WT mice. Synovial activation was 62% lower at day 42. Cartilage destruction was significantly lower in all surfaces and ranged from a 45% reduction in the lateral tibia to 73% reduction in the medial femur. When primary mouse chondrocytes were stimulated with S100A8 or S100A9, a strong upregulation of particularly MMP-3 mRNA level was found indicating a direct role of S100A8/A9 in cartilage destruction.

Conclusions: Alarmins S100A8/S100A9 are expressed by macrophages in biopsies of early OA patients. S100A8/A9 play a crucial role in synovial activation and cartilage destruction in an osteoarthritis model that shows clear synovial involvement. S100A8/A9 expression in the synovium causes pathology probably by stimulating MMP-mediated damage in the cartilage matrix.

Altered T Cell Signaling in Systemic Lupus Erythematosus (SLE): A Role for FcγRIII and Immune Complexes (ICs). Anil Chauhan[1], John P. Atkinson[3] and Terry L. Moore[2]. [1]Saint Louis University, Saint Louis, MO, [2]St Louis University, St Louis, MO, [3]Washington University School of Medicine, St Louis, MO

Purpose: The presence of immune complexes (ICs) in systemic lupus erythematosus (SLE) has been documented. In addition, a role for altered T cell responses has been suggested. Previously, we have shown the activation of T cell receptor (TCR) in response ICs and sublytic dose of memebrnae attack complex (MAC). In this study, we wanted to explore the presence of low affinity FcγRIII that are responsible for ICs binding to human peripheral naive $CD4^+$ T cells and explore their downstream signaling partners.

Methods: We used Alexa Floour 488 labeled model ICs to develop a flow based assay to evaluate the presence of the Fc receptor (FcR) on $CD4^+$ human naïve T cells. Thereafter, we used antibodies specific to FcγRIIIA/B or FcγRIIIB to achieve a 50% inhibition of the labeled IC binding. Subsequently, using immunoprecipitates generated from T cells treated with ICs purified from SLE patients plasama and Western blotting we explored the presence of FcγRIII. Furthermore, we co-localized the FcγRIIIA/B, FcRγ-chain and phosphorylated Syk in human naïve $CD4^+$T cells using confocal microscopy. In the immunoprecipitates generated with anti-FcγRIII, we analyzed the phosphorylation of Syk in response to ICs. The phopshorylated Syk was co-localizated with FcγRIII with confocal microscopy. The presence of the IC binding FcγRIII was carried out from peripheral $CD4^+$ T cells from SLE patients by flow cytometry.

Results: Human peripheral naive $CD4^+$ T cells show binding to labeled ICs. We show a 27 to 29 kD protein that correspond to previously reported mass for FcγRIIIA/B in the $CD4^+$ T cells. A total of 5 to 10% peripheral $CD4^+$ T cells from SLE patients show binding to labeled model ICs. The antibodies against FcγRIIIB and FcγRIIIA/B inhibited binding of labeled ICs by 50%. Upon treatment with ICs, the cells show recruitment of FcRγ chain with FcγRIIIA/B. Treatment of cells with ICs and sublytic MAC resulted in phosphorylation and association of Syk with FcγRIIIA.

Conclusions: For the first time, we show the presence of low affinity FcγRIIIA/B on human $CD4^+$T cells. FcR play critical role in B cell responses and are critical in IC clearance. However, the presence of FcR on human T cell is controversial (Nature reviews,(8) 34,2008). Although, the presence of FcγRIIIA has been shown in NKT and γδ T cells, the FcγRIIIB is only known to be expressed by neutrophils and macrophages and is shown on basophils recently. Using an antibody specific for FcγRIIIB, we demonstrate inhibition of model IC binding in flow based assay. We further show upon treatment of these cells with ICs, the FcRγ is recruited to the FcγRIIIA receptor. This also resulted in phosphorylation and recruitment of Syk with FcγR. Altered Syk mediated T cell signaling in SLE T cells has been reported earlier. We show that ICs and sublytic MAC activates Syk in peripheral T cells. The naïve $CD4^+$ T cells also proliferate in response to IC and sublytic MAC. We have previously shown TCR activation and T cell differentiation in response to ICs and sublytic MAC. It is for the first time, we demonstrate a possible role for FcR in activation of T cells in response to ICs and MAC, a complex of late complement cascade. This study provides a link between ICs, complement, and adaptive immunity.

C5aR Is Expressed by Macrophages and Dendritic Cells in Close Proximity to T-Cells in Synovial Tissue from Patients with Rheumatoid Arthritis. Ditte Tornehave[1] and Lars Hornum[2]. [1]Histology, Biopharmaceuticals Research Unit, Novo Nordisk A/S, Måløv, Denmark, [2]Immunopharmacology, Biopharmaceuticals Research Unit, Novo Nordisk A/S, Måløv, Måløv, Denmark

Objective: The aims of the present study were to investigate the expression of the C5a receptor (C5aR) and to characterize the C5aR-positive cells in the synovium of rheumatoid arthritis (RA) patients.

Method: Immunohistochemical studies investigating the C5aR protein expression were performed on synovial biopsies from patients with RA (n=35), osteoarthritis (OA) (n=15) and normal synovial biopsies (n=5). Characterization of C5aR-positive cells was performed by double immunofluorescence staining on another set of synovial biopsies: RA (n=19), OA (n=27) and normal (n=5) with markers for neutrophils (myeloperoxidase, MPO), T cells (CD3), dendritic cells (DCs) (CD1a), and macrophages (CD68).

Results: Infiltrating C5aR-positive ($C5aR^+$) cells were demonstrated in synovial tissue from 28 out of 35 patients with RA, and from 11 out of 15 patients with OA whereas no $C5aR^+$ cells were present in normal synovium. The $C5aR^+$ infiltrating cells in the sublining layer of OA synovial tissue were observed only when lymphoid aggregates were present, and with less positive cells present compared to RA. In the synovial lining $C5aR^+$ cells were observed in 18 out of 35 and 10 out of 15 patients with RA and OA, respectively. Double immunostainings for C5aR and neutrophils, T-cells, DCs and macrophages showed profound infiltration of neutrophils into the synovium (in 60% of patients with RA and 25% with OA), and most of these were C5aR-negative (> 95%), whereas 90% of neutrophils located in the lumen of synovial blood vessels were $C5aR^+$. $CD3^+$ T cells did not express C5aR in synovial tissue from patients with RA or OA. C5aR and CD1a double-positive DCs were observed in 8 out of 19 RA and 8 out of 27 OA patients. More than 95% of the $CD1a^+$ DCs in these patients co-expressed C5aR. All $C5aR^+CD1a^+$ DCs were found intermingled in lymphoid aggregates in close proximity to $CD3^+$ T cells. In the synovial sublining tissue 11 out of 16 patients with RA and 10 out of 21 patients with OA contained up to 50% $C5aR^+$ and $CD68^+$ macrophages. The $C5aR^+CD68^+$ macrophages were interspersed in the synovial tissue and the majority intermingled in lymphoid aggregates. In addition, in 10 out of 16 patients with RA, 12 out of 20 OA and 3 out of 4 normal synovial biopsies all $C5aR^+$ cells in the synovial lining were $CD68^+$ macrophage-like synoviocytes.

Conclusion: An association between C5aR expression and rheumatoid arthritis was demonstrated based on the finding that $C5aR^+$ cells were present in 80% of patients with RA, whereas no $C5aR^+$ cells were present in normal synovium. $C5aR^+$ cells were also found in patients with OA, but less $C5aR^+$ cells were observed in the lymphoid aggregates compared to patients with RA. The majority of infiltrating $C5aR^+$ cells are $CD68^+$ macrophages and a minor part are $CD1a^+$ DCs, whereas very few of the extravascular neutrophils are $C5aR^+$. The majority of the $C5aR^+$ macrophages and DCs were intermingled in lymphoid aggregates in close proximity to $CD3^+$ T cells, and it can be speculated that C5a-activated macrophages and DCs are interacting with T cells in the sublining synovial tissue.

Cellular Immunity in Rheumatoid Arthritis Patients Not Responding to Synthetic DMARDs. Andra Balanescu[3], Ionela Victoria Neagoe[5], Florian Berghea[3], Carolina Negrei[2], Magda Parvu[1], Ruxandra Ionescu[4], Denisa Predeteanu[4], Violeta Bojinca[4], Vasile Preoteasa[6] and Gina Manda[6]. [1]Colentina Clinical Hospital, Bucharest, Romaia, [2]Department of Toxicology, University of Medicine and Pharmacy Carol Davila, Bucharest, Romania, [3]Research Center of Rheumatic Diseases, Sf. Maria Hospital, University of Medicine and Pharmacy Carol Davila, Bucharest, Romania, [4]Research Center of Rheumatic Diseases, Sf. Maria Hospital, University of Medicine and Pharmacy Carol Davila, Bucharest, Romania, [5]Victor Babes National Institute of Pathology, Bucharest, Romania, [6]Victor Babes National Institute of Pathology, Bucharest, Romania

Background: Rheumatoid arthritis (RA) is considered a T cell-driven disease, but there are consistent evidences that the final bone and cartilage destruction is confined to the monocytic lineage.

Purpose: The aim of our study was to explore cellular immune markers in RA patients (pts) not responding to therapy with synthetic DMARDs, focusing on cellular immune response.

Methods: The study included 35 RA pts diagnosed according to the 1987 revised ACR criteria (age: 46.4±24.3 years; disease duration: 48.7±38.6 months; 86.6% were women). All RA pts had an erosive, seropositive (rheumatoid factor and/or anti-citrullinated peptide antibodies) and active disease (DAS28: 5.9±2.0), despite treatment with a synthetic DMARDs (Methotrexate or Leflunomide) for at least 6 months at standard doses. Clinical response was evaluated according to EULAR response criteria. None of them received corticosteroids or biological agents in the last 6 months. Peripheral blood samples were collected for assessing the cellular immune status: the phenotype of lymphocytes, their early activation capacity (CD69) when stimulated *ex vivo* with CD2, phytohemagglutinin (PHA), pokeweed mitogen (PWM) or IL-2, and the oxidative activity developed *ex vivo* by monocytes and granulocytes when challenged with *E. coli* or phorbol myristate acetate (PMA).

Results: RA pts exhibited high peripheral monocyte counts. Monocytes proved to be activated as a high percentage of cells developed constitutive oxidative burst and had an increased capacity to respond *ex vivo* to *E. coli* or PMA. Such abnormal monocytes released constitutively proinflammatory cytokines (IL-6, IL-8, TNFα, GM-CSF). Granulocytes had a less obvious abnormal oxidative activity. Peripheral lymphocytes were in the normal range (as counts and percentage of CD4+ or CD8+ lymphocytes). T lymphocytes proved to be activated as they expressed the early activation marker CD69. When challenged *ex vivo*, CD4+ lymphocytes, but not CD8+ ones, were less

able than normal cells to get activated. Similarly, NK cells were activated *in vivo*, but had a lower response to IL-2 *ex vivo*.

Conclusions: Our study emphasized that RA pts not responding to therapy with synthetic DMARDs presented functional disturbances at the level of peripheral CD4+ lymphocytes, monocytes and NK cells. These immune parameters could represent markers for monitoring the impact of therapy and the disease course.

Comprehensive Flow Cytometric Profiling of Peripheral Blood Dendritic Cells in Rheumatoid and Psoriatic Arthritis Patients. James Kobie[6], Ben Panepento[6], Jyh-Chiang E. Wang[6], Grace Chiu[6], Darren Tabechian[8], Allen P. Anandarajah[2], Richard J. Looney[3], Ralf G. Thiele[5], Jennifer H. Anolik[1], Ignacio Sanz[4], Sally Quataert[6], Alex Rosenberg[6] and Christopher T. Ritchlin[7]. [1]University of Rochester, Rochester, NY, [2]Univ of Rochester Med Ctr, Rochester, NY, [3]University of Rochester, Rochester, NY, [4]University of Rochester, Rochester, NY, [5]University of Rochester, Rochester, NY, [6]University of Rochester, [7]University of Rochester Medical Center, Rochester, NY, [8]University of Rochester School of Medicine, Rochester, NY

Purpose: Dendritic cells (DC) are pivotal cells in the initiation of adequate immune responses. Peripheral blood dendritic cells (PBDC) have pleiotropic effects on T and B lymphocytes, however, their phenotypic and functional properties in rheumatoid (RA) and psoriatic arthritis (PsA) and vaccine responses are not well understood. Therefore, we performed a comprehensive examination of the PBDC profile of RA and PsA patients.

Methods: Peripheral blood was collected longitudinally from a cohort of approximately 150 arthritis patients including, recently diagnosed RA (n=33), RA treated with methotrexate (MTX) (n=70), RA treated with TNF inhibitors (TNFi) (n=61), and PsA patients treated with anti-TNF (n=25). Samples from healthy control (HC) subjects (n=97) were also obtained. Peripheral blood was examined by an 11-color flow cytometry assay to identify, phenotype and assess endocytic ability of PBDC subsets. Subset analysis included resolution of previously characterized myeloid dendritic cell 1 (MDC1: CD11c+CD1c+), myeloid dendritic cell 2 (MDC2: CD11c+CD141+), and plasmacytoid (PDC: CD303+CD141-) populations in addition to several putative, poorly characterized PBDC subsets. A systems biology approach was utilized to assess differences in individual PBDC subsets and also differences in the overall composite PBDC profile.

Results: Examination of myeloid DC subsets did not reveal any significant differences in the frequency or endocytic ability of MDC1 among study groupsRecently diagnosed RA patients exhibited a consistent decrease in the frequency of MDC2 as compared to HC that reached significance at one time point. No consistent differences in the frequency of PDC was observed among study groups, although a trend toward decreased PDC in RA patients treated with MTX as compared to HC was observed. Principal components analysis of composite PBDC profiles revealed consistent significant differences in the PBDC profile of RA patients treated with MTX at multiple time points as compared to HC, that were largely influenced by relative changes in the frequency of PDC and a putative PDC-like subset. A significant decrease in MDC1, independent of study group was observed shortly after seasonal influenza vaccination.

Conclusions: Although variations were observed in the frequency of PBDC subsets in arthritis patients, no substantial dysregulation was observed that was specific to RA or PsA patients or treatment with methotrexate or anti-TNF. Subtle changes in the overall PBDC profile were observed in RA patients treated with MTX that warrant further examination and may reflect alteration in PBDC development. Decreases in MDC1 after influenza vaccination, likely reflecting altered trafficking, highlight the dynamic nature of the PBDC profile and may represent a surrogate marker of vaccine response. These data also demonstrate that anti-TNF therapy does not significantly impact the circulating frequency or ratios of PBDC.

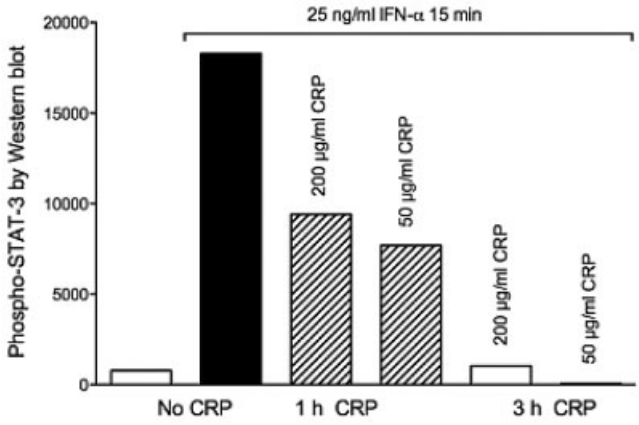
C-Reactive Protein Inhibition of the Response to Type I Interferon (IFN). Carolyn Mold[2], Daniel Goldberg[1], Carol Morris[1] and Terry Du Clos[1]. [1]University of New Mexico, [2]University of New Mexico, Albuquerque, NM

Background: A pivotal role for the type I IFN pathway in SLE is supported by expression analysis, genetic associations, in vitro experiments and animal models. In peripheral blood, plasmacytoid dendritic cells (pDC) are the primary producers of IFN, which acts on monocytes, myeloid DC and lymphocytes to promote antigen presentation and activation. This study investigated the regulation of this pathway by the pentraxins, C-reactive protein (CRP) and serum amyloid P (SAP). Both pentraxins recognize apoptotic cells and nuclear antigens and both bind to FcgR and activate complement. CRP promoter polymorphisms associated with decreased basal expression of CRP show increased risk of SLE. We hypothesized that pentraxins would regulate the IFN response to SLE autoantigens.

Methods: To determine whether pentraxins induce IFN, PBMC were incubated with CRP, SAP or serum containing anti-RNP and apoptotic cells or purified autoantigen (snRNP). Cytokine responses (TNF-a, IL-10, IFN- a) were measured at 24 h by ELISA. Purified monocytes or macrophages were incubated with CRP or CRP with apoptotic blebs and cytokines were measured by multiplex. To determine whether CRP treatment would affect the response to IFN, macrophages were preincubated with CRP for 1–3 h before 15 min treatment with IFN. Phosphorylation of STAT-1 and STAT-3 was determined by Western blot.

Results: PBMC produced IFN-a in response to immune complexes containing apoptotic cells or snRNP. In contrast, CRP or SAP complexed to these same autoantigens induced IL-10 and TNF-a but no IFN-a. Depletion of monocytes eliminated the cytokine responses to CRP complexes, but did not affect the IFN-a response to immune complexes, which is mediated by pDC. The IFN-a response to anti-RNP-snRNP complexes was sensitive to RNase treatment. Purified monocytes incubated with pentraxins complexed with apoptotic blebs released cytokines, IL-10, IL-6 and TNF-a, associated with a regulatory phenotype. The IL-10 response to CRP alone or CRP complexes was greatly increased by differentiation into macrophages with M-CSF. Pretreatment of macrophages with CRP for 3 h or longer completely blocked IFN-a-induced signaling.



Conclusions: These findings support the hypothesis that pentraxins regulate the IFN-a pathway. Although both CRP and SAP bind to apoptotic cells and nuclear autoantigens, in contrast to immune complexes, pentraxin complexes containing these autoantigens do not induce IFN-a. Instead monocytes dominate the response, producing TNF-a and IL-10, which both inhibit the pDC IFN response. Macrophages responded to CRP complexes with high amounts of IL-10 and after CRP incubation became unresponsive to IFN-a. Thus, pentraxins may provide both a non-inflammatory means to remove autoantigens exposed during cell death and a mechanism to decrease the stimulatory effects of IFN-a.

Endosomal Trafficking of Antigen in Antigen Cross-Presentation and the Cause of Lupus Tissue Injuries. Mai Takimoto[1], Ken Tsumiyama[1] and Shunichi Shiozawa[2]. [1]Department of Biophysics, Kobe University Graduate School of Health Sciences, Kobe, Japan, [2]Department of Biophysics, Kobe University Graduate School of Health Sciences/Department of Medicine, Kobe University Graduate School of Medicine/The Center for Rheumatic Diseases, Kobe University Hospital, Kobe, Japan

Objective: We previously showed that repeated immunization with a conventional antigen caused systemic autoimmunity in the mice otherwise

not prone to spontaneous autoimmune diseases; systemic autoimmunity necessarily takes place when host's immune 'system' is overstimulated by repeated exposure to antigen, to the levels that surpass system's self-organized criticality. This novel thesis 'self-organized criticality theory' explaining the cause of autoimmunity of ours (Tsumiyama K, *et al*. PLoS ONE 4(12):e8382, 2009) shows that overstimulating $CD8^+$ T cell into a full-matured MHC class I-restricted, antigen-specific effector cytotoxic T lymphocyte (CTL) *via* antigen cross-presentation in dendritic cell (DC) causes lupus tissue injuries. Here we examine molecular details of antigen cross-presentation to clarify how effector CTL is generated. The results indicate that the endosomal pathway, rather than the pathway through endoplasmic reticulum (ER), is essentially important for antigen cross-presentation and subsequent generation of lupus tissue injuries.

Methods: The bone marrow cells of BALB/c mice were stimulated with granulocyte-macrophage colony-stimulating factor (GM-CSF) to generate bone marrow-derived DC. The bone marrow-derived DC was cultured with fluorescent-labeled ovalbumin (OVA). Early endosome antigen-1 (EEA-1) and calnexin were detected to identify endosome and ER respectively, by using immunofluorescent staining. To examine whether or not engulfed antigen is exported from endosome to cytoplasm, Sec61, which is known as a translocon, was also detected by using immunofluorescent staining. Localization of OVA, endosome, ER and Sec61 was examined under confocal laser scanning microscopy.

Results: In the bone marrow-derived DC, upon engulfment, OVA was co-localized with EEA-1, an endosomal marker. However, by 15 min after engulfment, OVA was gradually separated from EEA-1. In contrast, OVA did not co-localize with calnexin, a marker of ER, until 30min after engulfment clearly indicating that OVA was not transferred into ER. Instead, Sec61 was found to be co-localized with OVA after 15 min to 30min, which indicated that OVA was transported from endosome to cytoplasm *via* Sec61.

Conclusion: The result shows that endosomal pathway, bypassing ER, is important in the case of antigen cross-presentation. Further, the export of antigen from endosome to cytoplasm *via* Sec61 could be the first step in antigen cross-presentation, hence the generation of lupus tissue injuries.

Exposure to U1-RNP Components Induces Bone Marrow-Derived Dendritic Cell Trafficking to the Lung. Luis Sorell[4], YunJuan Zang[4], Irina Fernandez[4], Laisel Martinez[1], Maria Carpintero[3] and Eric L. Greidinger[2]. [1]Miami VA Medical Center, [2]Miami VA Medical Center and University of Miami Miller School of Medicine, Miami, FL, [3]University of Miami Miller School of Medicine, Pembroke Pines, FL, [4]University of Miami Miller School of Medicine

Background: We have previously found that upon adoptive transfer into naive syngeneic mice, splenic dendritic cells (DCs) from anti-RNP immunized mice with clinical lung disease preferentially home to the lung and transfer interstitial pneumonitis, but that splenic DCs from naive mice or even from immunized mice without lung disease do not home to the lung or induce lung disease. We hypothesize that DC tissue targeting is determined by interactions between RNP targets and DCs directly, without the intervention of adaptive immune cells.

Methods: Bone marrow was harvested from B6 substrain study mice, and differentiated in vitro for a week with GM-CSF and IL-4 following published protocols. In the last 24 hours in culture, cells were transferred into fresh medium containing the same factors in the presence or absence of 50 mcg/ml each of 70k fusion protein and U1-RNA. Cells were harvested, loaded with CFSE or QTracker 655, subjected to FACS analysis and/or adoptively transferred into naive syngeneic hosts via the tail vein, 1 million cells per recipient. Recipients were subsequently sacrificed and analyzed by FACS for the presence of labeled cells in single cell suspensions from organ homogenates, and for the development of clinical manifestations of inflammatory disease.

Results: Bone marrow-derived DCs differentiated with GM-CSF/IL-4 showed evidence of preferential homing to the lung after incubation with 70k/U1-RNA, with mean of over 5% of pulmonary CD11c+ cells showing specific QTracker 655 labeling one week after cell adoptive transfer, compared to less than 1% of cells without 70k/U1-RNA. Persistence of lung-targeting DCs by vital dye staining was observed up to 2 months after cell transfer. In 6/6 mice receiving lung-targeting BM-derived DCs followed for at least 2 months, histologic evidence of interstitial pneumonitis was observed. Lung-targeting DCs were characterized by the development of CD11c+/CD11b+ surface expression, TLR3 expression, and preferential expression of a long form of the IRF5 mRNA 3' UTR similar to that observed in anti-RNP patients with lung disease.

Conclusions: Spliceosomal targets of anti-RNP autoimmunity can influence tissue targeting of autoimmune responses by direct effects on dendritic cells. A subset of myeloid dendritic cells targeting the lung mediates anti-RNP lung disease, and may represent a target for future therapeutic strategies.

Fas Expression in Myeloid Cells Is Required To Prevent Systemic Autoimmunity. Carla M. Cuda[1], Hemant Agrawal[1], Evan Weber[2], G. Kenneth Haines[3] and Harris R. Perlman[1]. [1]Northwestern University, Chicago, IL, [2]Northwestern University, [3]Yale University

Significance: Rheumatoid arthritis (RA) manifests in persistent synovial inflammation, cellular infiltration, and pro-inflammatory cytokine production, and results in progressive cartilage and bone destruction. While the mechanisms underlying these phenotypes are not fully elucidated, insufficient apoptosis is a key player in RA pathogenesis. A critical mediator of the extrinsic apoptotic pathway includes the death receptor (DR) Fas. Lymphocyte-specific deletion of Fas reveals non-apoptotic roles for this DR in proliferation, and although lymphocytes are necessary for the initiation of RA, macrophages are crucial for its persistence. These highly activated and non-proliferating cells contribute to synovial inflammation and cartilage and bone destruction through the production of degradative enzymes, cytokines, and chemokines. However, the impact of myeloid cell-specific loss of Fas and its relationship to RA development and/or progression has yet to be examined.

Methods: Mice with Fas flanked by loxP sites (Fasflox/flox) were crossed with mice expressing Cre under control of the murine lysozyme M gene promoter (CreLysM), which functions in mature lysozyme-expressing cells of the myelomonocytic lineage. CreLysMFasflox/flox mice were verified by Real-time PCR and examined to determine non-apoptotic roles of Fas in myeloid cells. Flow cytometric analysis was employed to characterize both myeloid and lymphoid cell distribution and activation in bone marrow, blood and spleen. Luminex-based assays and ELISAs were used to detect serum cytokine and Ig levels as well as in vitro cytokine production by macrophages in response to LPS. Immunofluorescent and immunohistochemical staining revealed kidney pathology.

Results: Myeloid cell-specific loss of Fas significantly increased both total numbers of peripheral circulating blood cells and splenocytes. Increased percentages of bone marrow resident macrophages were seen. Selective deletion also disrupted myeloid cell homeostasis in the periphery by increasing levels of peripheral blood resident and inflammatory monocytes, as well as increasing both the number and activation level of total and inflammatory splenic macrophages. Additionally, in vitro LPS stimulation of both peritoneal macrophages and bone marrow-derived macrophages lacking Fas resulted in increased production of IL-6, TNFα and IL-1β. Loss of Fas in myeloid cells also affected dendritic cells and T cells, with these populations presenting a more activated phenotype. CreLysMFasflox/flox mice displayed significantly increased serum IL-1α, IgG, total IgM and anti-dsDNA IgM levels and presented with more severe kidney pathology based on positive IgG staining, increased cellular infiltration and higher disease scores.

Conclusion: These results demonstrate that loss of Fas in myeloid cells is sufficient to induce inflammatory phenotypes in mice. Thus, we are the first group to show via myeloid cell-specific deletion of Fas that this DR typically associated with apoptosis also acts to prevent systemic autoimmunity. These data will have implications for RA by elucidating previously unknown functions of a potentially useful target for therapy.

FLIP: The Novel Regulator of Macrophage Differentiation and Granulocyte Homeostasis. Qi Quan Huang[2], Harris R. Perlman[2], Zan Huang[3], Robert Birkett[3], John D. Crispino[3] and Richard M. Pope[1]. [1]Northwestern Univ Med School, Chicago, IL, [2]Northwestern University, Chicago, IL, [3]Northwestern University

Background and Purpose: Macrophages are important mediators of innate immunity and chronic inflammation, and play an important pathogenic role in rheumatoid arthritis. In order to further understand the cellular

mechanisms contributing to the persistence of macrophages in RA, a myeloid lineage Flip knock out mouse line has been generated. Characterization of these mice demonstrated that FLIP was necessary for macrophage differentiation and survival, that macrophages are essential for maintaining granulocyte homeostasis.

Methods: Mice bearing floxed Flip alleles crossed with LysM-cre mice resulted in FLIP deletion in the myeloid cell lineage. The cell types in circulation and tissues were examined by morphology and by flow cytometry. Mixed chimera bone marrow reconstitution experiments were performed employing by CD45.1+ and CD45.2+ congenic C57BL/6 mice. Serum cytokines were quantified by LUMINEX 200. In vitro macrophage differentiation was performed from CD117+ bone marrow hematopoietic stem cells. Flip In vitro deletion was induced by recombinant Cre retro-virus.

Results: In addition to postnatal growth retardation and premature death, myeloid specific FLIP deficient mice exhibited a dramatic increase of circulating neutrophils and multi-organ neutrophil infiltration, which was mediated by increased cytokines and growth factors. Mature macrophages in the spleen, lymph nodes and the peritoneal cavity were significantly reduced. Further analysis of cells in peritoneal cavity discovered a significant inverse non-linear correlation of peritoneal macrophages and granulocytes. That is if macrophages were present, neutrophils were kept in a homeostatic level. In vitro, CD117+ bone marrow progenitor cells failed to differentiate into macrophages when Flip was deleted. This defect was observed not only in the mature macrophages, and there are also decreased numbers of the less mature myeloid progenitors. The bone marrow reconstitution experiments demonstrated that the primary defect was a cell autonomous defect of the bone marrow derived cells, since these cells were capable to transferring the disease, in the absence of competitor wild type cells. Further, the mixed chimera experiments demonstrated that knockout bone marrow cells were not able to compete with the wild type cells, due to increased cytokines and growth factors induced stem cell exhaustion, prior to cell transfer from the knockout mice.

Conclusions: These observations demonstrate that FLIP is necessary for macrophage differentiation and survival. The myeloid specific deletion of FLIP resulted in the loss of macrophages and consequently an increase of neutrophils. Neutrophilia and inflammation is secondary to the loss of macrophages and contributed by increased cytokines and growth factors. Since both macrophages and granulocytes are major inflammatory cell types involved in the pathogenesis of rheumatoid arthritis, further understanding of their homeostatic regulation will provide new insights into the mechanisms that control of inflammation.

IκB Kinase (IKK)ε: Bridging Innate and Adaptive Immunity in Collagen-Induced Arthritis (CIA). Deepa Hammaker[2], Katharyn Topolewski[3], David L. Boyle[1] and Gary S. Firestein[1]. [1]UCSD School of Medicine, La Jolla, CA, [2]Univ of California San Diego, La Jolla, CA, [3]University of California, San Diego

Purpose: The IKK related kinase IKKε regulates innate immune responses through the production of interferon-beta (IFNβ), pro-inflammatory cytokines and chemokines. Recent studies show that IKKε-deficiency can synergize with IFNβ therapy to reduce inflammation in passive K/BxN serum-induced arthritis, where the innate immune system is indispensable for disease initiation. However, there is no information on whether IKKε regulates inflammation in a model of arthritis that depends on adaptive immunity. Therefore, we evaluated whether IKKε plays a role in murine collagen-induced arthritis.

Method: Wild type (WT), and IKKε−/− mice were immunized on days 0 with type II bovine type II collagen in complete Freund's adjuvant and on day 21 in PBS. Joint histology on day 42 was evaluated for synovitis, bone erosion, extra-articular inflammation and proteoglycan damage (max score=16). Serum anti-type II collagen antibody levels were measured by ELISA. Levels of cytokines and chemokines in serum were measured by multiplex analysis. Gene expression in joint extracts was determined by quantitative real time PCR.

Results: Arthritis severity was significantly reduced in IKKε−/− mice compared with WT ($p=0.02$, n=13/group). Scores at peak arthritis severity on day 35 were 13.1±2.2 in WT compared with 8.3±2.2 in IKKε−/− mice. Histological analysis showed that bone erosion and proteoglycan loss in IKKε−/− mice was significantly reduced by 70% and 60%, respectively compared with WT ($p<0.04$). Surprisingly, levels of the pathogenic anti-collagen IgG2a antibody were reduced by 32±10% ($p=0.04$) in IKKε−/− serum while total IgG levels were similar to WT mice. Serum IL-6 and G-CSF levels were similar in WT and IKKε−/− mice with arthritis on day 35 and were significantly higher than in naive mice. Synovial MMP3 gene expression was significantly lower in IKKε−/− mice compared with WT mice (63±8% inhibition, $p=0.02$). Induction of MMP9 and IFNβ genes was also decreased in IKKε−/− mice by 45±13% and 84±4%, respectively ($p=0.058$). Despite improved clinical scores, IL-1Ra, IL-6 and MMP-13 gene expression was not significantly reduced in IKKε−/− mice compared with WT mice.

Conclusions: IKKε unexpectedly regulates adaptive immune responses as shown by decreased production of pathogenic anti-type II collagen antibodies. Diminished disease severity in the model is probably due to a combination of decreased anti-collagen antibody production and suppression of synovial innate immune responses. This kinase represents a novel therapeutic target to suppress synovitis by regulating complex components of the immune system implicated in RA.

IMO-3100, a Toll-Like Receptor (TLR) Antagonist, Suppresses TLR7- and TLR9-Mediated Immune Responses in Non-Human Primates. Lakshmi Bhagat[2], Jimmy X. Tang[2], Tim Sullivan[2], Ekambar R. Kandimalla[1] and Sudhir Agrawal[2]. [1]Idera Pharmaceuticals, Inc, Cambridge, MA, [2]Idera Pharmaceuticals, Inc

Background: Immune complexes containing host-derived nucleic acids have been shown to induce inflammatory responses mediated through TLR7 and TLR9 and manifest autoimmune diseases, such as lupus and psoriasis. Blocking TLR7- and TLR9-mediated immune responses through use of an antagonist represents a novel approach for the treatment of selected autoimmune diseases. IMO-3100 is a dual antagonist of TLR7 and TLR9, which has shown potent activity in preclinical disease models of lupus, collagen-induced arthritis, psoriasis, and hyperlipidemia. In the current study, we have evaluated IMO-3100 for its pharmacodynamic mechanism of action in non-human primates.

Methods: IMO-3100 was administered to cynomolgus monkeys (N=4) as a weekly dose of 1.5 mg/kg for 4 weeks. Blood samples were collected prior to and 72 hours after each IMO-3100 injection (i.e. Days 0, 3, 7, 10, 14, 17, 21, and 24) and also at days 28 and 35. PBMCs were isolated by Ficoll density gradient centrifugation method. PBMCs (1×10^6 cells/0.2 ml/well in 96 well plates) were incubated with agonists of TLR7 (50 μg/ml), TLR9 (3 μg/ml) or TLR4 (LPS, 100 ng/ml) for 24 hrs. Supernatants were harvested and IL-1β, IL-1Ra, IL-6, IL-8, IL-12, TNF-α, MIP-1α, MIP-1β, RANTES and MCP-1 levels in culture supernatants were determined using human cytokine antibody bead kits. IFN-α and IP-10 levels were measured by ELISA.

Results: Weekly administration of IMO-3100 for 4 weeks resulted in 25 to 95% reduction in various cytokines and chemokines induced by TLR7 and TLR9 agonists, including IL-1β, IL-6, IL-12, IP-10, IFN-α, MIP-1α and MIP-1β, compared with pre-dose cytokine levels. The magnitude and duration of inhibition varied for different cytokines. Weekly administration of IMO-3100 led to continued suppression of cytokines at all time points up to day 28. By day 35, two weeks after the last dose of IMO-3100 administration, secretion of cytokines/chemokines rebounded or started to rebound to pre-dose levels. IMO-3100 showed insignificant suppression of TLR4 agonist (LPS)-induced cytokines in isolated PBMCs, suggesting specific inhibition of TLR7- and TLR9-mediated immune responses.

Conclusion: These results demonstrate that weekly administration of IMO-3100 to non-human primates suppresses ex-vivo immune responses mediated through TLR7 and TLR9, but not TLR4. IMO-3100 is in phase 1 clinical evaluation for potential applications in autoimmune and inflammatory diseases.

Involvement of Toll-Like Receptor 2 in Pristane-Induced Lupus. Vilma Urbonaviciute[3], Silke Frey[2], Carsten Kirschning[1], Georg Schett[2] and Reinhard E. Voll[2]. [1]Essen, Germany, [2]Erlangen, Germany, [3]Department Internal Medicine 3, University Hospital Erlangen, University of Erlangen-Nuremberg, Erlangen, Germany

Background: Autoantibodies against nuclear autoantigens such as double-stranded DNA (dsDNA) and nucleosomes represent a serological hallmark of systemic lupus erythematosus (SLE) and may directly contribute to the pathogenesis of the disease (1). However, it is still unclear, how such poorly immunogenic ubiquitous nuclear components become targets of an immune response in patients with SLE. Recent data indicate that Toll–like receptors (TLRs) recognizing endogenous ligands may be critically involved in breaking peripheral tolerance against nuclear autoantigens (2). Results of our recent studies in non-autoimmune mice provide evidence of a critical role of TLR2 in the anti-dsDNA and anti-histone IgG autoantibody induction by High Mobility Group Box protein 1 (HMGB1)-nucleosome complexes purified from apoptotic cells, whereas TLR4 was dispensable (3).

Objective: Using the pristane-induced mouse model of SLE, we further investigated the requirement of TLR2 signaling for induction of lupus-specific autoantibody production and SLE like disease.

Methods: Female C57BL/6 wild type (wt), TLR2- and TLR2/4-deficient mice were injected intraperitoneally with a single dose of 500 μl of the hydrocarbon oil pristane (2,6,10,14 tetramethylpentadecane). The concentrations of autoantibodies in sera were measured by ELISA. Renal disease was assessed by semiquantitative measurement of proteinuria in spot urine and quantified over 24 hours after collection in metabolic cages as well as by histological analyses.

Results: TLR2-deficient mice displayed delayed and significantly reduced anti-dsDNA, anti-histone, and some anti-nuclear (ANA) antibody IgG responses compared to pristane treated wt controls. Interestingly, pristane treated TLR2/4-deficient mice developed even somewhat higher amounts of the autoantibodies than wt control mice, suggesting a so far unexplained protective function of TLR4. However, both, pristane-treated TLR2- and TLR2/4-deficient mice developed significantly milder renal disease compared to the wt control group, indicating a role of TLR2 and TLR4 in the inflammatory process in the kidneys.

Conclusion: TLR2 is specifically required for anti-dsDNA, anti-histone, and antinuclear autoantibody production as well as for development of renal disease in pristane-induced murine lupus model. Specific blocking of TLR2 signaling may therefore be a promising novel strategy for treatment of SLE.

Mir-19b Regulates TLR2 Expression in Rheumatoid Arthritis Fibroblast-Like Synoviocytes. Lucas Philippe[3], Guillaume Suffert[1], Ghada Alsaleh[3], Arnaud Theulin[3], Jacques Eric Gottenberg[3], Jean Sibilia[3], Sebastien Pfeffer[2] and Dominique Wachsmann[3]. [1]Architecture et Réactivité de l'ARN, Université de Strasbourg, Institut de Biologie Moléculaire et Cellulaire du CNRS, Strasbourg, France, Metropolitan, [2]Architecture et Reactivite de l'ARN, Universite de Strasbourg, Institut de Biologie Moleculaire et Cellulaire du CNRS, Strasbourg, France, Metropolitan, [3]Laboratoire de Physiopathologie des Arthrites, EA4438, Faculté de Pharmacie, 74 Route du Rhin, Illkirch-Graffenstaden, France, Metropolitan

Background: Rheumatoid arthritis (RA) is a chronic autoimmune disease of which the main characteristic is irreversible joint destruction. An excessive stimulation of resident cells such as fibroblast-like synoviocytes (FLS) seems to be a fundamental event. This activation is in part due to microbial components such as PAMPs (Pathogen Associated Molecular Patterns) or DAMPs (damage associated molecular patterns) that activate cells by interacting with Pattern Recognition Receptors (PRRs) such as Toll like receptors (TLRs). Their activation triggers the transcription of numerous genes coding for pro-inflammatory cytokines and metalloproteases implicated in cartilage and bone destruction. MicroRNAs (miRNA) are small non-coding RNA that have emerged as key players in the regulation of translation and degradation of target mRNAs. The aim of this work was to evaluate their potential involvement in the control of TLR expression by RA FLS.We focused on TLR2 expression which is up-regulated in RA synovium.

Materials and Methods: FLS were obtained from RA patients at the time of joint surgery.TLR2 mRNA and protein expression was assessed by RT-qPCR and western blot after stimulation of RA FLS with BLP, a ligand of TLR2. MiRNAs expression was analyzed using a microarray-based approach and confirmed by RT-qPCR. Transfection of FLS was performed using the AMAXA nucleofactor kit II (c) system. Identification of 19b targets was assessed by the luciferase assay using the psiCHECK™-2 Vectors. IL-6 secretion was evaluated using the ELISA sandwich method.

Results: We first showed that RA FLS expressed constitutively TLR2 and that TLR2 expression was up-regulated in response to BLP. Using a miRNA microarray analysis, we identified the downregulation of miR-19b which was predicted to target TLR2 mRNA. Down regulation of miR-19b was confirmed by qRT-PCR. Transfection of RA FLS with miR-19b mimic decreased TLR2 expression. Using a luciferase assay, we also showed that miR-19b targets directly TLR2 mRNA 3'UTR. In addition, direct targeting of TLR2 mRNA by 19b mimic inhibited IL-6 secretion by BLP activated RA FLS.

Conclusion: Together, these data demonstrated a critical functional link between miR-19b, TLR2 expression and IL6 secretion by RA FLS, which could play an important role in RA inflammation.

Myeloid but Not Lymphoid Bim Expression Is Required Suppress SLE-Like Disease. Hemant Agrawal[1], Evan Weber[1], Alexander Misharin[1], Carla M. Cuda[1], G. Kenneth Haines[2], Rosalind Ramsey-Goldman[1] and Harris Perlman[1]. [1]Dept Med/Div Rheumatology, Northwestern University, [2]Yale University

Purpose: Systemic lupus erythematosus (SLE) is a multifactorial autoimmune disease of unknown etiology characterized by production of autoantibodies and extensive end organ damage. While it is clear that T and B cells are critical to SLE pathogenesis, intrinsic differences in myeloid cells, such as macrophages (Mφ) and dendritic cells (DC), may influence the T and B cell phenotypes observed in patients with SLE. To date, few studies have focused on the loss of Bim, a pro-apoptotic member of the Bcl-2 family, specifically in monocytes/Mφ and its non-apoptotic roles such as activation, cytokine production, and presentation and their relationship to the pathogenesis of lupus.

Method: Peripheral blood from aged and sex matched healthy controls and patients with inactive (SLAM <2) or active SLE (SLAM >10) were analyzed for monocyte expression of Bim and markers of activation. Additionally, mice lacking Bim specifically in T cells (CreCD4Bimflox/flox), B cells (CreCD19Bimflox/flox) and monocytes/Mφ (CreLysMBimflox/flox) using the Cre-loxP system were generated and the deletion of Bim was verified by real time PCR. Bimflox/flox (Bim intact) mice were used as controls. Young (<2 mon) and aged mice (>6 mon) were phenotyped using histological and flow cytometric analyses. Luminex based assays and ELISAs were performed to detect antibody isotypes, autoantibodies, cytokines/chemokines, and activation of kinases. A pathologist blinded to the study scored all tissues for SLE-like disease.

Summary: SLE patients with active disease displayed reduced expression of Bim in monocytes but not in lymphocytes or granulocytes, which was associated with increased expression of HLA-DR, CCR2, CD62L, and CCR5 but not CD163. To further understand the importance of the reduction of Bim in monocytes, we studied mice lacking Bim in monocytes/Mφ. Young and aged CreLysMBimflox/flox mice showed severe splenomegaly compared to Bimflox/flox, CreCD4Bimflox/flox and CreCD19Bimflox/flox mice. While both young and aged CreLysMBimflox/flox mice had increased numbers of activated splenic Mφ and DC, only the aged CreLysMBimflox/flox mice had increased numbers of splenic Mφ. Furthermore, young and aged CreLysMBimflox/flox mice showed increased accumulation of activated splenic B and T cells. Mφ from young CreLysMBimflox/flox mice induced increased OT-II T-cell responses as compared to Bimflox/flox mice and displayed reduced phospho-AKT but increased phospho-cJun, and p38. Additionally, Mφ from aged mice showed reduced caspase 3/7 activation. There were elevated levels of circulating autoantibodies (total IgM and isotypes of IgG) and cytokines (IL-12p70 and IL-17) in CreLysMBimflox/flox mice serum. Moreover, CreLysMBimflox/flox mice displayed severe renal damage as evident by increased glomerular size, cellular infiltration, retention of immune complexes, and high kidney disease scores.

Conclusion: These data demonstrate that reduction of Bim leads to a novel and non-apoptotic phenotype in monocytes/Mφ and the loss or reduction of Bim in monocytes/Mφ is sufficient to activate lymphocytes and SLE-like disease. Thus, the level of Bim in monocytes/Mφ may be a biomarker of SLE-disease activity.

Natural Killer (NK) Cells Resident in Normal Human Skin Are Distinct from Blood and Lung NK Cells. Ahmed Gehad[1], Sandra King[1] and Robert Fuhlbrigge[2]. [1]Brigham and Women's Hospital, [2]Children's Hospital- Boston, Boston, MA

Normal human skin contains a broad collection of leukocytes, including T cells, dendritic cells and NK cells, that form an intricate network important for immunosurveillance and active in inflammatory skin disease. Although skin homing T cells and skin resident dendritic cell populations have been described in detail, little is known regarding the characteristics of NK cells resident in skin. Published studies of NK cell subsets in humans have focused primarily on surface receptor expression of NK cell populations circulating in peripheral blood, rather than cells recovered from tissue. We hypothesized that skin resident NK cells may represent a distinct subset of NK cells with phenotypic, homing and functional properties distinct from NK cells in peripheral blood and resident in other tissues. For this study, we used a short term non-enzymatic explant culture method for leukocyte isolation. Samples of non-inflamed human skin obtained from cosmetic surgery procedures in accordance with IRB guidelines were cultured on tantalum-coated carbon matrices in the absence and presence of various cytokines including IL-2, IL-15, IL-18, IL-21, and FLT-3 ligand. Leukocytes were recovered after 2–3 wk in culture and analyzed by flow cytometry. CD3- CD56+ NK cells present in normal skin represented a small but reproducible fraction (2–12%) of total skin leukocytes recovered. A combination of IL-15 and IL-18 yielded maximal recovery of NK cells, though analyses were performed on both cytokine stimulated and non-stimulated cultures. The majority of skin NK cells (as well as skin T cells recovered in parallel) expressed skin homing receptors (CLA, and E- and P-selectin ligands), as well as both α4 and αL integrins, but did not express L-selectin or CCR7, consistent with a peripheral tissue homing phenotype. However, in contrast to skin T cells, only a small fraction of NK cells expressed CCR4 and CCR6 and were negative for CCR10 and CXCR4, indicating skin homing NK cells utilize a different chemokine signal pathway than skin homing T cells. NK cells recovered from peripheral blood or cultures of normal lung tissue expressed much higher levels of CD16 and much lower levels of skin homing receptors (E- and P-selectin ligand) compared to skin resident NK cells, providing evidence for subset selection among the cells resident in skin. The majority of skin NK cells expressed both the surface receptor NKG2D and intracellular perforin and granzyme B, molecules required for NK cell cytotoxic function, and also produced IFN-γ and TNF, but not IL-10 or IL-6. These data show that NK cells in the skin represent a unique population with a distinct profile of homing receptors, cytokine production, and cytotoxic functions as compared to NK cells from blood or lung tissue and compared to T cells from skin. These data suggest that skin resident NK cells may play a role in innate and adaptive immune responses in the skin that is independent from cells recruited from blood, and suggests similar subsets with unique characteristics may be present as resident cells in other tissue sites.

p21 Suppression of Inflammatory Arthritis Requires the PCNA Domain and Inhibition of p38. Angelica K. Gierut[1], Melissa Mavers[3], Carla M. Cuda[2], Alexander Misharin[2], Evan Weber[2] and Harris R. Perlman[1]. [1]Northwestern University, Chicago, IL, [2]Northwestern University, [3]St. Louis University

Purpose: The etiology of rheumatoid arthritis (RA) is unknown. We have previously shown that RA patient synovium has a reduction of p21, a cell cycle inhibitor. We are also the first to demonstrate a novel role for p21 as suppressor of inflammation. Knock down of p21 in healthy human peripheral blood monocyte-derived macrophages leads to increased production of inflammatory cytokines IL-1β, TNF-α, and IL-6. In addition, mice deficient in p21 have increased in vivo production of inflammatory cytokines and mortality with lipopolysaccharide (LPS)-induced endotoxic shock. Here, we sought to determine the role and mechanism of p21-mediated suppression of experimental inflammatory arthritis.

Methods: WT or p21−/− (C57BL/6) mice were injected intraperitoneally (IP) with 300 μL of K/BxN serum and ankle circumference was measured over 7–25 days. Ankles were then harvested, sectioned, stained for histochemical or immunohistochemical analysis and scored by a pathologist blinded to the study. For phosphoprotein assays, WT or p21−/− mice were injected IP with thioglycollate, and peritoneal macrophages were harvested and cultured in vitro overnight. Cells were stimulated with 10 ng/mL of LPS and cell lysates were collected and analyzed for the phosphorylation status (activation) of various proteins using a multiplex bead array. Similarly, thioglycollate-elicited peritoneal macrophages from WT mice were incubated with several Tat-conjugated peptides corresponding to different domains of the p21 protein (10uM) for 2 hours prior to the addition of LPS (in the presence of peptide). Lysates were analyzed by multiplex bead array. For in vivo studies, WT mice were injected IP with 10 mg/kg peptide 30 minutes prior to K/BxN serum and daily throughout.

Results: Mice deficient for p21 developed increased ankle swelling, joint destruction, and inflammatory infiltrate, as compared to WT mice. There was increased numbers of macrophages in the pannus of p21−/− mice that correlated with bone destruction. Furthermore, the disease failed to fully resolve in p21−/− mice even after 25 days post injection of serum. Treatment with a peptide corresponding to the proliferating cell nuclear antigen (PCNA) binding domain of p21 was superior in suppressing inflammatory arthritis and reduced the numbers of synovial macrophages compared to control peptide. Peritoneal macrophages from mice deficient in p21 demonstrated a consistent increase in the phosphorylation status of the mitogen-activated protein kinase (MAPK), p38, following LPS stimulation compared to those from WT controls. In comparison, a peptide corresponding to the PCNA binding domain of p21 added before LPS significantly decreased the level of phosphorylated p38 compared to those treated with a control peptide.

Conclusion: These data indicate that deficiency of p21 augments experimental arthritis in mice, and that a peptide corresponding to the PCNA binding domain of p21 acts to decrease experimental arthritis via decreased activation of p38. These efforts suggest that p21 is a potential biomarker and/or therapeutic target for RA.

Peripheral Blood Mononuclear Cells and Plasmacytoid Dendritic Cells from Healthy Human Females Exhibit Altered TLR7-Mediated Immune Responses Compared to Males. Melissa Precopio[1], Dong Yu[2], Ekambar R. Kandimalla[2] and Sudhir Agrawal[2]. [1]Idera Pharmaceuticals, Cambridge, MA, [2]Idera Pharmaceuticals

Background: Toll-like receptors (TLR) are a family of pathogen-associated molecular pattern recognition receptors expressed by cells of the immune system. TLR7 and TLR9 are expressed in endosomal compartments of human B cells and plasmacytoid dendritic cells (pDCs) and recognize molecular patterns of nucleic acids. There is growing evidence that immune complexes containing nucleic acids induce proinflammatory cytokines through TLR7 and TLR9 and exacerbate certain autoimmune diseases. Women are more prone to manifestation of autoimmune diseases than men. This study was carried out to evaluate the differences in immune responses induced through TLR7 and TLR9 in peripheral blood mononuclear cells (PBMCs) and plasmacytoid dendritic cells (pDCs) of healthy female and male subjects.

Methods: We measured cytokine induction and costimulatory marker upregulation in response to specific TLR agonists in PBMCs and pDCs obtained from healthy male (n=15, age: 23–60 years) and female (n=15, age: 18–58 years) subjects. The agonists used in these studies include an RNA-based TLR7 agonist and a DNA-based TLR9 agonist. To further discern differences in TLR7- and TLR9-mediated immune responses in systemic lupus erythematosis (SLE) patients (n=9, age: 29–78 years) on treatment with plaquenil/hydroxychloroquine and healthy female subjects (n=10, age: 22–56 years), we measured cytokine induction in PBMCs in response to TLR7 and TLR9 agonists.

Results: In PBMCs from healthy females, TLR7 agonist induced higher levels of IFN-α, and IP-10 and lower levels of IL-1Ra, IL-1β, IL-6, IL-8 and IL-10 compared with PBMCs from healthy males. The levels of IL-12, MIP-1β, and MCP-1 induced by TLR7 agonist were not different in PBMCs from females and males. pDCs from females showed higher levels of TLR7

agonist-induced IL-12, IP-10, IFN-α, and TNF-α than pDCs from males. TLR9 agonist induced similar levels of immune responses in PBMCs and pDCs from females and males, except IL-1Ra levels were higher in PBMCs from males than females. In studies comparing SLE patients with healthy female controls, TLR7 agonist induced lower levels of IFN-α, TNF-α, IP-10, and IL-6 in PBMCs from SLE patients than healthy females. TLR9 agonist induced lower levels of TNF-α, IL-6, MIP-1α, and MIP-1β in PBMCs from SLE patients than PBMCs from healthy females. The lower levels of TLR7- and TLR9-mediated immune responses in PBMCs from SLE patients could be a result of treatment with plaquenil, an inhibitor of endosomal TLR-mediated immune responses through neutralization of endosomal acidification.

Conclusions: Notable differences in TLR7-mediated immune responses were observed in PBMCs and pDCs from healthy females compared with males that may play a role in autoimmune diseases afflicting females disproportionately.

Post-Translational Control Mechanisms Regulate Dendritic Cell Activation of T Cell Responses. Dana Orange[1], Jak Fak[2], Nathalie Blachere[2] and Robert Darnell[2]. [1]The Hospital for Special Surgery, [2]The Rockefeller University

Purpose: In addition to being some of the most potent of antigen presenting cells, dendritic cells (DCs) have the unique capability of cross presenting. When DCs phagocytose an apoptotic cell, antigen acquired from that cell can be presented on the cell surface in the context of MHCI in addition to MHCII to activate cytotoxic CD8 T cells. It has been demonstrated that in order for this cross presentation pathway to lead to CD8 T cell activation, the DC needs to be licensed by an activated CD4 T cell via CD40L stimulation. The steps downstream of CD40 signaling that allow for cross presentation remain unclear. Work from our group previously showed that although they are both calcineurin inhibitors, FK506 but not cyclosporine blocks DCs from being able to stimulate T cells via the cross presentation pathway. Microarray from cyclosporine and FK506 treated DCs failed to show any differences on the level of mRNA expression. The goal of this project was to evaluate whether new gene transcription or translation is required for DCs to cross present to CD8 T cells.

Methods: Healthy donors PBMCs were cultured with IL 4 and GMCSF for 6 days. Immature DCs were allowed to phagocytose flu infected apoptotic 3T3 cells and then matured with TNF and PGE2. Antigen presenting DCs were then treated with either actinomycin D or cycloheximide, inhibitors of transcription and translation respectively, and cocultured with MACS purified CD8 T cells + CD40L to substitute for CD4 help and assayed for IFNγ induction via RT-PCR.

Results: DCs treated with actinomycin D were blocked in their ability to accomplish any new gene transcription via PCR for IL12p35, IL12p40, TNF, IL6 and IP10 in response to LPS stimulation when compared to untreated control. Despite the transcriptional blockade, they were competent in their ability to cross present and activate antigen specific T cell responses as measured via RT-PCR for T cell induction of IFNγ mRNA. Similarly, cycloheximide treated DCs were also competent to activate T cell responses via the cross presentation pathway.

Conclusion: This work demonstrates that DC licensing for the cross presentation pathway is under a mechanism of post-translational control. In the absence of CD40L signaling, DC cross presentation results in cross tolerance. The finding that transcriptionally and translationally blocked dendritic cells can still activate CD8 T cell responses indicates that key signaling events downstream from CD40L stimulation do not require transcription or translation. As immune responses require some of the fastest reaction times in the body, it stands to reason that a critical switch between activation and tolerance would not require the time for new gene transcription or translation. Instead, we propose that the essential control of DC licensing is likely to be a protein that has been translated but held in a conformationally inactive state.

Reduced T-Cell-Dependent Humoral Immune Response in Microsomal Prostaglandin E Synthase-1 Null Mice. Rahul G. Matnani[2], Fumiaki Kojima[2], Jerold G. Woodward[2] and Leslie J. Crofford[1]. [1]Univ of KY, Lexington, KY, [2]Univ of KY

Microsomal prostaglandin E synthase-1 (mPGES-1) is an inducible enzyme that specifically catalyzes the conversion of prostaglandin (PG)H_2 to PGE_2, most prominently in inflammatory conditions. We previously showed that mPGES-1 null mice had a significantly reduced incidence and severity of collagen-induced arthritis (CIA) compared to wild-type mice. Reduced CIA was associated with a marked reduction of antibodies to type II collagen, known to be required for developing autoimmune inflammatory arthritis in this model. In the present study, we further elucidated the role of mPGES-1 in the humoral immune response. Basal levels of serum IgM and IgG were significantly reduced in mPGES-1 null compared with wild-type mice ($P<0.05$), but IgM and IgG production in splenocytes treated *ex vivo* with LPS were not different. Immunization with either the T-cell independent type-1 antigen TNP-LPS or the T-cell independent type-2 antigen DNP-Ficoll revealed minimal differences in hapten-specific antibody levels when comparing mPGES-1 null and WT mice. However, mPGES-1 null mice exhibited significant reduction of hapten-specific serum antibodies compared with wild-type mice in response to immunization with the T-cell dependent antigen DNP-KLH in CFA including IgM (days 7–21 post-immunization, $P<0.05$) and IgG (days 7–28 post-immunization, $P<0.05$). Germinal center formation in the spleen of mPGES-1 null mice was phenotypically similar to WT mice in response to immunization with DNP-KLH when evaluating the %PNA positive germinal centers to IgD positive regions (43.5 ± 1.8 vs 40.8 ± 2.1, P=NS). To determine if the effect of mPGES-1 and PGE_2 was related to hematopoietic or non-hematopoietic cells, we generated bone marrow chimeras. The results indicate that mPGES-1 deficiency in non-hematopoietic cells was the critical factor for reduced antibody production after immunization with DNP-KLH since transfer of mPGES-1 null bone marrow (BM) to non-lethally irradiated WT recipients expressed hapten-specific antibodies equal to the WT BM→WT, but WT BM→mPGES1 null expressed reduced antibodies similar to mPGES1 null BM→null. We conclude that PGE_2-dependent inflammation during immunization plays a key role in T-cell dependent humoral immune responses, likely as a result of altered T-cell phenotype. These findings may have relevance to the pathogenesis of autoimmune inflammatory arthritis associated with autoantibodies such as rheumatoid arthritis.

Regulation of VLA-4 in SLE Monocytes. Homaira Rahimi[1] and Kathleen E. Sullivan[2]. [1]Children's Hosp Philadelphia, Philadelphia, PA, [2]Childrens Hosp of Philadelphia, Philadelphia, PA

Objectives: The development of atherosclerosis and subsequent increased risk of cardiovascular disease (CVD) is known to be associated with inflammation. Studies have shown an increased risk of CVD in systemic lupus erythematosus (SLE). Inflammation seen in atherosclerosis involves various immune mediators, including interactions between adhesion molecules on endothelial cells and on monocytes. Very late antigen-4 (VLA-4) is an adhesion molecule in the integrin family found on monocytes and has been implicated in monocyte recruitment during development of atherosclerosis. A recent study noted an increased expression of VLA-4 in SLE monocytes, but the regulation is poorly understood. We aimed to further define variables governing the expression of VLA-4 on monocytes in patients with SLE compared to healthy controls.

Methods: CD14+ human monocytes were obtained from whole blood of healthy adult patients and SLE patients. Flow cytometry was used to measure expression of VLA-4 at rest and upon exposure to various agents, including interferon gamma, interferon alpha, interleukin-4, and vitamin D. VLA-4 mRNA expression in SLE and healthy monocytes was measured using qRT-PCR. Healthy monocytes were incubated in control and SLE sera, and VLA-4 was expression evaluated using flow cytometry and immunofluorescence (IF).

Results: VLA-4 (CD49d) expression was significantly higher on control monocytes compared to SLE monocytes as measured by mean fluorescence intensity ($p<0.05$). However, levels of VLA-4 mRNA were significantly lower in control monocytes compared to SLE monocytes ($p<0.05$). Exposure

of healthy monocytes to healthy human sera compared to SLE sera did not result in differences in cell surface expression of VLA-4; however, VLA-4 was redistributed to the interior of the cell. IF staining of VLA-4 of healthy monocytes incubated in SLE sera demonstrated VLA-4 in a vesicular compartment whereas healthy monocytes incubated in healthy sera or RPMI media alone exhibited VLA-4 staining on the surface or diffusely in the cytoplasm.

Conclusion: There was a significant down-regulation of cell surface expression of VLA-4 in SLE monocytes as compared to the healthy population, although mRNA levels were increased. We demonstrated that exposure to SLE sera causes increased internal IF staining of VLA-4, suggesting that decreased surface expression, in spite of increased RNA levels, in SLE is due to altered distribution. VLA-4 has increased expression in atherosclerosis and understanding its up-regulation in SLE patients could have implications for the prevention and treatment of advanced atherosclerosis in SLE. In addition, VLA-4 is capable of intracellular signaling. If there is an altered distribution of VLA-4 in SLE monocytes, this might affect the inflammatory pathway in SLE. These data provide a context for considering novel therapeutics to treat atherosclerosis in SLE.

The Cholinergic Anti-Inflammatory Pathway as a Modulator of Immune Complex-Induced Acute Inflammation. Milena Vukelic[2], Gloria Koo[2] and Jane E. Salmon[1]. [1]Hospital for Special Surgery, New York, NY, [2]Hospital for Special Surgery, New York, NY

Purpose: The "cholinergic antiinflammatory pathway" is a neural mechanism by which the efferent vagus nerve leads to stimulation of nicotinic acetylcholine receptors (nAchR) on immune cells and thereby inhibits their synthesis of proinflammatory mediators in response to innate immune stimuli. Its role in antibody-mediated injury, such as that present in SLE, has not been explored. We hypothesized that ligation of nAChRs would downmodulate C5aR- and FcγR-triggered activation of neutrophils and monocytes and limit immune complex-triggered inflammation. We examined effects of nAChR ligation on in vitro markers of activation related to tissue damage generation of reactive oxygen species (ROS), production of TNFα, IL-6 and expression of adhesion molecule, as well as in vivo effects with the peritoneal Arthus reaction.

Methods: Human or mouse (C57/Bl6) neutrophils (PMNs) and human monocytes were incubated with C5a (100nM) or model IC (heat-aggregated IgG) in a presence of cholinergic agonists, acetylcholine (Ach) (10mM), nicotine (1mM) or GTS21 (specific α7nAChR agonist) (1mM), nAchR agonist with a competitive nAchR antagonist meccamylamine, or control medium. ROS was measured by dihydrorhodamine$_{123}$ by FACS. TNF$^{\alpha}$, IL-6 levels were analyzed by ELISA. Peritoneal reverse passive Arthus reaction was initiated by injecting OVA i.v. and anti-OVA IgG i.p. After 3hrs PMN recruitment in peritoneal lavage fluid was assessed by FACS.

Results: In human PMN ligation of nAchR with $^{\alpha}$7nAChR agonist GTS21, Ach (naturally occurring nAchR ligand) or nicotine markedly inhibited C5a-induced ROS generation (vs control, 69±8%,p=0.014; 48±9%, p=0.035; 30±5%, p<0.05, respectively). This effect was partially reversed by nAchR antagonist meccamylamine. Similarly, FcγR-mediated ROS was decreased by nicotine (38±11%; p=0.029) and ROS generation by immune complexes (IC) in a presence of normal human serum, reflecting the synergism between C5aR and FcγR in PMN, was also attenuated (63±14%; p=0.029). Experiments with mouse PMN showed similar results. PMN recruitment to the sites of inflammation in response to C5aR requires upregulation CD11b, another effect inhibited by nicotine (251±46 vs. 139±20; p<0.05). At sites of IC deposition, proinflammatory cytokine release is blunted by nAchR. C5aR-triggered TNFα release by human monocytes was abrogated (9045±4402 vs. 49±10pg/mg). There was a similar, albeit less dramatic, decrease in FcγR-mediated cytokines production (TNFα 45±44%; IL-6 46±2%). In vivo effects of nAChR ligation confirmed our in vitro studies. In the peritoneal Arthus reaction, a single i.p. dose of the nAChR agonist GST21 or nicotine decreased PMN recruitment by 65% (342±50×10^6 vs. 122±29x 10^{6}cell/ml;p<0.05) and by 54% (318±27×10^6 vs. 144±7×10^{6}cell/ml;p<0.05), respectively. In addition, GTS21 decreased TNFα levels in the peritoneal fluid (35±2.4 vs. 23±3.2pg/ml).

Conclusions: Our data show that cholinergic anti-inflammatory pathway modulates responses to elements of the adaptive immune system, FcγR and C5aR. We identified nAchR as a novel target to attenuate release of oxidants, influx of inflammatory cells and generation of injurious cytokines at sites of IC deposition.

The Help of Autoantibody-Inducing CD4$^+$ T Cell and Antigen Cross-Presentation Are Required for the Full-Maturation of Cytotoxic T Lymphocyte and Subsequent Lupus Kidney Disease. Yumi Miyazaki[1], Ken Tsumiyama[1] and Shunichi Shiozawa[2]. [1]Department of Biophysics, Kobe University Graduate School of Health Science, Kobe, Japan, [2]Department of Biophysics, Kobe University Graduate School of Health Science/ Department of Medicine, Kobe University Graduate School of Medicine/The Center for Rheumatic Diseases, Kobe University Hospital, Kobe, Japan

Objective: A novel 'self-organized criticality theory' explaining the cause of systemic lupus erythematosus (SLE) of ours (Tsumiyama K. *et al.* PLoS ONE 4(12):e8382, 2009) shows that overstimulation of CD4$^+$ T cell beyond its self-organized criticality results in *de novo* generation of autoantibody-inducing CD4$^+$ T (*ai*CD4$^+$ T) cell with T cell receptor (TCR) revision. The *ai*CD4$^+$ T cells induced not only autoantibodies including rheumatoid factor (RF), anti-Sm and anti-dsDNA antibody but also full-matured cytotoxic T lymphocyte (CTL) *via* antigen cross-presentation, after which the CTL caused lupus kidney disease. Here we investigated the contribution of *ai*CD4$^+$ T cell-help to the pathogenesis of immune tissue injury, and show that *ai*CD4$^+$ T cell-help and antigen cross-presentation are both essentially required for generating full-matured effector CTL and subsequent lupus tissue injuries.

Methods: BALB/c mice were immunized 12x with ovalbumin (OVA). The mice were depleted CD4$^+$ T cells by treating anti-CD4 antibody 24 hours prior to 6x, 9x, and 12x immunization with OVA, and IFNγ$^+$CD8$^+$ T cell in spleen and proteinuria were examined. The *ai*CD4$^+$ T cell of the mice immunized 12x with keyhole limpet hemocyanin (KLH) was transferred into the CD4$^+$ T cell-depleted mice immunized 8x with OVA, and IFNγ$^+$CD8$^+$ T cell and proteinuria were examined. We also transferred pre-mature CD8$^+$ T cell of the mice immunized 8x with OVA into the mice immunized 12x with KLH to induce *ai*CD4$^+$ T cell. These recipient mice were immunized 1x with OVA and KLH, followed by treating with chloroquine to inhibit antigen cross-presentation.

Results: In the mice immunized 12x with OVA, depletion of CD4$^+$ T cells by treating anti-CD4 antibody abrogated the induction of IFNγ-producing effector CD8$^+$ T cell and lupus kidney disease. To test whether this CD4$^+$ T cell-mediated help is mediated by *ai*T cells or antigen-specific T cells, we have transferred CD4$^+$ T cells from mice immunized 12x with KLH into the CD4$^+$ T cell-depleted BALB/c mice immunized 8x with OVA. The result showed that both immune tissue injury and OVA-specific IFNγ$^+$CD8$^+$ T cells arose in these mice after transfer, indicating that *ai*CD4$^+$ T cells with *de novo* TCR revision are required for the full-maturation of CD8$^+$ T cell and lupus kidney disease. We next studied if *ai*CD4$^+$ T cell could induce effector CTL and/or tissue injury in the absence of antigen cross-presentation or not, we transferred the pre-matured CD8$^+$ T cells obtained from the mice immunized 8x with OVA, in which CTL was not full-matured, into the mice immunized 12x with KLH containing *ai*CD4$^+$ T cells. Upon booster immunization 1x with KLH and OVA, *ai*CD4$^+$ T cell, IFNγ-producing effector CD8$^+$ T cell (CTL) and proteinuria were all increased. However, when chloroquine which inhibits antigen cross-presentation was added, IFNγ-producing effector CTL and proteinuria were both abolished, indicating that *ai*CD4$^+$ T cell-help and antigen cross-presentation are required for the development of lupus kidney disease.

Conclusion: The help of *ai*CD4$^+$ T cell and antigen cross-presentation are *sine qua non* for the full-maturation of effector CTL and subsequent lupus kidney disease.

Unique Role of the FcγRI (CD64) Cytoplasmic Domain in Mediating Phosphorylation Dependent Lipid Raft Localization. Andrew G. Gibson[3], Xinrui Li[3], Jeffrey C. Edberg[2] and Robert P. Kimberly[1]. [1]Univ Alabama at Birmingham, Birmingham, AL, [2]University of Alabama at Birmingham, Birmingham, AL, [3]University of Alabama at Birmingham

The overproduction of type I Interferon and systemic inflammation in lupus patients correlates with increased monocyte surface expression of FcγRI (CD64), a receptor for both IgG and C reactive protein (CRP). Despite signaling through the common ITAM motifs shared by other activating FcγRs, FcγRI mediates distinct cellular programs such as the cell surface cleavage and release of functional soluble BLyS/BAFF upon FcγRI cross-linking by CRP or IgG. To explore the mechanism(s) of additional unique

FcγRI properties, we probed the critical contributions of the distinct cytoplasmic tail (CY) of FcγRI α-chain in inducing receptor functions. Unlike other FcR, the FcγRI CY domain contains serine residues that are phosphorylated by CK2 in vitro, and the cytoplasmic domain of FcγRI is constitutively phosphorylated in resting cells. As a consequence, the binding of protein 4.1G, a novel partner associated with FcγRI α-chain CY but not with other FcR CY, is greatly promoted when FcγRI CY is phosphorylated. Since other members of the protein 4.1G family (the Four.1 protein, Ezrin, Radixin, Moesin (FERM) family) have been shown to facilitate lipid raft association of TCR and BCR to promote formation of immunological synapses, we hypothesized that serine phosphorylation of FcγRI CY with increased association with protein 4.1G would further promote the ability of FcγRI to associate with lipid rafts. Consistent with earlier reports, we observed that FcγRI constitutively resides in lipid rafts in macrophages transfected with human FcγRI. However, in cells transfected with a mutated form of human FcγRI lacking the ser-based CK2 phosphorylation site(s), FcγRI was distributed predominately outside of lipid microdomains, indicating that phosphorylation of FcγRI CY is required for lipid raft colocalization. These results are consistent with a role for protein 4.1G in tethering FcγRI within lipid rafts. The phosphotyrosine-based γ-chain signaling plus the phosphoserine-based α-chain signaling form a unique FcγRI signaling pathway. These results provide additional insights into the unique signaling potential of FcγRI that can explain the previously documented unique functional potential of FcγRI. Further mechanistic studies into the regulation of FcγRI function will allow a determination of the importance of increased expression of this receptor in patients with lupus.

A Prospective Study of Correlates of Axial Gout. Rukmini M. Konatalapalli[4], Elena Lumezanu[3], James Jelinek[3], Mark Murphey[1], Elizabeth Carter[2] and Arthur Weinstein[3]. [1]Armed Force Institute, [2]Medstar Health Research Institute, [3]Washington Hospital Center, [4]Washington Hospital Center, DC

Objective: Axial gout is considered to be a rare manifestation of gouty arthritis. In our earlier retrospective study we found prevalence of axial gout to be 14%. This prospective study was done to determine the prevalence of axial gout in a population of patients with established gouty arthritis and to analyze potential clinical, laboratory and radiological correlates.

Methods: Forty eight subjects with a history of gouty arthritis (ACR criteria) for 3 or more years and who had an attack of acute gouty arthritis or had hyperuricemia in the previous year, were included. Subjects were questioned about back pain, examined clinically for arthritis, joint deformities and subcutaneous tophi, and had radiographs of the hands and feet, as well as computerized tomographic (CT) scan without contrast (the preferred imaging modality to detect gouty erosive disease in the spine) of the cervical spine, lumbar spine and sacroiliac joints (SIJs), serum uric acid level and serum creatinine. CT scans were read by one of three radiologists who were blinded to results of the radiographs and the radiographs were read by an experienced rheumatologist (AW) who had no knowledge of CT scan results. Patients with characteristic erosions and/or tophi in the spine or SIJs were considered to have axial or spinal gout. For statistical analysis Fisher's exact test and Wilcoxon Two-Sample tests were used.

Results: Seventeen patients (35%) had CT scan evidence of spinal gout-erosions and/or tophi. Tophi in the axial skeleton were identified in 7 of the 48 subjects (14.6%). In the entire studied population the mean age was 61years, mean duration of gout was over 10years in 26 (54%) and less than 10years in 22 (46%), mean serum uric acid level was 7.7mg/dl and 22 (46%) had clinical tophi. Thirty five (73%) were men and 42 (87%) were African American. No correlations were found with these variables and spinal gout nor was there any correlation with the presence of back pain which occurred in 24 (50%) patients. The location of the characteristic CT changes of axial gout was 7 (42%) cervical, 16 (94%) lumbar and 1 (6%) SIJs. Fourteen patients (82%) had axial gout in more than one location. Abnormal hands and feet radiographs were found in 21 (44%) patients and strongly correlated with CT scan evidence of axial gout ($p < 0.0005$). All patients with tophi in the spine had abnormal hand and/or feet radiographs ($p<0.005$).

Conclusion: Axial gout may be a common feature of gouty arthritis, at least in our predominantly African American population with poorly controlled gouty arthritis. The lack of correlation with clinical back pain, the use of magnetic resonance imaging rather than CT imaging in patients with back pain and the lack of recognition of the problem of spinal gout by physicians, suggest that this diagnosis is often missed.

Acute Gout Results in Increased Plasma Myeloperoxidase: A Potential Mechanism for Increase Cardiovascular Risk? Lisa K. Stamp[1], Irada Khalilova[2] and Tony Kettle[2]. [1]University of Otago, Christchurch, New Zealand, [2]University of Otago

Background: Gout is the most common form of inflammatory arthritis in men >40 years age. While the joint manifestations of gout dominate, patients with gout have a substantially increased risk of cardiovascular disease (CVD). However, not all of the increase is explained by traditional cardiovascular risk factors. Myeloperoxidase (MPO), which is released from neutrophils as part of the inflammatory process, has been implicated in the pathogenesis of CVD and is associated with coronary artery disease. The aim of this study was to determine whether MPO concentrations were increased in patients with acute and/or controlled gout.

Methods: 40 patients with gout (20 with acute gout, 20 with inter-critical gout) and 12 healthy controls were recruited. Plasma was assayed for urate, MPO protein and MPO activity. Urate was measured by HPLC and MPO protein and activity by ELISA.

Results: 4/12 healthy controls (HC), 17/20 acute gout and 19/20 inter-critical gout patients were male. The age (mean (range)) was 40.5 years (20–52) HC, 55.5 years (34–91) acute gout, and 63.2 years (42–82) inter-critical gout. As expected plasma urate was significantly higher in the subjects with acute gout ($465 \pm 101 \mu M$) as compared to those with inter-critical gout ($357 \pm 87.8 \mu M$) ($p<0.05$). Plasma MPO protein was significantly higher in patients with acute gout compared to healthy controls, but not significantly different from those with inter-critical gout. MPO activity was significantly increased in patients with acute gout as compared to those with inter-critical gout and HC (Figure 1).

Conclusions: MPO is released during the acute inflammatory response associated with gout flare. This increase in MPO provides another mechanism for the increase in cardiovascular disease seen in gout patients. More active MPO in patients with acute gout may contribute to oxidative stress in the vasculature and the increased CVD risk. Further studies are required to determine the association between MPO and CVD in patients with gout.

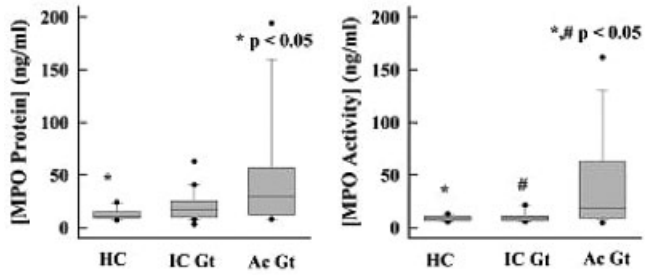

Figure 1. Plasma MPO protein and activity in 12 healthy controls (HC), 20 patients with inter-critical gout (IC Gt), and 20 patients with acute gout (Ac Gt). Comparisons were made using ANOVA on ranks and Dunn's method for post-hoc analysis.

A-SAA Induces Cytokine Production and Matrix Metalloproteinase Activity in Adipose and RA Synovial Tissue. Jennifer McCormick, Ronan M. Mullan, Mary Connolly, Chin Teck Ng, Ursula Fearon and Douglas J. Veale. Dublin Academic Medical Centre, Dublin, Ireland

Background: Rheumatoid Arthritis (RA) is associated with a significant increase in cardiovascular (CV) mortality. Serum Amyloid A (A-SAA), an acute phase protein with cytokine-like properties is increased 1000 fold

during inflammation. Previously we showed A-SAA correlates with RA disease activity and is produced at high levels in the synovial joint. Elevated A-SAA production has been observed in metabolic syndrome in adipose tissues (AT) of type II diabetics but to date the role and regulation of A-SAA in human AT remains to be fully elucidated.

Aim: To examine the relationship of A-SAA to CV risk in RA and whether a common pro-inflammatory pathway exists for A-SAA in RA and obesity.

Methods: Forty RA patients were recruited and assessed at baseline, 0.5, 1 and 4 years. RA disease activity measures and paired serum were collected. Baseline CV risk criteria were obtained and CV events were recorded in follow up. A-SAA serum levels were quantified by specific ELISA. Adipose tissue was obtained under direct visualisation from patients undergoing bariatric surgery or colonoscopy and primary adipocytes and whole tissue adipose explants were cultured. RA synovial biopsies were obtained at arthroscopy and whole tissue synovial explants established. Cell cultures were incubated in the presence of A-SAA (10–50 g/ml) and interleukin-6 (IL-6) and interleukin-8 (IL-8) production were quantified by specific ELISA. Matrix metalloproteinase-2 and −9 activation were assessed by gelatin zymography.

Results: RA patients who developed CV events up to 4 years later had significantly higher baseline A-SAA levels ($p<0.05$) which remained elevated in the follow-up period. No significant difference was found in traditional CV risk factors. A-SAA (10 and 50 g/ml) increased baseline production of IL-8 from 1528588 to 5194462 and 10963497 pg/ml and IL-6 from 549564 to 3392226 and 6629568 pg/ml in adipose tissue explant cultures in vitro. In adipocyte cultures, A-SAA (10 g/ml) markedly increased levels of IL-8 from 21495 to 33333 pg/ml and IL-6 from 4483 to 7566 pg/ml. Furthermore, a dramatical increase in MMP-9 activation was observed in adipose tissue explants, an effect greater than that on MMP-2 activity. Similar to adipose tissue cultures a dramatical upregulation of IL-8 from 1948 to 4739 and 5075 pg/ml production and activation of MMP-2 and 9 was demonstrated in RA synovial explant cultures in response to A-SAA (10 and 50 g/ml).

Conclusion: High serum A-SAA levels are associated with increased cardiovascular events over a 4 year period. Ex-vivo/in vitro A-SAA induced similar pro-inflammatory pathways in synovial and adipose tissue, which may represent common pathogenic pathways in RA and metabolic syndrome.

Association of Vitamin K and Chondrocalcinosis of the Knee: The MOST and Framingham Osteoarthritis Studies. Devyani Misra[3], Sarah L. Booth[8], Micheal LaValley[3], Irina Toltsykh[6], Micheal Nevitt[6], C. Elizabeth Lewis[5], James Torner[7], Piran Aliabadi[4], David T. Felson[2] and Tuhina Neogi[1]. [1]Boston Univ Schl of Med, Boston, MA, [2]Boston University School of Medicine, Boston, MA, [3]BUSM, Boston, MA, [4]BWH, Harvard University, Boston, MA, [5]UAB, Birmingham, AL, [6]UCSF, San Francisco, CA, [7]U-Iowa, Iowa City, IA, [8]USDA HNRCA, Tufts University, Boston, MA

Purpose: Vitamin K (VK) plays a key role in regulation of calcification in soft tissue. A knockout mice model demonstrated that in absence of a VK–dependent protein (MGP), there was excessive calcification of cartilage. Because chondrocalcinosis (CC) has a low prevalence in the general population, we studied the association of VK with CC in two cohorts: The Multicenter Osteoarthritis (MOST) Study and the Framingham Osteoarthritis Study, to obtain sufficient numbers for this study.

Method: Participants were from the MOST Study (cohort of persons with or at high risk for knee osteoarthritis (OA) and the Framingham Osteoarthritis Study (community-based cohort unselected for OA) who had knee x-rays obtained and serum VK (phylloquinone) measured. X-rays for both studies were read for presence of CC at baseline and follow up visits by the same academically based MSK radiologist. A person was classified as having CC if it was present in either knee at either of two time points. We examined the association of VK with prevalent CC in both cohorts combined, with VK assessed as 1) dichotomous variable, deficient (serum phylloquinone <0.5 nM) vs not deficient and 2) quartiles, using Poisson regression to calculate prevalence ratios (PR), adjusting for age, sex, BMI, BMD, 25(OH)-D, warfarin use, race, cohort and history of knee injury. We also performed local regression (LOESS), which avoids assuming a parametric form, plotting phylloquinone concentrations (log-transformed) against prevalence of CC. Effect measure modification by cohort was tested separately.

Result: Among 1795 participants (1180 from MOST, 615 from Framingham; mean age 59±9.2 yrs, 59% women, mean BMI 29±5.6 kg/m^2, mean serum phylloquinone concetration 1.7±1.8 nM, range 0–22nM), there were 126 subjects with prevalent CC. Those who were VK deficient had 40% higher prevalence of CC compared with those who were not VK deficient, although this was not statistically significant (PR 1.4, 95% CI 0.8–2.4, $p=0.3$), and did not change with exclusion of warfarin users. Although all VK deficient individuals (n=173) were in the lowest quartile of VK, the analysis using serum VK quartiles did not demonstrate a dose-response relation, but rather suggested a potential U-shaped relation (adjusted PR: 1.0 (ref), 0.8, 0.9, 0.9 for quartiles 1 through 4, respectively). However, the local regression plot did not suggest any linear or other association (Fig. 1). There was no effect measure modification by cohort.

Conclusion: Although there seems to be a plausible biologic rationale for an association of deficient VK with CC, we were unable to find such an association in our study using serum phylloquinone. Because this association remains unclear, further studies are warranted to explore potential effects of VK on extra-skeletal mineralization, using different measures of VK.

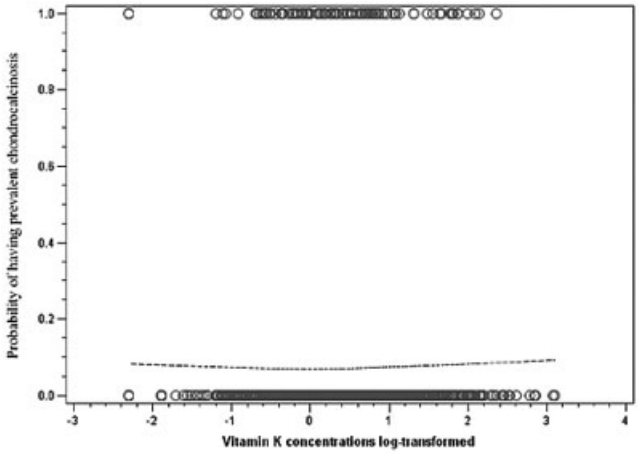

Fig. 1. Local regression (LOESS) plot of association of vitamin K with prevalent chondrocalcinosis.

Calcium Pyrophosphate Crystal Arthritis (CPPA) Is a Frequent Cause of "Refractory Gout". Fernando Perez-Ruiz[1], Ana M. Herrero-Beites[3], Alberto Alonso-Ruiz[2] and Marcelo Calabozo[2]. [1]Hospital de Cruces, Jopelana, Spain, [2]Hospital de Cruces, [3]Hospital de Górliz

Background: Proper treatment of hyperuricemia of gout is associated with a reduction in the number of flares to less than 10% of patients after 12-month therapy suffer from gout flares (Schumacher HR, Rheumatology 2009, Becker MA, J Rheumatol 2009).

Objective: to evaluate the impact of coexistent CPPA in joint flares in patients with gout.

Methods: analysis of data from a cohort of 610 patients with a diagnosis of gout based on monosodium urate (MSU) crystal observation and who showed proper control (serum urate <6 mg/dl) of uric acid at 12-month follow-up, and colchicine prophylaxis stopped. CPPA was defined as presence of CPP crystals in the cytoplasm of white cells in synovial fluid (SF) samples and radiographic chondrocalcinosis. Microscopy procedures for observation and identification of MS and CPP crystals included normal light and polarized light with first order red compensator 400x. Contrast-phase 400x and 1000x microscopy was used was used in addition to further investigate SF samples negative for crystals with normal and polarized microscopy.

Results: 23/610 (3.8%) patients with crystal-proven gout also had a diagnosis of CPPA. Of them, 6 showed both MSU and CPP crystals in the same synovial fluid sample, prior or during the first year of urate-lowering treatment, so they were maintained on colchicine prophylaxis and not included in further analysis. The remaining 17 patients showed CPP crystals during further follow-up, CPPA appearing at mean follow-up of 40±16 months (range 18 to 94). Overall, 49/610 (8.03%) patients had at least an episode of acute arthritis that was attributed to "refractory" gout, 17/49 (34.7%) showing CPP crystals in the cytoplasm of leukocytes and Xray chondrocalcinosis. There was no difference in any feature in patients with gout vs. patients with gout+CPPA, except for mean age (59±12 vs.

71±12 years), BMI (28.1±3.6 vs.26.5±3.3 kg/m^2), and clearance of creatinine (87±33 vs. 62±30 ml/min).

Conclusions: definite CPPA in patients with crystal proven gout is found in up to 4% of patients with gout. CPP arthritis comprised for one third of the flares that appeared after 1-yr control of hyperuricemia. Synovial fluid samples should be obtained and carefully studied before considering "refractory gout" diagnosis.

Clinical and Genetic Subtypes of Hyperuricemia in a Renal Transplant Cohort. Gabriela Hernandez-Molina, Julio Granados, Adriana Torres, Antonio Cachafeiro-Vilar and Marina Rull-Gabayet. Instituto Nacional de Ciencias Medicas y Nutricion, Mexico City, Mexico

Background: Hyperuricemia, a highly frequent condition (84%) in renal transplant (RT) patients, has been mainly associated with the use of calcineurin inhibitors. We reported a higher incidence of gout in patients with hyperuricemia pre-transplant than patients who developed this condition after the allograft (19.7 vs. 2.6 ×1000 patient-years). The use of cyclosporine and tacrolimus were not the major variables linked to this finding.

Objective: We hypothesized that a specific HLA background may influence the development or not of hyperuricemia in RT patients.

Methods: We included 162 RT patients with at least one year of follow-up post-transplant. Hyperuricemia was defined as at least one elevated serum uric acid determination of >6 mg/dl in women and >7 mg/dl in men. Patients were divided in groups: 1) without hyperuricemia pre-transplant but with it after the allograft (n=40), 2) without hyperuricemia pre and post-transplant (n=28) and 3) with established pre-transplant hyperuricemia (n=94). HLA class I (HLA-A, HLA-B) and HLA class II (HLA-DRB1, HLA-DQB1) were assessed by a PCR-SSP procedure. Gene frequencies were compared using the Mantel-Haenszel chi-square or Fisher's exact test. HLA allele and haplotype frequencies were obtained by gene counting. Hardy–Weinberg (HW) equilibrium and LD (Arlequin ver. 2.0) as well as admixture estimations using the HLA-B typing in a trihybrid model with the *maximum likelihood* method (Leadmix software) were calculated. Ethnic-specific HLA-A/-B/-DRB1/-DQB1 haplotypes in a Mexican-mestizo parental population (n=381) were used as controls.

Results: The mean follow-up of the cohort was 4.7±2.9 years. Group 1 had a tendency to be increased of HLA-B*35 and B*39 as compared to Group 2 (p=0.07). HLA-B*35 and B*39 were significantly increased in Group 2 as compared to Group 3 (p=0.04, RR=1.6, CI 95%=1.0–2.7); likewise these alleles were also significantly increased in Group 2 as compared to ethnically matched healthy controls (p=0.008, OR=2.3, CI 95%=1.2–4.4 for B*35; and p=0.03 OR=2.3, CI 95%=1.0–4.8 for B*39). The HLA-B*07 allele was significantly increased in Group 3 as compared to healthy controls (p=0.03, OR=2.1, CI 95%=1.0–4.5). None patient belonging to Group 2 was positive for HLA-B*07. Group 2 also had an increased frequency of HLA-DR*08 as compared to healthy controls (p=0.04, OR=2.1, CI 95%=1.0–4.4) that was independent for that observed in alleles at the HLA-B locus. The frequency of the rest of the HLA-B and HLA-DR alleles as well as the haplotype analysis was similar among groups.

Conclusion: The hyperuricemia observed in RT patients is clinical and genetically heterogeneous, suggesting subgroupsof patients with different physiopathogenic mechanisms. Typing for the MHC alleles might select patients highly sensitive or refractory for its development and may help in the selection of immunosuppressive and hypouricemic treatments.

Diffuse Calcium-Containing Crystal Deposits in Human Osteoarthritic Articular Cartilage: Not Limited to the Medial Compartment. Christelle Nguyen[4], Hang-Korng Ea[4], Didier Hannouche[2], Michel Daudon[3], Dominique Bazin[1] and Frédéric Lioté[4]. [1]Laboratoire de Physique des Solides; Paris Sud University; Orsay; France, [2]Orthopaedic Surgery Department; Lariboisière Hospital; Paris Diderot University; Assistance Publique-Hôpitaux de Paris (AP-HP), Paris, [3]Service de Biochimie A; Necker Hospital; Paris Sud University; AP-HP; Paris, [4]UMR-S 606, INSERM & Paris Diderot University; PRES Sorbonne Paris-Cite; Lariboisiere Hospital; Paris; France

Purpose: Calcium-containing crystals (CC), including basic calcium phosphate crystals (BCP) and calcium pyrophosphate crystals (CPP) are associated with destructive forms of osteoarthritis (OA). Recent reports showed that mineralization of articular cartilage of the medial compartment is an indissociable process of end-stage OA. However, accurate characterisation of CC by conventional techniques remains challenging.

Objectives: To assess biochemical composition and spatial distribution of mineral phases in human OA cartilage, and to determine their morphological aspects.

Methods: Fourteen patients (12 women and 2 men), who underwent total knee joint replacement for primary OA, were prospectively included. A 24-year-old woman who underwent total knee joint replacement for chondrosarcoma served as control. Specimen included femoral condyle and tibial plateau cartilages, from both medial and lateral compartments. Clinical data and preoperative knee X-rays were obtained. For each femoro-tibial compartment, 4 samples (2 from femoral condyles and 2 from tibial plateau) were collected, consisting in 1-mm-thick slices. Slices were cut tangentially to the articular surface, within the superficial and deep layers of the articular cartilage, respectively. Biochemical composition was assessed using Fourier-transform infra-red (FTIR), and morphological aspects were determined using scanning electron microscopy (SEM). All results are expressed as mean (SD).

Results: Age and body mass index at the time of intervention were 74.4 (8.3) years, and 28.8 (6.2) kg/m^2, respectively. Preoperative X-rays found uni-, bi- or tricompartmental knee OA in 2, 8 and 4 cases, respectively. In all cases, the compartment mainly affected was medial femoro-tibial, and Kellgren and Lawrence score was 3.8 (0.4). Joint calcifications were detected in only 2 cases on preoperative X-rays, but in 11 cases under macroscopic examination. FTIR analysis showed CC in all 14 specimens. CC were absent from the control sample. The overall mineral content represented 9.1 (12.6)%. CC were identified as BCP only in 6 patients, and as both BCP and CCP in 8. Remarkably, CC were widespread in all knee joint compartments and involved at least 3 areas out of 8 in all specimens. In addition, CC distribution was similar between superficial and deep layers, and between medial and femoral compartments (11.1 [14.7]% vs 7.3 [10.2]%, and 8.1 [11.2]% vs 9.5 [13.1]%, p=NS, respectively). Finally, SEM identified 2 different morphological aspects: 1/spherical structures, typical of biological apatite, resulting from an agglomeration of nm-scale cristallites surrounded by proteins, and localized in structures suggestive of chondrons, in the BCP-containing samples; 2/ acicular or cubic structures of different sizes, in the CPP-containing samples.

Conclusions: CC are constantly found in human OA articular cartilage at the time of knee joint replacement. Cartilage calcifications occur in all knee joint compartments, even in less weight-bearing ones, suggesting that cartilage mineralization process may reflect a generalized chondrocyte disease. In addition, their morphological aspects are specific to the crystal type.

Factors Associated with an Acute Attack of Chronic Gout without Hyperuricemia. MinWook So[1], SeungGeun Lee[3], YongGil Kim[3], ChangKeun Lee[3], HeeBom Moon[3], Jiseon Oh[4] and Bin Yoo[2]. [1]ASAN Medical Ctr, Seoul, Korea, Republic of, [2]ASAN Medical Ctr, Seoul, Korea, Republic of, [3]ASAN Medical Ctr, [4]Ulsan University

Background: Gout is a disease caused by deposition of monosodium urate crystals in articular and periarticular tissues. Hyperuricemia has been reported to be closely linked to the development and recurrence of gouty arthritis. Although, theoretically, gout cannot develop without hyperuricemia, there have been reports of development of gout without hyperuricemia. And in the clinical setting, some patients receiving a urate-lowering agent for chronic gout have experienced recurrent attacks of gout without hyperuricemia.

Purpose: To identify the factors associated with an acute attack of chronic gout without hyperuricemia.

Method: We reviewed the medical records of 860 patients with chronic gout and who regularly received allopurinol at one tertiary hospital from 2003 to 2009. Among these 860 patients, 135 maintained a serum urate level less than 6.0mg/dl. To minimize the effect of serum urate level change, we excluded all patients whose serum urate level exceeded 6.0mg/dl at least once. We divided the study patients into an Attack group (n=51) and a No-attack group (n=84). The patients who experienced an acute attack, even though with normouricemia (≤6.0mg/dl) at least once during follow-up period, were classified as the Attack group. The others were classified as the No-attack group. We prescribed colchicine to prevent gout attacks during the first six months of the study, and attacks which occurred during this period were not included.

Results: Fifty-one (37.8%) patients experienced at least one recurrence of an acute attack without hyperuricemia during the follow-up period (Attack group).

The remaining 84 (62.2%) patients never experienced an acute gout attack (No-attack group). During the follow-up period, the sampling frequency was similar in the two groups. The baseline characteristics of the patients in each group, including age, alcohol drinking, hypertension, chronic kidney disease, heart disease, type II diabetes mellitus, diuretics, and aspirin therapy showed no significant difference in the two groups. The presence of tophi and the number of involved joints were strongly associated with acute attacks of chronic gout without hyperuricemia, respectively (OR 5.9, P=0.001 and OR 1.7, P=0.001). On multivariate analysis, the presence of tophi and the number of involved joints were also independently associated with acute attacks of chronic gout, respectively (OR 4.2, P=0.010 and OR 1.5, P=0.028).

Conclusion: Our study revealed that the presence of tophi and multiple joint involvement were associated with acute attacks of chronic gout without hyperuicemia. We, therefore, recommend that patients with these risks should maintain a lower target level of serum urate.

Hyperuricemia and Gout: Nature Versus Nurture. Eswar Krishnan[3], Christina N. Lessov-Schlaggar[4], James F. Fries[2], Ruth Krasnow[1] and Gary E. Swan[1]. [1]SRI International, [2]Stanford Univ Medical Ctr, Palo Alto, CA, [3]Stanford University, Palo Alto, CA, [4]WUSTL

Background: Hyperuricemia and gout are known to have both genetic and environmental components in their etiology. However the relative significance of each has not been well studied.

Methods: We performed heritability analyses of hyperuricemia (SUA>7.0 mg/dL) and gout (self-reported physician diagnosis and/or use of gout medications) among the participants of a twin study. This study prospectively observed 508 twin pairs (253 monozygotic, MZ, and 261 dizygotic, DZ) over a period of 34 years. Pairwise-correlation was measured using Spearman's correlation coefficient. The relative contribution of genetic and environmental influences on phenotypic variance was estimated using standard twin methodology implemented in Mx software (PMID: 8024529).

Results: The mean (±SD) age of the cohort was 48 (± 3) years at baseline. The baseline prevalence of gout and hyperuricemia were 3.1% and 24%, respectively. The cumulative incidence of gout did not differ between MZ and DZ twins (11.1% and 10.9%). The concordance of hyperuricemia was 56% in MZ and 31% in DZ twin pairs (p<0.001). Twin modeling showed little to no genetic influences on individual variability in gout, but substantial influence of environmental factors shared between co-twins. In contrast, individual differences in hyperuricemia were influenced by significant genetic factors with little to no evidence for an effect of shared environmental factors.

Relative contribution of genetic (A), shared environmental (C) and non-shared environment (E) influences on dichotomous measures of gout and hyperuricemia

Model	A (95% CI)	C (95% CI)	E (95% CI)	χ^2	df	p	AIC	χ^2 diff	df diff	p diff
Gout										
ACE	0 (0, 55.0)	45.0 (0, 61.7)	54.6 (35.5, 73.6)	0.710	3	0.871	−5.290

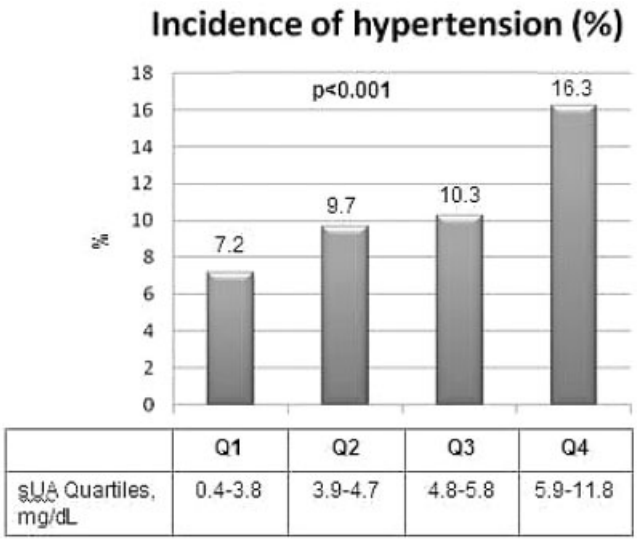
Hyperuricemia as a Risk Factor for Hypertension among Young Adults without Metabolic Syndrome. Eswar Krishnan[1], Bhavik Pandya[2], Ali Hariri[3] and Omar Dabbous[2]. [1]Stanford University School of Medicine, Stanford, CA, [2]Takeda Pharmaceuticals International, Inc, Deerfield, IL, [3]Takeda Pharmaceuticals North America, Inc, Deerfield, IL

Objective: Hyperuricemia has been shown to cluster with components of metabolic syndrome. A previous study[1] documented that hyperuricemia is a risk factor for hypertension independent of metabolic syndrome among middle-aged adults (aged 35–57). The objective of this analysis is to assess whether hyperuricemia is a predictor of hypertension independent of metabolic syndrome in young adults.

Methods: We analyzed data from the CARDIA (Coronary Artery Risk Development in Young Adults) cohort, a prospective observational study of 5,115 individuals in the community who were aged 18–30 years at baseline and followed for 15 years (1986–2001) with visits 2–5 years apart. We excluded individuals with hypertension (per The Seventh Report of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure [JNC 7] criteria) or any other components of metabolic syndrome (Third Report of the Expert Panel on Detection, Evaluation, and Treatment of High Blood Cholesterol in Adults [ATP III] criteria) at baseline. The serum urate (sUA) cutoffs for quartiles were <3.9; 3.9–4.7; 4.8–5.8; and >5.8 mg/dL. Multivariate Cox regression analyses were utilized to adjust for the effects of potential confounders such as age, gender, race, serum creatinine concentration, and waist circumference.

Results: Data from 4,918 participants were included in this analysis; 45% were men, and 51% were African American. Baseline mean (standard deviation) for age, body mass index, sUA concentration, and systolic and diastolic blood pressure were: 25 (4) years; 24 (5) kg/m^2; 5 (1) mg/dL; and 110 (10) mmHg and 68 (9) mmHg, respectively. The incidence of hypertension increased with succeeding sUA quartiles (Figure).



In multivariable regressions, the hazard ratio (95% confidence interval) for the second, third, and top quartiles of sUA concentration compared with the bottom quartile were: 1.2 (0.9–1.7); 1.5 (1.1–2.1); and 1.8 (1.2–2.6), respectively.

Conclusions: The incidence of hypertension was higher with increase in sUA. Hyperuricemia is an independent predictor of hypertension among young adults and is independent of metabolic syndrome.

Individuals in the US General Population with Gout and Hyperuricemia Have Significantly Higher Comorbidities: The National Health and Nutrition Examination Survey (NHANES) 2007–2008. Bhavik Pandya[2], Yanyan Zhu[1] and Hyon Choi[1]. [1]Boston University of School of Medicine, Boston, MA, [2]Takeda Pharmaceuticals International, Inc, Deerfield, IL

Objective: While the comorbidity burden of gout and hyperuricemia in the US has been considered substantial and has increased over the past decade, no contemporary data are available. The objective of the study was to estimate current prevalence of major comorbidities according to both gout status and hyperuricemia status based on NHANES 2007–2008 data.

Methods: Using data from 5,707 participants (2,797 men and 2,910 women) aged 20 years and older from NHANES 2007–2008, we determined the prevalence of major comorbidities according to both gout and hyperuricemia status, including hypertension, renal impairment, nephrolithiasis, diabetes, myocardial infarction, heart failure, stroke, and obesity. Obesity was defined as body mass index $\geq$30 kg/m^2. Other comorbidities and gout were defined based on an affirmative answer to a question asking if a physician or a health professional had diagnosed the corresponding condition. The primary NHANES definition of hyperuricemia was serum urate level >7.0 mg/dL in men and >5.7 mg/dL in women.

Results: Among the US adults with both gout and hyperuricemia, 78% had hypertension, 9% renal impairment, 20% nephrolithiasis, 27% diabetes, 12% myocardial infarction, 12% heart failure, 12% stroke, and 56% obesity (Table). These prevalences were substantially higher than those among individuals without gout or hyperuricemia. Having hyperuricemia was associated with a higher prevalence of comorbidities among individuals without gout. A similar trend was observed among individuals with gout, although the patterns are more difficult to characterize accurately due to smaller sample sizes (Table).

Table. Prevalence of Comorbidities According to Hyperuricemia and Gout in NHANES 2007-2008

	Gout		No Gout	
Comorbidities	Hyperuricemia	No Hyperuricemia	Hyperuricemia	No Hyperuricemia
Hypertension	77.7 (66.6-88.8)	70.8 (60.8-80.8)	47.2 (43.0-51.4)	24.3 (21.8-26.7)
Renal Impairment	8.8 (4.4-13.3)	4.1 (2.0-6.1)	3.1 (2.1-4.2)	1.8 (1.4-2.3)
Nephrolithiasis	20.2 (10.3-30.2)	26.2 (15.6-36.9)	11.6 (8.9-14.3)	7.8 (6.7-8.8)
Diabetes	26.9 (9.7-44.1)	21.4 (14.9-28.0)	12.2 (8.7-15.6)	6.7 (5.4-8.1)
Myocardial Infarction	11.6 (4.5-18.7)	14.1 (10.9-17.3)	4.5 (3.3-5.6)	2.6 (1.8-3.1)
Heart Failure	11.7 (5.1-17.4)	8.2 (4.4-12.0)	4.5 (3.4-5.5)	1.4 (0.8-2.0)
Stroke	11.8 (0.4-23.1)	8.0 (3.3-12.7)	5.1 (3.6-6.7)	2.3 (1.4-3.1)
Obesity	55.6 (45.5-65.7)	50.2 (35.7-64.7)	54.2 (49.0-59.4)	27.0 (23.9-30.1)

Conclusions: These findings from the latest nationally representative sample of US adults highlight that having gout and/or hyperuricemia substantially increases the prevalence of comorbidities. These prevalences are highest among individuals with both gout and hyperuricemia. These comorbidities add to the overall illness burden of gout and hyperuricemia to society, and provide support for consideration of these issues in optimizing gout and hyperuricemia care in the US.

Low Prevalence of Coexistent Gout and Rheumatoid Arthritis in a Population of Veterans. Armine Tumyan[1], Kara H. Prescott[2] and Andreas M. Reimold[1]. [1]Dallas VA Medical Center and Univ of TX Southwestern Med Ctr, Dallas, TX, [2]Dallas VA Medical Center and Univ of TX Southwestern Med Ctr, Cross Roads, TX

Background: Clinical observations indicate that the coexistence of gout and rheumatoid arthritis in the same patient is rare, occurring at a lower frequency than the incidence of the two conditions would predict. Gout is a male-predominant disease with an estimated prevalence of 1 to over 7%, while the incidence of both gout and RA increases with older age. A population of veterans was studied to describe the overlap of gout and RA.

Methods: Medical records for all patients with ICD-9 codes for RA (714.0, 714.2 and 714.81) and gout (274.xx) from 01/01/1999-12/31/2007 were identified and reviewed in the north Texas Veteran's Integrated Service Network. In addition, a random sample of 50 gout and 50 RA patient records were reviewed for accuracy of ICD-9 codes. ACR criteria for RA and ACR 1977 Preliminary Criteria for diagnosis of gout were used, and lab data (joint fluid crystal analysis, hyperuricemia, RF, CCP), imaging, and medication use (allopurinol, DMARDs, TNF inhibitors) were documented. Patients were classified as having definite gout (joint fluid or tophi showing MSU crystals), presumed gout (met 6/13 ACR 1977 Preliminary Criteria for gout) or unlikely gout (failed to meet 6/13 gout criteria or gout was ruled out by a rheumatologist).

Results: A search of ICD-9 codes identified 2572 patients with RA codes and 8508 with gout codes, resulting in 277 patients with both RA and gout codes (overlap). By such codes, 10.8% of RA patients have a gout diagnosis, and 3.3% of gout patients have an RA diagnosis. In contrast, our longitudinal study of 545 well-characterized RA patients contained 10 with a comorbidity diagnosis of gout (1.8%) and 5 were confirmed by chart review (0.9%). Overlap patients were a mean of 71 years old, were 94.6% male, and 66.4% Caucasian. Patients with gout alone rarely saw a rheumatologist (8%, compared to 56% for patients with RA ICD-9, $p<0.001$). Definite or presumed gout was found in 40.4% of the overlap group, RA was confirmed in 19.2%, while not enough information was documented in the charts to confirm gout in 43.3% and RA in 62.4%. There were 16 cases (5.8% of 277 overlap patients) of definite or presumed gout with RA. Therefore, in this population 0.62% of RA patients had confirmed or presumed gout, and 0.19% of confirmed/presumed gout patients had RA.

	RA Registry	Veteran Population
RA ICD-9 (n)	545	2572
Gout ICD-9 (n)	10	8508
RA/Gout Overlap by ICD-9 (n)	10	277
RA confirmed in Overlap	10 (100%)	53 (19.2%)
Gout confirmed in Overlap	5 (50%)	112 (40.4%)
RA/Gout confirmed in Overlap	5 (50%)	16 (5.8%)
RA/Gout Overlap in Those With RA ICD-9	0.9%	0.62%

Conclusions: Diagnoses of either RA or gout are often assigned to patients by non-rheumatologists and frequently do not meet ACR criteria. Documentation of ACR criteria for both RA and gout in the same patient occurred in only 5.8% of patients carrying both diagnoses. Both in a general population of veterans carrying an RA ICD-9 code and a well-characterized registry of RA patients, the overlap of RA and gout was found in less than 1% of patients, a rate of gout far below the 6.5% incidence published previously for males in this age group.

Monosodium Urate Monohydrate Crystals Inhibit Osteoblast Viability and Differentiation; Implications for Development of Bone Erosion in Chronic Gout. Ashika Chhana[2], Karen Callon[2], Bregina Pool[2], Dorit Naot[2], Fiona M. McQueen[2], Jillian Cornish[2] and Nicola Dalbeth[1]. [1]Univ Auckland, Auckland, New Zealand, [2]University of Auckland, Auckland, New Zealand

Background: Bone erosion is a frequent manifestation of chronic gout, and may lead to joint damage and disability. Recent research has implicated an imbalance of bone remodeling in the development of bone erosion in gout, with enhanced formation of bone-resorbing osteoclasts in patients with erosive gout. We hypothesized that changes in the bone-forming osteoblasts also contribute to bone erosion in chronic gout. In this study we investigated the effects of monosodium urate monohydrate (MSU) crystals on osteoblasts.

Method: MSU crystals were prepared by recrystallisation of uric acid. Flow cytometry and the MTT assay were used to assess cell viability following culture with MSU crystals in the murine MC3T3-E1 and ST2 osteoblast-like cell lines, and in primary rat and human osteoblasts. Quantitative real-time PCR and von Kossa stained mineralised bone nodule formation assays were used to assess the effects of MSU crystals on the differentiation of MCT3-E1 osteoblast-like cells.

Results: MSU crystals rapidly reduced viability in all osteoblast assays in a dose-dependent manner (Figure). The inhibitory effect was maximal at the higher concentrations of 0.3 and 0.5mg/mL MSU crystals and was independent of crystal phagocytosis. The reduction of osteoblast viability was specific to urate crystals, as soluble uric acid did not alter cell viability. Furthermore, the effects on cell viability did not alter with different crystal lengths or addition of serum. Long term culture of MC3T3-E1 cells with MSU crystals showed decreased mineralisation (bone nodule formation) in a dose-dependent manner, and reduced expression of genes related to osteoblast differentiation such as *Ibsp* (bone sialoprotein), *Runx2*, *Sp7* (osterix) and *Dmp1*.

Conclusion: MSU crystals have profound inhibitory effects on osteoblast viability and differentiation. These data indicate that MSU crystals may contribute to bone erosion in gout not only through promotion of osteoclast formation, but also through reduction of osteoblast survival and function.

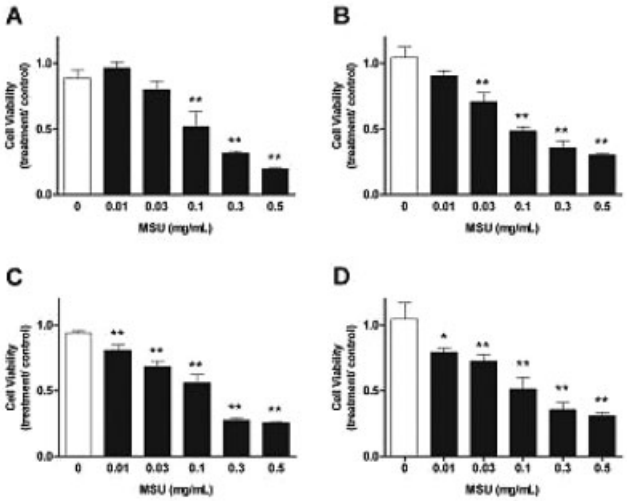

Figure. Effects of MSU crystals on cell viability in A. MC3T3-E1 cells; B. ST2 cells; C. primary rat osteoblasts; and D. primary human osteoblasts. Cell viability was assessed in the MTT assay following 26 hours of culture with MSU crystals. Data shown are mean (SEM); *p<0.001, **p<0.0001 versus control (no MSU crystals), one-way ANOVA with *post hoc* Dunnett's test.

882

Number of Flares Are Associated with Both Gastrointestinal and Vascular Complications in Patients with Gout. Another Issue for Early Intervention. Fernando Perez-Ruiz[1], Ana M. Herrero-Beites[2] and Miguel A. Gonzalez-Gay[3]. [1]Hospital de Cruces, Spain, [2]Hospital de Górliz, Spain, [3]Hospital Universitario Marqués de Valdecilla, Spain

Background: Before long-term serum urate control, patients with gout experience multiple flares that may expose them to the risk of complications, while EULAR recommendations suggest treating patients with recurrent flares or severe gout.

Objective: to evaluate risk factors associated with de development of severe vascular or gastrointestinal complications in patients with gout.

Methods: data from a prospective cohort of 787 patients with gout. Variables included age, gender, body mass index, number of flares-yr, number of joints involved, tophus present, diuretics, renal function, hypertension, diabetes, hyperlipidemia, and ethanol intake. Vascular events and BPO (Bleeding, Perforation, Obstruction) events were considered when there was a association recorded in the file of the patient with treatment of a flare or gout complaints and the event. Time from the onset of gout to the event was considered as time variable for exposure. Mantel-Hazel analysis with log-rank tests were used to select variables associated ($p<0.20$) with each group of events, and they were afterwards included in multivariant Cox proportional hazard regression analysis.

Results: mean age 58.8±12.6, 93% male, 5,352 patient-yr exposure, 31.3% tophaceous, 35.6% over 4 joint involved, 3.4±2.8 (0–24) flares-yr, 34.6% over 20 g-day ethanol intake, 42.7% hypertension, 19.6% diabetes, 41.9% hyperlipidemia, 24.2% obese. Prior urate-lowering treatment (ULT) in 38.5%. Overall, there were 65 events (1.21 per 100 patient-year exposure) in 62 patients (7.88%). There were 41 vascular events: 2 congestive heart failure, 30 acute renal failure, 2 pulmonary embolisms, and 7 ictus associated to flares or gout treatment, and 24 gastrointestinal events: 22 bleedings, 1 obstruction, and 1 perforation. The number of flares in the year previous to the event was associated with an increased risk of both vascular and BPO events. Polyarticular gout was also associated with and increased risk of BPO events, while diuretics were associated with vascular events. Higher rates of clearance of creatinine and previous urate-lowering treatment were associated with decreased risk of vascular events (Table).

Variables	Hazard ratio	95% CI limits	P
BPO			
Number of flares	1.089	1.002–1.183	0.044
Over 4 joints	9.591	3.124–29.441	0.000
Vascular			
Number of flares	1.084	1.014–1.159	0.017
Creat Clearance	0.987	0.975–0.998	0.023
Previous ULT	0.322	0.159–0.653	0.002
Diuretics	3.259	1.165–6.436	0.001

Conclusions: the number of recurrent flares in the year previous to the event was associated with an increased risk of both vascular and gastrointestinal events, which appeared in 8% of the patients. Also, polyarticular gout was associated with gastrointestinal events, while previous ULT seemed to be protective for vascular events. Early treatment of gout should be considered in recommendations.

Patients with Gout May Have a Decreased Risk of Colonic Polyps Relative to Patients with Osteoarthritis (OA): Insights from the NY VA Gout Database. Aaron Lehmann[3], Laura Schneck[4], Robert T. Keenan[1], William O'Brien[2], Daria Crittenden[2], Kristen Lee[2], Rekha Tadoori, Fritz Francois[2] and Michael H. Pillinger[4]. [1]Duke University, Durham, NC, [2]NYU Langone Medical Center, [3]NYU Langone Medical Center, Flushing, NY, [4]NYU Langone Medical Center, New York, NY

Introduction: The role of uric acid (UA) in modulating immunity is an evolving area of investigation. UA can act as a "danger signal," alerting the immune system to damaged cells (tumor and/or virally-infected cells) and triggering removal of potentially dangerous altered host. In a murine model, UA supplementation promoted, and UA lowering inhibited tumor rejection (Hu et al, Canc Res 2004). UA also scavenges singlet oxygen, which can induce tumorigenic mutations. UA also activates the inflammasome, driving IL-1β production. One of us (Francois et al, unpublished) has shown in patients with obesity (associated with elevated serum UA), IL-1β levels correlate significantly with serum levels of IFNγ, TNFα, IL-2, IL-17, and that individuals with the IL-1βT allele are less likely to have colonic polyps. Based on possible relationships between uric acid and tumor immunity in general, and uric acid, IL-1β and colonic polyps in particular, we tested whether patients with gout (a hyperuricemic state) have lower rates of colonic polyposis vs patients with OA.

Methods: Using the EMR of the New York Harbor Healthcare System (N=40,107), we identified all patients receiving an ICD-9 gout code at the Manhattan, Brooklyn and Queens VA Hospitals in New York City between 2007 and 2008. Age, sex, BMI, UA level, smoking history and colonic polyp diagnosis were collected by chart review (problem list and note review as appropriate). Patients with OA (ICD-9 diagnosis) but no gout were identified to serve as controls.

Results: 1,287 gout patients were identified, and 1,287 patients with OA/no gout were randomly selected from 3,300 potential control enrollees. Gout and OA patients were identical in mean age (71), sex (99% male), BMI (29) and smoking history (11% vs 14%, ns). Average serum UA was 7.64 (gout, n=1124) vs. 6.026 (OA, n=730) mg/dL. Gout patients had a 12-fold decrease in colonic polyp diagnosis vs OA patients. Prevalence of colonic polyp diagnosis was 0.62% (n=8) in the gout vs. 8% (n=103) in the OA group (p=0.0001, 2 tailed Fisher's exact test). Pathology reports for the two groups were: for gout, hyperplastic (4), tubular (3), tubulovillous (2), no report available (4); for OA, tubular adenoma (55), hyperplastic (16), tubulovillous adenoma (11), villous adenoma (3), tubular adenoma with focal adenocarcinoma (2), serrated adenoma (2), well-differentiated adenocarcinoma (1), colonic mucosa with lymphoid aggregate (1), leiomyoma (1), no report available (29). Patients with gout had no decrease in lung or prostate cancer diagnosis vs OA controls (0.9% vs 1% for lung cancer and 11.8% vs 12.8% for prostate cancer, respectively, both ns).

Conclusion: In this retrospective study, presence of gout was associated with a significant decrease in colonic polyp diagnosis relative to

OA/no gout patients. The effect of gout presence on polyp risk may be unique, since similar effects were not seen in two other malignancies. The role of UA in this effect remains to be determined. We are currently re-analyzing our population to account for NSAID use, and to evaluate polyposis and colon cancer rates in a subpopulation undergoing screening colonscopy.

P-Homocysteine Levels Are Independently Correlated to S-Urate but Not to Urate Lowering Treatment. Results of an Observational Study of 112 Patients with Gout. Ole Slot. Dept. of Rheumatology, Copenhagen University Hospital, Glostrup, Denmark

Background: Gout is associated with an increased incidence of cardiovascular disease (CVD). In a previous report elevated levels in plasma homocysteine (p-HCT), a marker of CVD risk, was found in a group of gouty patients [1]. P-HCT was independently correlated to s-urate. The effect of urate lowering treatment (ULT) on p-HCT is not clear. Thus, the objective of this study was to examine the levels and correlations of p-HCT and metabolic factors that might effect the levels of p-HCT in gouty patients with or without ULT.

Methods: Data including results of routine laboratory tests from patients diagnosed with crystal proven gout during 18 months in an out-patient clinic were collected and analyzed for differences in unpaired samples (+ULT *vs* -ULT) and non-parametric correlations to p-HCT. The correlations were analyzed for co-variance in a backward multivariate regression analysis.

Results: 112 gouty patients of whom 50 received ULT (allopurinol: 47, probenecid: 1, benzbromarone: 2) were included. Data are shown in Table I.

Table 1. Medians (range) [Laboratory's reference values]

	Gout, all n = 112	Gout, −ULT, n = 62	Gout, + ULT, n = 50
N, Females/Males	24/88	15/47	9/41
Age, Females/Males	76 (49–90)/60 (33–86)	75 (49–90)/58 (33–85)	77 (49–86)/63 (40–86)
P-Homocysteine μmol/l [<15.0]	18.5 (7.3–94.5)	19.0 (8.2–94.5)	17.0 (7.3–34.4)
S-Urate mg/dl [2.7–8.0]	8.2 (3.2–13.5)	8.7 (5.7–13.5)*	7.0 (3.2–13.3)*
S-Urate mmol/l [0.16–0.48]	0.49 (0.19–0.81)	0.52 (0.34–0.81)*	0.42 (0.19–0.80)*
P-Folate nmol/l [1>6.0]	15.7 (3.0–45.0)	15.5 (3.0–45.0)	16.9 (4.3–44.1)
S-Cobalamine pmol/l [> 200]	243 (89–1480)	248 (89–756)	238 (107–1480)
S-CRP mg/l [<10]	6 (4–159)	6 (4–159)	6 (4–45)
S-Creatinine μmol/l [50–90]	91 (56–263)	92 (64–263)	85 (56–193)

*: P <0.001. Mann-Whitney test.

S-urate was significantly lower in the +ULT group. No differences in p-HCT or other parameters were found between the –ULT and +ULT groups. Overall 89 patients (80%) had p-HCT over the laboratory's upper limit of the normal range. Four patients (4%) had p-folate under the lower limit of the normal range of 6 nmol/l while 75 patients (68%) had p-folate below 20 nmol/l. 35 patients (32%) had S-cobalamine below the lower limit of the normal range. 55 patients (50%) had s-creatinine above the upper limit of the normal range.

P-HCT was correlated to s-urate, p-folate, s-creatinine, age (Spearmen's rho 0.34, −0.39, 0.46, and 0.44 respectively, $p<0.001$ for all), and s-cobalamine (rho –0.2, $p<0.05$). P-HCT was not correlated to CRP and ULT. In regression analysis age, p-folate, s-creatinine, s-cobalamine, and s-urate were independent predictors for p-HCT.

Conclusion: In patients with gout p-HCT, a marker of increased risk of cardio-vascular disease, is independently correlated to high levels of s-urate and s-creatinine and low levels of p-folate and s-cobalamine. P-HCT was not correlated to ULT in this observational study although s-urate levels were lower in the group of patients on ULT. The relations between p-HCT, s-urate and ULT should be examined in future prospective controlled studies.

Rates of Meniscal Tearing Seen on Arthroscopy of Patients with Chondrocalcinosis. William Chun[1], Humaira Hussain[3], Vincent J. Zarro[1], Carolyn R. O'Connor[1] and Angel E. Checa[2]. [1]Drexel University College of Medicine, Philadelphia, PA, [2]Drexel University College of Medicine, Cherry Hill, NJ, [3]Drexel University College of Medicine

Background: Internal derangement of the knee secondary to chondrocalcinosis (CC) is well established. Although several publications have shown cases of CC with meniscal tears, there is no data about the prevalence of meniscal tears in CC and vice versa.

Methods: The study population was a cohort of 1031 consecutive outpatients who underwent arthroscopy of the knee from 1991–2006. The specific subgroup of interest was 58 knees from 58 patients (25 males and 33 females) with CC. Mechanical symptoms or failure of conservative treatment were the main indications for arthroscopy. Although the study was cross sectional in design, surgical response was prospectively evaluated. The rates of meniscal tears in patients with and without CC as well as their response to surgery were analyzed by Chi square test.

Results: The mean age of patients with CC was 67 (range 47–83) years. Most patients with CC who underwent arthroscopy had mechanical complaints or failed conservative treatment (69% and 45% respectively). Pseudogout flare was documented in 7% of cases with meniscal tear and 40% with intact meniscus. Thirty-seven knees with meniscal tear and 13 knees with intact meniscus were classified as pseudo-osteoarthritis. Trauma was present in only 7 knees with meniscal tear and in 3 knees without meniscal involvement. Patients with CC had significantly higher rates of meniscal tear compared to those without CC (74.1% vs. 28.7%, $p<0.001$). An absolute and attributable risk of tear was 74% and 8% respectively in knees with CC. Relative risk of tear in knees with CC versus knees without CC was 2.58 (95% confidence interval 2.16–3.10). Arthroscopic surgery achieved good or excellent results in 22 (55%) knees with meniscal tearing. Knees with mild changes in the hyaline cartilage and involvement of only one compartment in the knee showed better response to surgery than knees with advanced degenerative changes and involvement of more than one compartment ($p=0.004$).

Conclusion: Although the prevalence of CC in this study population was 5.6% and therefore accounted for only 8% of the tears, CC was a strong predictor for meniscal tear. These patients represent an underestimated clinical-pathological subgroup and can often be successfully managed by arthroscopy. The low frequency of trauma in this study group suggests that CC is a factor in fibrocartilage fragility leading to meniscal tearing. Future controlled studies are needed to further characterize the impact of CC in meniscal vulnerability as well as its role in the hyaline cartilage.

Screening for Hereditary Hemochromatosis in the Rheumatology Practice. Gunther Neeck[1], Helge Wernitzsch[2], Andreas Klüter[2], Martin Schulz[2] and Helmut Dotzlaw[2]. [1]Center for Rheumatology at Hospital Bad Doberan, Hohenfelde, Germany, [2]Center for Rheumatology at Hospital Bad Doberan, Germany

Objective: The most prominent features of hereditary hemochromatosis (HH) are joint pain and / or swelling, and this disease is often diagnosed by chance. We therefore systematically investigated iron metabolism in patients entering our rheumatology center for the first time over a time period of 2 ½ years in order to evaluate the incidence of HH in our rheumatology practice.

Methods: The serum concentrations of iron, ferritin, and transferrin were measured in 4244 patients and the iron-transferrin saturation was calculated. Patients with an iron-saturation > 45% and elevated ferritin levels were tested for HH by determination of mutations of the HFE-gene C282Y and H63D. If no mutations were detected and iron overload persisted we analyzed the non-HFE-genes hemojuvelin, herceptin, transferrin, transferrin receptor and ferroportin for possible mutations.

Results: Thirty seven patients showed iron overload (iron transferrin saturation > 45% and elevated ferritin). Of these, 21 patients were diagnosed as having HH by genetic analyses: 15 C282Y homozygotes, 2 H63D homozygotes, 2 compound heterozygotes C282Y/H63D, 1 homozygote for the non-HFE-gene ferroportin and 1 homozygote for the transferrin receptor 2. All patients suffered from arthralgias and 12 had typical HH-arthopathy of

the metacarpalia-phalangeal joints II and III of the hands. Most patients could be treated successfully by phlebotomy or iron chelation therapy.

Conclusions: In undifferentiated joint pain HH is an important differential diagnosis, and as such parameters of iron metabolism should be routinely determined in those patients.

Synovial Extracellular Matrix Remodeling in Experimental Model of Diabetes. Sandra Aparecida Atayde[1], Priscila Cristina Andrade[2], Sérgio Catanozi[2], Edna Regina Nakandakare[2], Marisa Passarelli[2], Ana Paula Pereira Velosa[2], Vera Luiza Capelozzi[2], Edwin Roger Parra[2], Natalino Hajime Yoshinari[2] and Walcy Rosolia Teodoro[2]. [1]University of São Paulo, São Paulo, Brazil, [2]University of São Paulo

Purpose: Diabetes mellitus has been linked to disorders of bones and joints whose etiologic mechanisms could be linked to micro vascular disease. The synovia is the most vascularized tissue in the joint, therefore, can be made more resilient to endothelial injury in diabetic process. Our purpose was to evaluate the extracellular matrix components and specially the vascular lesion in this tissue after diabetes induction in rats.

Methods: Wistar young rats, were divided into diabetic group (DG; n=15) and control group (CG; n=15). Diabetes was induced by tail injection of streptozotocin (35mg/kg), while control group received saline solution. Weight, blood glucose and plasmatic anti-carboxymethyl lysine analysis had been done after 70 days. After euthanasia, knee joints were isolated, and included in paraffin. Histological sections stained with Hematoxilin-Eosin and Picrosirius were obtained for histomorphometric analysis. Total collagen quantification of this tissue was done in Picrosirius under polarized light. The distribution of collagens I, III and V and also carboxymethyl lysine receptor were assessed by immunofluorescence and immunochemistry was used for endothelin −1 detection in synovial tissue.

Results: Higher levels of blood glucose and plasmatic anti-carboxymethyl lysine was viewed in DG when compared to CG ($p<0,05$). Moreover the final weight was lower in DG than CG($p<0,05$). Histomorphometric analysis showed increased of thick collagen content and decrease of thin collagen fibers in synovial tissue. Immunofluorescence test demonstrated increase of collagen I expressions in synovial tissue of DG. The endothelin −1 and carboxymethyl lysine receptor were highly expressed in DG synovial tissue.

Conclusion: There were intense remodeling and collagen deposition in the synovia of animals with diabetes induced by streptozotocin, which may explain the pathophysiology of musculoskeletal dysfunctions observed in diabetic patients.

The GOSPEL 1000 Study. Features of the Metabolic Syndrome in 1003 French Patients with Gout. Frédéric P. Lioté[7], Hang-Korng Ea[2], Pascal Guggenbuhl[1], Alain Saraux[6], Charles Lambert, Sabine Lanz[4], Pierre Chiarelli[3] and Sylvie Lancrenon[5]. [1]Rennes, France, [2]Paris, France, [3]Courbevoie, France, [4]Chatou, France, [5]Bourg-la-Reine, France, [6]CHU de la Cavale Blanche, Brest Cedex, France, [7]Hopital Lariboisiere, Paris, France

Background: Gout is often poorly managed in primary care settings. 2006 EULAR gout recommendations (EULARrecs) have been developed on aspects related to the management of gout, but poorly evaluated in clinical practice. A key feature present in these EULARrecs was to determine and to treat specifically the metabolic syndrome (MS). In the GOSPEL study, we aimed to assess and compare the prevalence, features and management of MS associated with gout in primary care and in rheumatology, in concordance with the EULARrecs.

Methods: A prospective national survey of 1003 patients (pts) with gout or suspicion of gout was done between September 2008 & July 2009. A panel of 398 general physicians (GP) and 109 rheumatologists (RH) was randomly selected in France, each including 2 consecutive gouty pts. A structured questionnaire, including history with predefined items, allowed to monitor ACR classification criteria, as well as EULAR management recs (proposals 2 & 3); co-morbidities (CM), mainly cardiovascular (CV); clinical evaluation (BMI, MS (FID definition)); medications at visit. MS features and management were compared with the EULAR recs.

Results: 1003 pts were included as gout. 879 pts were male (M, 88%; age: 61.6(11), mean(±SD)) and 124 female (F, 12%; age:70.2(11.9)). 810 pts (81%) were seen by GP and 193 (19%) by RH. Mean disease duration was 7.9(8.1) yrs (GP) and 8.6(9.2) yrs (RH). Gout classification ACR criteria were present in 85.2% of pts (87.3% (GP); 76.7% (RH)). 48.6% of pts had acute gout, 24.4% chronic gout. Tophi were present in 19.4%. Mean BMI was 28.4(3.8) in M (BMI≥30: 28.1%) and 28.2(5.7) in F (BMI≥30: 33.1%). Overweight was present in 51.5%. MS was present in 440 pts (47.2%; M: 46.0%, F: 55.8%); with respect to MS features (hypertension (HT) 54.5%; high glycemia 43.6%; low HDL (43.7%); high TG (40.7%)); MS prevalence was more frequent in GP pts (51.9%) vs RH (27.0%). MS severity was also higher (# criteria) in GP pts. CKD was present in 43% (CrCl <60 ml/min). Coronary heart disease was present in 8.9% and 8.4%, GP and RH pts, respectively, whereas CVA was present in 3.5% and 1.6%, respectively.

EULAR proposal (P) #2: increased calories intake was identified in 27.2% pts. Diet modifications were proposed to 149/286 obese pts (56%), and to 22.6% of the total population. High beer (n=56 pts) and alcohol intake (M: 52.4%; F: 22.8%**)** were reported by GP<RH (7% and 49%, respectively). Advices for alcohol consumption reduction were only offered to 12.6 pts. Physical activity was recommended in 54 pts (6.0%) (39: GP; 15:RH). **P#3:** CV CM were present in 71% pts. Treatment was already appropriate or given at time of clinics in 87.2% of pts, with differences between GP (89.0%) and RH (78.7%). Overall 10%, 20%, 5% of pts with dyslipidemia, diabetes, and HT, respectively, were not treated.

Conclusion: MS is more frequent and severe in French gouty pts followed in general practice. Non pharmacological recs are not appropriate. However pharmacological of key features of the MS are largely implemented. Implementation of EULARrecs for management of gout should be regularly recalled since MS and identification of risk factors are underscored by both GP and RH, with differences related to clinical practice and education.

Ultrasound Detects More Erosions in Gout Than Conventional Radiography. Ralf G. Thiele[2] and Naomi Schlesinger[1]. [1]UMDNJ/RWJMS, [2]University of Rochester, Rochester, NY

Background: Ultrasound (US) can be helpful in the assessment of gout. Typical tophaceous deposits, erosions and synovial hyperemia can be detected [1, 2]. Conventional radiography (CR) is widely used to image characteristic erosions with sharp margins and overhanging edges. However, in the detection of erosions, CR has inherent disadvantages when compared with cross-sectional imaging. In CR, a three-dimensional bony structure is summarized on a two-dimensional film. Bony erosions can therefore only be confirmed if they are seen in profile, and a break in the cortical margin is demonstrated. Cross-sectional imaging including US detects more erosions in rheumatoid arthritis (RA).

Previous studies compared 2 radiographic views with US findings. In this study, 3 radiographic views are compared with findings on standardized US examination.

Objectives: To compare detection of erosions with US and CR in chronic gout.

Methods: Retrospectively, US studies performed during a 12 months period were reviewed. 42 patients with a history of crystal proven gout, US images and CR of corresponding joints were identified. The study was limited to assessment of first MTP joints. Complete data for 62 joints were available. All US studies were performed according to published guidelines, by a rheumatologist certified in musculoskeletal ultrasound, with >15 years US experience. Linear transducers with frequencies between 14–18 MHz were used. Erosions were defined as breaks in the cortical contour of metatarsal head or proximal phalanx, seen in two perpendicular planes. Tophaceous material was defined as hyperechoic crystalline concrements with a "wet clumps of sugar" appearance. Calcified tophi were defined as hyperechoic concrements with a pronounced posterior accoustic shadow.

In contrast to previous studies, 3 different radiographic views of the feet were obtained to facilitate detection of erosions. The radiologist's final impression was counted. At the time of the study, the sonographer was unaware of the CR results.

Results: Using US, erosions were seen in 41/62 joints (66%). Using multiview CR, erosions were seen in 21/62 of the same joints (34%). Intra-articular calcification was seen in 3/62 joints (5%) using US and 3/62 joints (5%) using CR. Intra-articular tophaceous material was seen in 59/62 joints (95%) using US and 0/62 joints (0%) using CR. Tophaceous material was seen within the erosion in 36/62 joints (58%).

Conclusion: US identified almost twice as many erosions as CR in gouty joints. The addition of a third radiographic view improved the yield only marginally over previous studies that used two CR views to assess erosions in gout. If tophi calcify, they are seen both with CR and US, but uncalcified tophaceous material escapes CR visualization. Similar to findings in RA, CR remains an imperfect tool for the assessment of erosions in gout when compared with US.

A Comprehensive Tuberculosis Screening Program in Patients with Inflammatory Arthritis Treated with Golimumab, a Human Anti-TNF Antibody, in Phase 3 Clinical Trials. Elizabeth C. Hsia[4], John J. Cush[1], Eric L. Matteson[5], Anna Beutler[2], Mittie K. Doyle[4], Benjamin L. Hsu[3] and Mahboob U. Rahman[4]. [1]Baylor Research Institute, Dallas, TX, [2]Centocor Research and Development, Inc., Collegeville, PA, [3]Centocor Research and Development, Inc./Univ. of Pennsylvania School of Medicine, Wynnewood, PA, [4]Centocor Research and Development, Inc./Univ. of Pennsylvania School of Medicine, Malvern, PA, [5]Mayo Clinic, Rochester, MN

Background: Reactivation of *Mycobacterium tuberculosis* infection is a major complication in patients (pts) with inflammatory diseases treated with anti-tumor necrosis factor (TNF) agents. Screening and appropriate treatment (tx) for latent TB infection (LTBI) before initiation of TNF blockers, as well as prompt diagnosis (dx) of active TB cases, can decrease morbidity and mortality.

Objectives: To summarize active TB case reports by wk52 across 5 SC GLM studies (3 RA, 1 PsA, and 1 AS).

Methods: Pts enrolled from North & South America, Europe (Western + Eastern), Australia/New Zealand, and Asia. TB eligibility criteria included: no history of latent/active TB; no signs/symptoms of active TB; negative (-) tuberculin skin test (TST) and QuantiFERON®-TB Gold test In-Tube (QFT) *or* if newly identified +TST *or* +QFT with active TB ruled out, had tx for LTBI initiated before or at 1st dose. TST done using Mantoux method and + per local guidelines for immunosuppressed or if ≥5mm if no guidelines. All pts had chest x-ray (CXR) ≤ 3 months before 1st dose. Targeted questions for early dx of active TB were asked q4wks.

Results: Among 2294 randomized pts, 316 (13.8%) had either TST+ or QFT+ screening test and required tx for LTBI. Through wk52, none of those tx for LTBI developed active TB while on GLM. Active TB occurred in 5 pts by wk52 (Table). Cases were in countries with high background rates of TB. 2 cases occurred by wk24 and were more consistent with reactivation. There were no deaths due to TB.

Conclusion: Despite 2 screening tests and CXR, to detect LTBI, there were still cases of TB reactivation. However, given that many enrolled pts resided in TB endemic areas, the number of active TB cases may have been higher with a less conservative TB screening strategy. Even if TB screening tests are -, clinicians should remain vigilant for development of active TB after initiation of TNF blockers, as prompt dx and tx can lead to improved outcomes.

Anakinra in Adult Onset Stills Disease (AOSD). Clinically Beneficial Results in an Open, Randomized, Multicenter Study. Dan C. Nordström[3], Ann Knight[11], Reijo Luukkainen[8], Ronald V. Vollenhoven[5], Vappu Rantalaiho[9], Anna Karjalainen[7], Johan Brun[2], Anne Proven[6], Lotta Ljung[10], Hannu Kautiainen[1] and Tom Pettersson[4]. [1]Central Finland Central Hospital, Finland, [2]Haukeland University Hospital, Norway, [3]Helsinki Univerity Central Hospital, Finland, [4]Helsinki University Central Hospital, Finland, [5]Karolinska Hospital, Sweden, [6]Martina Hansens Hospital, Norway, [7]Oulu University Hospital, Finland, [8]Rauma Hospital, Finland, [9]Tampere University Hospital, Finland, [10]Umeå University Hospital, Sweden, [11]Uppsala University Hospital, Sweden

Background: AOSD is a rare systemic inflammatory disease of unknown cause characterized by spiking fevers, polyarthritis, evanescent rash, and other multiorgan involvement. The outcome is unpredictable and varies from monophasic, remitting/relapsing to chronically progressing. No etiology has emerged but high levels of pro-inflammatory cytokines (IL-1, IL-6, IL-18) involving possible polymorphisms, and acute phase reactants have been proposed as being pathogenetically relevant. Frequently, systemic immunosuppressive therapy is required for treatment, but for patients irresponsive to systemic steroids and immunosuppression, especially IL-1 suppression (anakinra) has given even striking responses. This is the first randomized study comparing IL-1 suppression therapy with traditional DMARDs.

Objectives: To follow the changes in clinical status and disease activity in patients receiving anakinra, compared to those of a traditional DMARD (methotrexate, azathioprine, leflunomide, or cyclosporin A) in addition to corticosteroids in patients with corticosteroid dependent, refractory AOSD.

Methods: Open 24 week, randomized, comparative, multicenter study. 22 patients on corticosteroids were randomized to receive anakinra (n=12) or DMARD (n=10). Patients entered the study only if considered refractory to corticosteroids (prednisolone equivalent ≥10 mg/day for at least two months after disease onset). Primary end point identified the proportion of patients reaching remission of disease after two months of study treatment (stated as afebrile [≤37°C of body temperature], acute phase reactants [C-reactive protein, ferritin] within normal limits, and joint scores being normal). Secondary end points included identification of patients reaching remission at two consecutive visits during 24 weeks, follow-up of acute phase reactants and corticosteroid dosage and identifying changes in disease related parameters such as general health, HAQ and SF-36.

Results: Patient groups (anakinra vs. DMARD) were comparable except regarding baseline ferritin levels (354, range 18–1740 vs. 186, range 17–680) and baseline prednisolone dose (22.5 mg, range 10–60 vs. 18.5, range 10–25), respectively. At week 4, 6/12 and 3/10 were in remission; at week 8, 7/12 and 5/10 were in remission; and at 24 weeks 6/12 and 2/10 were still in remission, respectively. In the Physical Health Summary of the SF-36 anakinra produced significantly more rapid and sustained responses compared to DMARD (p=0.011). Only patients on DMARDs (N=5) withdrew prematurely.

Conclusion: In refractory AOSD both DMARD therapy and especially anakinra showed good therapy responses during the 24 week intervention period. Responses were more robust with anakinra at 24 weeks with 50% of patients in strict remission according to criteria above. Withdrawals due to lack of efficacy occurred only in DMARD patients.

Anti-Double Stranded DNA and Other Autoantibodies Are Common in Alaska Native Autoimmune Hepatitis Patients. Elizabeth D. Ferucci[1], Kathy J. Hurlburt[1], Stephen Livingston[1], Julia Plotnik[1], James Gove[1], Brian J. McMahon[1] and Judith A. James[2]. [1]Alaska Native Tribal Health Consortium, [2]Oklahoma Medical Research Foundation, Oklahoma City, OK

Purpose: Autoimmune hepatitis has been associated with rheumatoid arthritis and other autoimmune diseases. The purpose of this study was to determine the prevalence of autoantibodies related to rheumatoid arthritis (RA) and connective tissue diseases in autoimmune hepatitis (AIH).

Methods: Alaska Native study participants were recruited at hepatitis clinics provided by the Alaska Native Tribal Health Consortium Liver Disease and Hepatitis Program. Patients with definite or probable AIH defined by the International Autoimmune Hepatitis Group (IAHG) criteria provided informed consent for participation in an observational study of AIH. Sera from a study visit were tested for the following autoantibodies: IgG rheumatoid factor (RF) by ELISA, CCP antibody by ELISA, anti-double stranded DNA (dsDNA) by immunofluorescence with Crithidia luciliea and ELISA testing, and anti-nRNP, Sm, Ro, La, and ribosomal P. Rheumatologic diagnoses were determined by medical record review. Diagnoses were documented by a clinical rheumatologist using established criteria, including American College of Rheumatology (ACR) criteria for RA and systemic lupus erythematosus (SLE).

Results: Sera were available from 70 patients with AIH. Of the 70 AIH patients, 66 (94.3%) were female, and the mean age at consent was 52.1 years (SD 18.2, median 56.7). Fourteen AIH patients (20%) had an established rheumatologic diagnosis (9 (12.9%) with RA, and 1 each with SLE, Sjogren's syndrome, mixed connective tissue disease, adult Still's disease, and psoriatic arthritis). In the 9 AIH patients with RA, 5 (55.6%) had RF present, 6 (66.7%) CCP, 5 (55.6%) both RF and CCP, 3 (33.3%) dsDNA, 3 (33.3%) nRNP, 5 (55.6%) Ro, and 2 (22.2%) La. In AIH patients without any known rheumatologic diagnosis (n=56), the most common autoantibody found was dsDNA (26/56, or 46.4%); followed by RF (6/56, or 10.7%), and Ro (6/56, or 10.7%). Other autoantibodies found were CCP in 2 patients, La in 2 patients, and anti-nRNP in 1 patient. No patient with or without a rheumatologic diagnosis had Sm or ribosomal P antibodies.

Conclusion: Antibodies to double stranded DNA are commonly found in Alaska Native patients with AIH, in the absence of diagnosed SLE. This information provides rheumatologists with additional information when considering the differential diagnosis of a positive dsDNA antibody, suggesting that anti-dsDNA is not universally associated with only SLE.

893

Anti-U1C Autoantibody Specifically Interferes with the U1RNP-Mediated Splicing of Angiopoietin-1 (*Ang1*) Gene and Induces Functionally Defective *Ang-1*/ins Variant in the Patients with MCTD. Yuka Kosugi[1], Koichiro Komai[1], Shogo Funaki[1], Aya Mashida[1], Kazuko Shiozawa[3], Akira Hashiramoto[2] and Shunichi Shiozawa[2]. [1]Dep. of Biophysics, Graduate School of Health Sciences, Kobe Univ., Kobe, Japan, [2]Dep. of Biophysics, Graduate School of Health Sciences, Kobe Univ./Dep. of Medicine, Graduate School of Medicine, Kobe Univ./The Center for Rheumatic Diseases, Kobe Univ., Hosp., Kobe, Japan, [3]Rheumatic Diseases Center, Konan Kakogawa Hosp., Kakogawa, Japan

Purpose: Angiopoietin-1 (*Ang1*) is the ligand of endothelial tyrosine kinase receptor Tie2 and induces cell proliferation *via* ERK phosphorylation. *Ang1* is strongly up-regulated in the lung of patients with mixed connective tissue disease (MCTD) accompanied by pulmonary hypertension (PH) indicating that *Ang1* can play a key role in the pathogenesis of PH associated with MCTD. We previously showed that the frequency of the splicing variant of *Ang1* mRNA with nt805GGT insertion (*Ang1*/ins) encoding ^{269}Gly was significantly increased in the Japanese patients with MCTD and those with PH as compared with *Ang1*/del with nt805GGT deletion (Arth. & Rheum. 52 (9): S283, '05). We also found that *Ang1*/ins dose proliferate pulmonary endothelial cells and potentially induce hyperplasia of smooth muscle cell in relation to the pathogenesis of PH as compared with *Ang1*/del (Arth. & Rheum. 58 (9): S659, '08 and 60 (10): S8, '09). On the other hand, anti-U1RNP antibodies (Abs), elevated in MCTD significantly induced *Ang1*/ins mRNA in Jurkat cells (Arth. & Rheum. 58 (9): S224, '08). We have now studied the contribution of subclass of Abs against U1A, U1C or U1–70K to the induction of *Ang1*/ins variant. We also evaluated the reactivity of anti-U1RNP auto-Abs against each components of U1RNP in sera of patients with MCTD.

Methods: Anti-U1A, U1C and U1–70K Abs (LifeSpan Biosc. and Bio Acad.) were introduced into human pulmonary artery smooth muscle cells (HPASMC) using PULS-in reagent (Polyplus transfection), followed by treatment with IL6 and TNFα (20ng/ml each) for 24 h. *Ang1* mRNA was obtained by using RT-PCR and subjected to length analysis by using ABI3130xl sequencer. Expression levels of *Ang1* variants were evaluated with calculated peak areas. Anti-U1RNP Ab titer in sera of Japanese patients with MCTD was determined by using Autoimmune EIA Test (BIO-RAD) and the *Ang1* mRNA phenotype was determined. We also constructed ELISA by using recombinant U1A, U1C and U1–70K proteins (DIARECT), as coated antigen and Ab titers in sera of patients were determined.

Results: Anti-U1C and U1–70K Abs significantly induced *Ang1*/ins mRNA with IL6 and TNFα ($P<0.05$). Otherwise, neither anti-U1A, U1C nor U1–70K Abs did alter the *Ang1* splicing without cytokine. We also confirmed that *Ang1*/ins wasn't induced with cytokine. Frequency of the patients with MCTD having anti-U1RNP Ab titer exceeding 200 was 81.3% (39/48) and 50.0% (6/12) ($P<0.05$) among those with *Ang1*/ins dominant and *Ang1*/del dominant phenotypes, respectively. While comparison between *Ang1*/del and *Ang1*/ins dominant phenotypes wasn't possible because of 2 sera specimens of those *Ang1*/del dominant phenotype, the titer of each subclass of anti-U1RNP Ab in the sera of patients with MCTD among those with *Ang1*/hetero (n=13) and *Ang1*/ins dominant phenotypes (n=18) was: 11.8 ± 23.6 and 47 ± 58.9 ($P<0.05$) for anti-U1A Ab, 13.6 ± 25.7 and 122.1 ± 124.5 ($P<0.005$); for anti-U1C Ab, 406.2 ± 599.5 and 5512.9 ± 12484.7 (not significant); for anti-U1–70K Ab.

Conclusions: It is suggested that anti-U1RNP Ab, especially those reactive with U1C affect the splicing of *Ang1* with cytokines and induce functionally defective *Ang1*/ins in the patients with MCTD.

894

Autoimmune Phenomena in Muckle-Wells Syndrome (MWS). Katharina Gramlich[1], Reinhild Klein[4], Sandra Hansmann[3], Susanne M. Benseler[5] and Jasmin B. Kuemmerle-Deschner[2]. [1]Division of Pediatric Rheumatology, Department of Pediatrics, University Hospital Tübingen, Tuebingen, Germany, [2]Division of Pediatric Rheumatology, Department of Pediatrics, University Hospital Tübingen, Tuebingen, Germany, [3]Division of Pediatric Rheumatology, Department of Pediatrics, University Hospital Tübingen, Germany, [4]Division of Rheumatology, Department of Internal Medicine, University Hospital Tübingen, [5]The Hospital for Sick Children, Toronto, ON, Canada

Background: Muckle-Wells Syndrome (MWS) is a rare inherited autoinflammatory disease which is driven by excessive interleukin-1β (IL-1β) production. IL-1 blocking therapies including anakinra and canakinumab have been shown to be safe and effective. Absence of autoantibodies is the hallmark of autoinflammatory diseases, discriminating them from autoimmune diseases. The aim of this study was to determine the frequency of autoantibodies in MWS-patients prior to therapy and during anakinra and canakinumab therapy.

Methods: A single center observational study was performed. Patients with confirmed MWS were tested for autoantibodies at baseline prior to IL-1 blockade, within 6 months of treatment with anakinra or canakinumab respectively, and at 6–12 months of treatment. Monitoring included antinu-

clear antibodies (ANA), smooth muscle antibodies (SMA), anti-endothelial antibodies (AEA), anti-sarcolemmal antibodies (ASA) by immunofluorescence test, and antibodies against serotonin, gangliosides and CNS-tissue of the IgG and IgM type by ELISA.

Results: We included 20 patients, 8 males, 12 females, median age at diagnosis, 34 years (3,5–72). All patients were screened for the presence of autoantibodies before starting anti-IL-1 therapy. Positive ANA were detected in 3 patients (15%); SMA, AEA or ASA were found in 6 patients (30%). 2/4 tested were positive for anti-serotonin antibodies and 2/15 for anti-ganglioside antibodies. Antibodies against CNS-tissue were detected in 5/15 tested.

During anakinra therapy no formation of ANA in initially ANA-negative patients was observed, ANA newly emerged in 4/14 during canakinumab therapy. New antibody formation against gangliosides occurred in 2 patients during anakinra and in 1 patient during canakinumab therapy. Antibodies against serotonin and CNS-tissue were frequently detected during both anakinra and canakinumab therapy; however there was no evidence of new formation of these antibodies. SMA, AEA and ASA were unchanged over the whole study period. During the overall study period, 15/20 patients (75%) were positive for antibodies against serotonin, gangliosides and/ or CNS-tissue at least at one time point.

Conclusions: Patients with MWS can have ANAs and antibodies against serotonin, gangliosides and CNS-tissue. IL-1 blockade may increase the formation of autoantibodies in previously antibody-negative patients. The clinical relevance of the presence of autoantibodies in patients with MWS is still unclear.

Background: CAPS (a disease spectrum consisting of familial cold auto-inflammatory syndrome [FCAS], Muckle-Wells syndrome [MWS], neonatal-onset multisystem inflammatory disease [NOMID]) is a rare systemic inflammatory disease associated with mutations in NLRP3 causing excessive production of interleukin-1β (IL-1β). The fully human monoclonal antibody canakinumab provides prolonged selective blockade of IL-1β. This study evaluated the long-term efficacy and safety of canakinumab subcutaneous (sc) injections every 8 weeks in a large cohort of CAPS patients.

Methods: Patients enrolled in this open-label, multi-center study were canakinumab-naive or rolled-over from earlier studies. Patients received canakinumab 150 mg sc or 2 mg/kg sc (body weight ≤40 kg) every 8 weeks. The primary objective was to assess the long-term safety and tolerability of canakinumab in CAPS patients. Secondary objectives included assessment of response (for naive patients), maintenance of response for those patients who had achieved a complete response, percentage of patients requiring dose adjustment. Complete response was defined as: physician's global assessment of disease activity and skin assessment score ≤minimal and normal CRP and/or SAA values (<10 mg/L). Relapse was defined as: serum levels of CRP and/or SAA >30 mg/L and physician's global assessment of disease activity >minimal or physician's global assessment of disease activity minimal along with the assessment of skin disease >minimal.

Results: 166 (47 pediatric) patients aged 3–91 years were enrolled (30 FCAS; 103 MWS; 32 MWS/NOMID [14 NOMID]; 1 child did not have CAPS and was discontinued [protocol violator]). 109 patients were canakinumab-naive, while 57 had been pre-treated with canakinumab. 151 (91%) patients completed the study and 15 patients discontinued (4 due to adverse events [AEs]). Median duration of exposure to canakinumab was 414 days (range 29–687 days) and the mean number of injections per patient was 7.2. A complete response (CR) was achieved in 85/109 (78%) canakinumab-naive patients (80 patients achieved CR within 8 days, the others achieved CR within 21 days). Of the 141 patients who were included in the relapse assessment, 127 (90%) had no relapse, while 14 (10%) experienced a relapse. Dose adjustments were required in 36 (22%) patients (17% adults vs 34% children). In canakinumab-naive patients median CRP and SAA levels rapidly decreased within 7 days (2.5 and 4.9 mg/L [baseline levels were 19.6 and 35.6 mg/L, respectively]) and these levels were maintained within normal levels (<10 mg/L) during the study in the entire patient cohort. Predominant AEs were infections (65%), mostly mild to moderate in severity. Most frequent AEs were nasopharyngitis, headache and rhinitis. Serious AEs were reported in 18 patients. Majority of patients (92%) had no injection site reactions, 8% reported reactions which were all mild or moderate.

Conclusions: Canakinumab 150 mg sc every 8 weeks provided rapid improvement of symptoms and sustained remission in a large cohort of CAPS patients across different severity phenotypes. Long-term safety profile was comparable to that established in earlier trials of shorter duration.

Celecoxib Analogue Lacking COX-2-Inhibitory Activity Inhibits Arthritis by Supressing IL-23 and Inflammatory Cytokines. Asako Chiba[2], Ryohsuke Tajima[2], Miho Mizuno[2], Chiharu Tomi[2], Iraide Alloza[3], Takashi Yamamura[2], Koen Vandenbroeck[3] and Sachiko Miyake[1]. [1]Department of Immunology, National Institute of Neuroscience, NCNP, Kodaira Tokyo, Japan, [2]Department of Immunology, National Institute of Neuroscience, NCNP, [3]Neurogenomiks Laboratory, Ikerbasque and Universidad Del País Vasco (UPV/EHU), Parque Tecnológico de Bizkaia

Background: Previously we reported that a trifluoromethyl analogue of celecoxib (TFM-celecoxib) lacking COX-2-inhibitory activity induces cellular retention of IL-12 and IL-23. Because these cytokines are involved in autoimmune or inflammatory diseases, we asked whether TFM-celecoxib suppresses animal models of arthritis.

Methods: To induce collagen-induced arthritis (CIA), DBA1/J mice were immunized with bovine type II collagen (CII) (150μg) in Freund's complete adjuvant containing 250μg of H37Ra *Mycobacterium tuberculosis* on day 0 and CII in IFA on day 21. Antibody-induced arthritis (AIA) was induced in C57BL/6 mice by injecting a mixture of anti-CII antibodies followed by lipopolysaccharide (LPS) administration 2 days later. Experimental autoimmune encephalomyelitis (EAE) was induced in C57BL/6 mice by immunizing with MOG_{35-55}-peptide (100μg) in CFA followed by pertussis toxin administration. Peritoneal recruitment of leukocytes was induced by injecting 1ml of 4% thioglycollate. Mice recieved 10μg/kg of TFM-celecoxib (TFM-C) every other day from day 1 in EAE and AIA experiments, every day from day 21 in CIA experiments. The control animals were injected with vehicle alone, and in some experiments another group of mice were treated with celecoxib. Bone marrow-derived dendritic cells (BMDCs) or splenic macrophages from mice treated with TFM-C were stimulated by LPS in vitro in the presense or absence of TFM-C, and cytokine consentration in the culture supernatants was measured by ELISA

Results: TFM-C strongly suppressed CIA and AIA, although celecoxib did not inhibit these models. Histopathological analysis of arthritic joints revealed that TFM-C treatment inhibited mast cell degranulation whereas celecoxib treatment failed to suppress mast cell activation. TFM-C suppressed mast cell-dependent neutrophil influx into peritoneal cavity after injection of thioglycollate. TFM-C treatment in vivo inhibited inflammatory cytokines production from macrophages. Moreover, TFM-C suppressed the clinical and pathological features of EAE in association with the reduction of IL-23 production by dendritic cells, which subsequently suppressed IL-17 production by lymph node cells when re-challenged by MOG in vitro.

Conclusion: TFM-C suppressed murine models of arthritis by suppressing innate immune cell activation and autoreactive T cell responses, high-

lighting the therapeutic potential of TFM-C for autoimmune diseases such as rheumatoid arthritis and multiple sclerosis.

Comprehensive Analyses of MEFV, TNFRSF1A, MVK, and CIAS1 Mutations in 63 Patients with Clinically Periodic Fever Syndrome in Japan. Sayuri Kataoka[2], Manabu Kawamoto[1], Yasushi Kawaguchi[3], Takahisa Gono[1], Masanori Hanaoka[1], Hisae Ichida[1], Yasuhiro Katsumata[1], Yuko Okamoto[4], Yuko Ota[2], Ikuko Masuda[1] and Hisashi Yamanaka[1]. [1]Tokyo Women's Medical University, [2]Tokyo Women's Medical University, Japan, [3]Tokyo Women's Medical University, [4]Tokyo Womens Med Univ

Purpose: Periodic fever syndrome refers to a group of autoinflammatory disease sharing similar symptoms and characterized by recurrent unprovoked inflammation in the absence of infection. These diseases primarily include familial Mediterranean fever (FMF), TNF receptor-associated periodic syndrome (TRAPS), hyperimmunoglobulinemia D syndrome (HIDS), and cryopyrin-associated periodic syndrome (CAPS). The genetic studies revealed predominant mutations of MEFV gene in FMF, TNFRSF1A gene in TRAPS, MVK gene in HIDS, and CIAS1 gene in CAPS. A number of studies about hereditary autoinflammatory disease have already established in Europe and USA, while it has not been fully understood in the Japanese population. In the present study, we investigated a comprehensive analysis of mutations in MEFV, TNFRSF1A, MVK and CIAS1 in patients with clinically periodic fever syndrome.

Methods: We have defined clinically periodic fever syndrome as recurrent episodes of systemic inflammation in the absence of pathogens (i.e.: bacterial infection, viral infection), autoantibodies (i.e.: collagen diseases), or antigen specific T cells (i.e.: malignancy, allergy). Sixty-three patients were matched to those criteria and enrolled in the present study. All patients were Japanese. The median (range) of age was 13 years old (3 to 36), and the ratio of female/male was 29/34. All genotyping of exon 3 and exon 10 in the MEFV gene, exon 2 to exon 5 in the TNFRSF1A gene, exon 10 and exon 11 in the MVK gene, and exon 3 in the CIAS1 gene were determined by direct sequencing using ABI PRISM3100.

Results: The mutations of M694I and P369S + R408Q in the MEFV gene were found in 4 and 5 patients with clinically periodic fever syndrome, respectively. In the TNFRSF1A gene, the mutations of C30R and T61I were found in 1 and 3 patients, respectively. In the MVK gene, one patient was observed rare mutation of G326R, and E304K mutation in the CIAS1 gene was detected in one patient. Those 15 patients had only a mutation described above, while one patient had two mutations of the MEFV (M694I) and TNFRSF1A (T61I) genes. Finally, we detected gene mutations in 16 out of 63 patients with clinically periodic fever syndrome by these methods. Interestingly, only two in 16 patients had the family history of periodic fever: one has sister and one has brother and mother. Fourteen patients had no family history.

Conclusion: This comprehensive analysis can detect 16 patients (25%) with hereditary periodic fever syndrome, as a result of evaluating 63 patients with clinically periodic fever syndrome. These observations suggest FMF and TRAPS were common in the Japanese population, although it has been believed that hereditary periodic fever syndrome was a very rare disease in Japan.

Table 1. Summary of mutations in patients with clinically periodic fever syndrome

Mutation	Number of patient
MEFV	
P369S + R408Q	5
M694I	4
TNFRSF1A	
C30R	1
T61I	3
MVK	
G326R	1
CIAS1	
E304K	1
MEFV (M694I) + TNFRSF1A (T61I)	1
Total	16

Defining the Aromatase Inhibitor Musculoskeletal Syndrome: A Prospective Trial. Ora Singer[1], Alana B. Levine[1], Tessa Cigler[3], Anne B. Moore[2], Huong T. Do[1] and Lisa A. Mandl[1]. [1]Hospital for Special Surgery, New York, NY, [2]NY Presbyterian - Weill Cornell Medical Center, New York, NY, [3]NY Presbyterian-Weill Cornell Medical Center, New York, NY

Background: Aromatase Inhibitors (AIs) are standard of care therapy for post-menopausal breast cancer, AIs have been associated with debilitating musculoskeletal symptoms, predominantly in the hands and wrists. Up to 15% of symptomatic patients discontinue this potentially life saving therapy. The purpose of this study is to define the AI syndrome.

Methods: Post-menopausal women with hormone-sensitive, non-metastatic breast cancer and no rheumatic disease were included in this prospective cohort study. Subjects were evaluated by a rheumatologist before starting AIs and at 6 months. Women who reported new or worsening musculoskeletal symptoms were classified as "symptomatic." The primary outcome was grip strength; secondary outcomes included 66/68 swollen and tender joint count, HAQ-DI, SF-36, AUSCAN Hand Index, and serum testing for CPK, CRP, ESR, CCP, SSA, SSB, RF, ANA. Contrast enhanced MRIs of the hands and wrists were performed at baseline and 6 month or at symptom onset. MRIs were read by two blinded radiologists using the OMERACT Rheumatoid Arthritis MRI Scoring with Tenosynovitis subscale (RAMRIS-TS).

Results: Of 35 women enrolled, 19 (54%) were symptomatic and of these 2 (5.7%) discontinued the AI. Mean time to onset of symptoms was 6 weeks (range 2 to 18). Fifty-eight percent of symptomatic subjects had involvement of the hands. Two had De Quervain's TS, 4 had tenderness over the flexor digitorum tendons, including 1 trigger finger, and 5 had generalized bilateral hand and wrist stiffness. Three subjects had ball of the foot and/or heel pain with weight bearing. Cancer stage was the only significant predictor of symptom development, (OR 5.9; 95% CI 1.2, 28.1) There was no difference in the mean change in grip strength between the symptomatic and asymptomatic groups, (−2.3 kg vs −1.4 kg, p-value=0.97). There were also no differences in the mean change in HAQ, SF 36, 66/68 tender and swollen joint counts and laboratory values. There was a statistically significant worsening of the AUSCAN pain, stiffness and total subscales in the symptomatic group (P-values = 0.004, 0.001 and 0.001, respectively). Although some symptomatic subjects with hand/wrist involvement had MRI abnormalities, there was no significant change in any RAMRIS score. ICC's were 0.8, 0.76, 0.19 and 0 for erosion, edema, synovitis and TS RAMRIS scores respectively

Conclusions: In this prospective study, more than half of subjects reported new or worsening musculoskeletal complaints on AIs. Later stage cancer increased the risk of developing pain, and clinical exam suggested underlying tenosynovial pathology. While TS was detected on MRI in some symptomatic subjects, the RAMRIS, developed for inflammatory arthritis, was not able to differentiate symptomatic from asymptomatic women. There was no difference in serum findings between the two groups. These findings suggest the AI syndrome is not due to the triggering of an autoimmune or systemic inflammatory process. Although symptoms were not limited to the hands and wrists, the AUSCAN was associated with increased pain, suggesting this instrument may be discriminative in diseases other than OA.

Hearing Loss in Muckle-Wells-Syndrome. Assen Koitschev[1], Katharina Gramlich[3], Sandra Hansmann[3], Susanne M. Benseler[5], Stefan Plontke[2], Christiane Koitschev[2], Ina Koetter[4] and Jasmin Kuemmerle-Deschner[3]. [1]Department of Otorhinolaryngology, Klinikum Stuttgart, Germany, [2]Department of Otorhinolaryngology, University Hospital Tübingen, Germany, [3]Division of Pediatric Rheumatology, Department of Pediatrics, University Hospital Tübingen, Germany, [4]Division of Rheumatology, Department of Internal Medicine, University Hospital Tübingen, Tuebingen, Germany, [5]The Hospital for Sick Children, Toronto, ON, Canada

Background: Muckle-Wells syndrome (MWS) is an inherited autoinflammatory disease associated with excessive Interleukin-1 (IL-1) release caused by NLRP3 gene mutations. MWS patients are at high risk of

developing devastating sensorineural deafness. The study aims to report the otologic characteristics in severe MWS.

Patients and Methods: A single center observational cohort study of consecutive children and adults diagnosed with MWS between 2000 and 2008 was performed. Genetic testing of the NLRP3 gene was completed. All patients had standardized neurotologic assessments including hearing threshold and speech audiograms, caloric vestibular testing and a structured tinnitus questionnaire. The audiograms of members of the same family were compared in order to describe the family specific risk of progressive hearing loss.

Results: A total of 19 MWS-patients ages 3–72 years from 4 families with 3 different NLRP3 gene mutations were included. Almost all patients (89 %, 17/19) presented with sensorineural hearing loss of different range compared to normal hearing threshold of a same age population. 15 of 19 patients had symmetric bilateral hearing thresholds. In 3 patients minimal asymmetry of the hearing threshold in the higher frequencies was demonstrated. One female patient age 19 appeared deaf since birth on the left side. Hearing thresholds uniformly decline toward the higher frequencies starting with an isolated pitch above 4 kHz in younger patients. Increasing age was significantly associated with worsening hearing impairment. The vestibular caloric reactivity was normal in all, including patients with profound hearing loss. Non-debilitating intermittent or permanent tinnitus was reported by half of the adult patients. In this cohort, patients with the mutation V198M were the least affected by hearing loss, patients with the T348M mutation were severely affected.

Conclusion: Progressive sensorineural hearing loss without vestibular involvement is the characteristic symptom of MWS. Progression is age dependent with large variation by intra- and interfamilial comparison. Different mutations appear to be associated with different risk levels of hearing loss, T348M mutation being most severely affected. Early diagnosis and specific therapy by IL-1 inhibition may be essential to prevent severe disease consequences.

Hearing Loss in Muckle-Wells-Syndrome—Effects of IL-1 Inhibitiony. Assen Koitschev[1], Katharina Gramlich[3], Sandra Hansmann[3], Susanne Benseler[4], Stefan Plontke[2], Christiane Koitschev[2], Ina Koetter[6], Ralph Preiss[5] and Jasmin Kuemmerle-Deschner[3]. [1]Department of Otorhinolaryngology, Klinikum Stuttgart, Germany, [2]Department of Otorhinolaryngology, University Hospital Tübingen, Germany, [3]Division of Pediatric Rheumatology, Department of Pediatrics, University Hospital Tübingen, Germany, [4]Division of Rheumatology, Department of Pediatrics, The Hospital for Sick Children, Toronto, Canada, [5]Novartis Pharmaceuticals Corporation, East Hanover, NJ, [6]University Hospital, Tuebingen, Germany

Background: Muckle-Wells syndrome (MWS) is a rare inherited autoinflammatory disease. The most devastating symptoms are sensorineural deafness and amyloidosis. NLRP3 gene mutations are associated with excessive Interleukin-1 (IL-1) release. Specific Il-1 inhibition has been shown to be safe and effective in the treatment of MWS. The study aims to systematically evaluate the effect of IL-1 inhibition on hearing in MWS.

Patients and Methods: A single center observational cohort study of consecutive children and adults with confirmed MWS was performed. Prospective standardized audiologic assessments were conducted at baseline and during treatment with the IL-1 receptor antagonist Anakinra or the fully human monoclonal IL-1β-antibody Canakinumab. Comparison was based on pure tone thresholds at 500, 1000, 2000 and 4000 Hz and defined as an increase or decrease of 20 dB in hearing threshold at one or more frequencies, or of 10 dB at two or more consecutive frequencies.Comparisons were made using paired t-tests, chi-squares or Fishers exact test, when appropriate.

Results: A total of 19 patients with MWS, ages 3–72 years from 4 families with 3 different mutations of the NLRP3 gene were included. At baseline, 13 patients (68%) indicated subjective hearing loss, 4 (21%) showed high frequency hearing loss without subjective impairment and two (11%) had normal hearing threshold. Treatment with Anakinra significantly improved hearing in 2/12 patients (16 and 44 years). Hearing did not deteriorate in 10/12 (83%) patients during a median treatment course of 12 months (range 5–14). Canakinumab therapy was given to 14 patients. Hearing improved in 1/14 patient (19 years). No deterioration of hearing loss was observed in 13/14 (93%) patients during a median treatment course of 11 months (range 6–15).

Conclusion: lL-1 inhibition in MWS prevented progression of hearing loss in all MWS patients. Reversal of hearing loss occurred in a small group. Factors associated with reversal have to be explored in order to optimize therapy and improve long-term outcome of MWS patients.

Inflammatory Arthritis Associated with Isolated Anti-CBir1 Antibodies: Part of the Spectrum of "Seronegative" Arthritis? Melissa A. Peda[1] and Stanford L. Peng[2]. [1]Benaroya Research Institute, [2]Benaroya Research Institute and Virginia Mason Medical Center, Seattle, WA

Background: Despite serological advances in the diagnosis of inflammatory polyarthritis (iPA) conditions, such as anti-CCP antibodies in RA, current rheumatological practice continues to encounter many patients with "seronegative" arthritis. Such patients are often treated as seronegative rheumatoid arthritis; however, further insight regarding the classification of such patients could help guide investigations into pathogenesis and/or treatment. Since some inflammatory arthritis conditions, especially spondyloarthropathies, have been associated with subclinical bowel inflammation, this study sought to explore the potential utility of the inflammatory bowel disease (IBD)-associated toll-like receptor (TLR) 5 ligand flagellin antibody, anti-CBir1, in the classification of "seronegative" inflammatory arthritis.

Methods: We performed a retrospective chart review of patients seen in the rheumatology clinic at the Virginia Mason Medical Center in Seattle, WA between Q4 2009–Q1 2010. Records of patients who had been tested for anti-CBir1 reactivity via the Prometheus® IBD Serology 7 panel, which includes also anti-*Saccharomyces cerevisiae* antibodies (ASCA) and outer membrane porin C (OmpC) specificities (San Diego, CA), were reviewed.

Results: In the timeframe specified, 132 patients had been tested with the IBD Serology 7 panel. Of these, 81 (61%) had at least one positive IBD serological marker (61%); the most prevalent was anti-CBir1, which was positive in 36 (27%), compared to ASCA (12.9% positive for IgA, 6% positive for IgG) and OmpC (10.6% positive). Interestingly, 7 of these CBir1-positive patients were otherwise "seronegative," with negative ANA, RF, anti-CCP, ANCA, Celiac serology, and HLA-B27: these patients generally exhibited synovitis of the medium and/or large joints. Clinical evidence of psoriasis, inflammatory bowel disease, or antecedent infection was absent in all patients. Interestingly, these patients seemed to respond to treatments often used in spondyloarthropathies, such as NSAIDs, sulfasalazine, or etanercept.

Patient	Age	Gender	Right knee, Left sternoclavicular	Anti-CBir1 (EU/mL)	Treatment Response
1	71	F	Bilateral shoulders and ankles	21.1	Prednisone
2	74	M	Right ankle, knee and wrist	31.7	Sulfasalazine
3	55	F	Right wrist	87.6	Etanercept
4	77	M	Bilateral knees and shoulders	36.6	Ibuprofen
5	62	M	Right knee, Left sternoclavicular joint	23.8	Indomethacin
6	66	M	Right wrist and knee, bilateral shoulders	22.2	Etanercept
7	89	M	Bilateral wrists; right knee	29.7	Sulfasalazine

Conclusions: Anti-CBir1 positivity may identify a subset of otherwise seronegative iPA patients, perhaps within the spectrum of inflammatory spondyloarthropathies. The bowel flora flagellin specificity of CBir1 reactivity raises the possibility of a linkage between bowel inflammation and arthritis: as a result, not only might CBir1 and/or other IBD-associated biomarkers be useful in the diagnosis of iPA, they may also provide further insight into the pathogenesis of these inflammatory disorders. Systematic investigation is therefore warranted to ascertain the clinical relevance of CBir1 reactivity in the diagnosis or classification of rheumatic conditions.

Long Term Treatment with Anakinra in Patients with Adult-Onset Still Disease. Giampietro Cecilia[1], Ridene Meriem[2], Fautrel Bruno[3], Bourgeois Pierre[3] and CRI. [1]University of L'Aquila, L'Aquila, Italy, [2]University of Tunis, Tunis, Tunisia, [3]University Paris 6–Pierre et Marie Curie University; Rheumatology, Pitie-Salpêtriere Hospital, Paris, France

Background: Adult-onset Still disease (AOSD) is a rare systemic inflammatory disorder. Aetiology is still unknown, however recent advances suggest IL-1 to play a pivotal role in his pathogenesis.

Several observations have demonstrated the rapid efficacy of the anti-IL1 receptor antagonist anakinra in refractory cases treatment, but other studies are needed to evaluate his long term effects.

Objective: To assess the long term efficacy and safety of anakinra treatment in patients with AOSD.

Methods: Patients were identified by their participation to a precedent study and by a survey conducted in the CRI website.

19 patients affected by AOSD as defined by Yamaguchi diagnostic criteria and treated with anakinra were recruited contacting by mail all departements of rheumatology and internal medicine in France. Medical informations were retrospectively collected using a standardised questionnaire.Anakinra was given subcutaneusly at a daily dose of 100mg.

Patients were classified at remission if all symtoms of AOSD were disappeared, partial response if some general or articular signs persisted and failure if no response were observed.

Results: Patients were mean aged 40.6 ± 11.5 years (range 23 to 73), with mean disease duration at anakinra start of 9.4 years. Clinical expression was predominantely systemic in 6 patients and polyarticular in 13. All patients have previously failed to corticosteroids, synthetic DMARDs and for 10 of them to anti-TNFα and anti-CD20.

Anakinra was well tolerated in patients with AOSD and adverse events were rated as mild. The most common adverse event observed was a rash at the site of injection. It motived treatment discontinuation in only 1 patient. No augmentation of infection rate was observed.

At a mean follow up of 30.7 months, complete remission occurred in 13 cases. Partial response was observed in 4 cases. The symptoms that persisted were mainly articular manifestation whereas systemic ones disappeared early in the cours of treatment. 2 patients experienced a loss of efficacy after a mean of 15 months.

Anakinra allowed corticosteroid sparing and reduction of dose of eventually associated DMARDs. At the last visit, 4 patients withdrawn treatment because remission has been obtained and reduction of anakinra dose was possible in 4 cases without observed relapse of disease.

Evolution in Long-term Follow-up

Complete remission (n = 13) (68.4%)	Anakinra discontinued without relapse (n = 4) (21%)
	Dose reduction without relapse (n = 4) (21%):
	- 1 subcutaneous injection 3 time a week (n = 1)
	-1 subcutaneous injection 2 time a week (n = 2)
	- 1 subcutaneous injection 6 time a week (n = 1)
	Same dose continued (n = 5) (26.3%)
Partial response (n = 4) (21%)	Desappearance of systemic manifestations
	Persistence of articular manifestations
Loss of efficacy (n = 2) (10.5%)	Switch to anti-IL6 (1 infusion/4 weeks) with remission

Conclusion: AOSD patients experience a drastic response to Anakinra. In our long term study this efficacy is maintained without relapse or serius side effects.

Lymph Node and Bone Marrow Expression of Macrophage Migration Inhibitory Factor and IL18 in Adult-Onset Still's Disease. Sung-Hoon Park[1], Hwa-Jeong Lee[2], Seong-Kyu Kim[2] and Jung-Yoon Choe[2]. [1]Catholic University of Daegu, School of Medicine, Arthritis and Autoimmunity Research Center, Daegu, Korea, Republic of, [2]Catholic University of Daegu, School of Medicine, Arthritis and Autoimmunity Research Center

Background: Adult-onset Still's disease(AOSD) is a systemic inflammatory disorder, involving dysregulated production of proinflammatory cytokine. In the previous studies, although its mechanism is not precise, serum IL18 and macrophage migration inhibitory factor(MIF) level was significantly elevated in the disease patients and was shown to be correlated with disease activity. In this study, we investigated a expression of macrophage MIF and IL18 in lymph node(LN) and bone marrow(BM) specimen of AOSD patients and compared it with normal marrow or reactive lympadenopathy.

Methods: LN or BM section of 13 AOSD patients were prepared(both LN and BM in 6 of them). 3 of 6 patients showed a features of the macrophage activation syndrome(MAS), and were underwent both LN and BM biopsy. Immunohistochemical stain using anti-MIF antibody(Abcam, Cambridge, UK) and anti-IL18 monoclonal antibody(R&D Systems, Minneapolis, MN, USA) was done according to the recommendations of the manufacturer's instructions. 3 specimens of normal BM section and 3 specimens of reactive lymphadenitis were compared as control group. Correlation of serum ferritin and C-reactive protein(CRP) level with tissue cytokine expression was investigated.

Results: After staining with anti-MIF antibody and anti-IL18 monoclonal antibody, the staining intensity was measured by counting a total number of reactive cells(positive dot) in $100\times100\mu$m field manually. All cell counts were performed by the same observer for the entire study and verified by a second observer blinded to the study group. Mean age of LN group was 43.56±12.45 years old(2 male and 11 female patients) and 41.03±18.79 years old(3 male and 5 female patients) in BM group. Stain intensity of IL18 and macrophage MIF in LN group was significantly higher than reactive LN group. BM of AOSD patients expressed stronger IL18 and macrophage MIF than normal BM. Both IL18 and macrophage MIF overexpressed in MAS patients group, but there was no statistically significant difference($p=0.065$) compared with other AOSD patients without MAS(Table 1). Serum ferritin and CRP level was not quantitatively correlated with stain intensity.

Table 1 LN and BM immunohistochemical stain intensity

	LN N = 13	BM N = 8	Reactive LN N = 3	Normal BM N = 3	MASLN N = 3	MAS BM N = 3
Mean age, year	43.56 ± 12.45	41.03 ± 18.79				
Sex, M/F	2/113/5	0/3	1/2	1/2	1/2	
IL 18 stain	198.66 ± 91.36	142.32 ± 74.28	15 ± 12.31	11 ± 8.01	210.52 ± 42.23	148.74 ± 25.17
MIF statin	122.64 ± 110.11	102.46 ± 123.20	9 ± 16.14	5 ± 9.22	132.74 ± 46.04	114.24 ± 56.91

Conclusion: Tissue IL18 and macrophage MIF was overexpressed in both LN and BM of AOSD patients. Their pathophysiologic correlation and therapeutic implication should be elucidated.

New Onset of Uveitis under Anti TNF Therapy. A Nationwide Series. Daniel Wendling, Julien Paccou, René-Marc Flipo, Emmanuelle Dernis, Guillaume Direz, Veronique Ferrazzi, Séverine Guillaume, Jean-Michel Ristori and Club Rhumatismes et Inflammation (CRI). Rheumatology, University Hospital, Besançon, Besançon, France

Background: Uveitis may be associated with various inflammatory diseases. Previous reports suggested that TNF blockers, especially anti TNF monoclonal antibodies, may reduce the incidence of uveitis flares in those diseases. Under these circumstances, de novo occurrence, i.e. new onset of the first episode of uveitis under anti TNF therapy is uncommon.

Aim: The aim of this study was to collect cases of new onset of uveitis under anti TNF therapy, using a nationwide network, and to describe such cases.

Methods: All French rheumatologists and internal medicine practitioners registered on the Club Rhumatismes et Inflammation web site (1,400 physicians) were contacted by 3 electronic newsletters in an attempt to declare the cases of new onset of uveitis, diagnosed by an ophthalmologist, in patients treated with TNF blockers. A previous episode of uveitis before anti TNF therapy was an exclusion criteria. Informations were recorded about the patient (age, gender), the disease (diagnosis, duration), the TNF blocker (type, duration), the uveitis (type, severity, outcome).

Results: Thirteen cases were recorded, 7 men, mean age 43 (5–70) years. Other causes of uveitis were excluded (e.g. infection). The underlying disease was ankylosing spondylitis (6 cases, 5 HLA-B27 positive), psoriatic arthritis (3 cases), rheumatoid arthritis (2 cases), juvenile spondyloarthritis, psoriatic spondyloarthritis (1 case each). The mean duration of the disease was 13.5 (1.5–35) years. The TNF blocker at time of uveitis was etanercept 9 times (3 cases after adalimumab), adalimumab 2 times (with previous infliximab and etanercept), infliximab 2 times (one with previous etanercept). The mean duration of exposure to anti TNF agents was 28.3 (4–65) months at uveitis occurrence. Eleven of the patients were good responders to TNF blockers at time of uveitis onset. Uveitis was acute anterior in 12 cases (bilateral in 2), and one bilateral chronic anterior uveitis. Uveitis was treated locally in 12 cases, and with systemic steroids in one case. The cases of acute anterior uveitis resolved within one month, TNF blocker was stopped in two cases,

and maintained in the others. Uveitis recurrence occurred in 5 cases, with sequelae in one case, with a mean follow-up of 16.9 (1– 77) months.

Conclusion: Uveitis occurs de novo under anti TNF therapy mainly in spondyloarthropathies, but also in rheumatoid arthritis patients; this new onset seems more frequent under etanercept and uveitis is time-limited without discontinuation of the TNF blocker in most of the cases. This illustrates a new possibility of paradoxical effects of anti TNF agents, and rheumatologists should be aware about this event.

Introduction: While auto-inflammatory disorders [AIDs] affect clinically the same organs with a variable intensity or frequency, we hypothesized that a common effort to define disease activity scores could make sense and would help simplify the decision tree in the management of these diseases. Moreover standardized activity score are needed to better capture the efficacy of new medications.

Objective: To develop preliminary activity scores for four auto-inflammatory diseases: Familial Mediterranean fever [FMF], Mevalonate Kinase deficiencies [MKD], TNF-receptor associated periodic syndrome [TRAPS] and Cryopyrin associated diseases [CAPS].

Methods: The study was conducted by using well-recognized consensus formation methodology, specifically designed to combine opinions from a group of experts in a particular field: the Delphi Technique and Nominal Group Technique (NGT). Results from a two steps web-survey plus data from parents/patients interviews provided an agenda for a consensus conference aimed to build provisional core sets for each diseases.

Results: Twenty-four of 65 pediatric and adult AIDs experts (PRES/EUROFEVER network and ISSAID society) from 20 countries answered the web questionnaire and 16 attended the consensus conference. Consensus was obtained to develop separate activity scores for each diseases but on the same format. All participants agreed for a patient designed diary scored 0 to 1 for fever >38 and any pain relief taken. A 0-to 3 score was applied for each clinical variables (according to the diseases). Then, three-month scores are calculated as Score = Σ (n variables) for each month divided by the number of days in the trimester. Mean scores vary from 0 to 16 (0 to 13 for CAPS). According to consensus vote, a final four-domain (clinical and visual global assessment, rescue treatment, biological, QoL) composite score was built-up for purpose of clinical studies. We included a damage scale for severe CAPS that will not be counted in these scores but will serve for targeted clinical trials.

Conclusion: Using consensus formation techniques, we formulated preliminary scores to measure disease activity in four main AIDs. The prospective validation will follow.

Prevalence and Clinical Significance of Cryofibrinogenemia in Patients with Renal Disorders. Benjamin Terrier, Hassan Izzedine, Lucile Musset, David Saadoun and Patrice Cacoub. Pitié-Salpétrière

Background: Cryofibrinogenemia (CryoFg) is an under-recognized cryoprotein that can be life-threatening when untreated. Symptoms of CryoFg are mainly cutaneous including purpura, ecchymosis, ulcerations, livedo and ischaemic necrosis. Renal lesions rarely develop in patients with CryoFg, but the detection of CryoFg was identified in patients with nephropathy.

Objective: Our aim was to describe the prevalence and the significance of CryoFg in patients with renal disorders.

Methods: 101 consecutive patients (mean age 58 $\pm$ 18, female/male 35/66) admitted in the Nephrology Department of a single university hospital for the management of renal disorders (mean age 58 $\pm$ 18, female/male 35/66) were consecutively included in the study and tested for cryoglobulinemia and CryoFg. Anticoagulant-free tubes for cryoglobulin detection or citrated tubes for CryoFg detection were collected. When positive, CryoFg quantification was performed. Patients who were CryoFg positive were defined as having plasma CryoFg over 0.05 g/L. We analyzed clinical and biological factors associated with the presence of CryoFg.

Results: Among the 101 patients, 11 patients had positive CryoFg without detectable cryoglobulin (11%). Median CryoFg level was 0.07 g/L (0.05–1.16). Main epidemiological features and causes of nephropathy, in particular vascular nephropathies, were similar between CryoFg- and CryoFg+ patients. No biological difference (hematuria, proteinuria, creatinine level and glomerular filtration rate using MDRD) was found between CryoFg- and CryoFg+ patients. In contrast, CryoFg+ compared to CryoFg- patients had more frequently severe thrombotic events (36 vs. 0%, $p<0.0001$). Severe thrombotic events included renal arteries thrombosis in 2 patients, recurrent arteriovenous fistula thrombosis in 1, and recurrent dialysis catheter thrombosis with superior vena cava obstruction in 1. The presence of CryoFg was not associated with other manifestations, in particular cutaneous manifestations.

Conclusion: Cryofibrinogenemia is detected in up to 11% of patients with renal disorders. In such patients, the presence of CryoFg is associated with thrombotic events.

Pseudo-Hypertrophic Osteoarthropathy in Lung Transplant Recipients on Long Term Voriconazole Therapy. Rajan Saggar[1], Tisha Wang[3], Rajeev Saggar[3] and Roy D. Altman[2]. [1]UCLA, Los Angeles, CA, [2]UCLA, Agua Dulce, CA, [3]UCLA

Objective: Report a series of patients with a newly described syndrome

Method: Seven cases of lung transplant recipients on long term voriconizole developed a musculoskeletal syndrome.

Results: Lung transplantation was undertaken for end-stage emphysema, sarcoidosis, and idiopathic pulmonary fibrosis. Oral voriconazole was initiated as prophylaxis after isolation of Aspergillus spp. after surveillance bronchoscopy. After 6 to 26 months of therapy with vori-

conizole (200mg bid), this subset of patients presented with non-specific, diffuse bony pain involving arms, shoulders, thighs, knees and shins. Serum alkaline phosphatase was elevated to 1.1 to 7 times the upper limit of normal. Bone scanning with Tc-99m revealed localization of the nuclide to long bones in a spotty distribution atypical for hypertrophic osteoarthropathy. None of the cases had associated clubbing. 2 cases demonstrated periostitis on plain radiograph. Symptoms remised within 2–4 weeks of discontinuation of voriconazole. Repeat bone scan within 6 weeks of voriconazole discontinuation demonstrated significantly reduced accumulation of nuclide.

Conclusion: A syndrome of diffuse extremity pain with periostitis can be seen in lung transplant patients on long term voriconizole. It is suspected that this syndrome may also be seen with azole therapy in long term use for other transplant recipients.

QuantiFERON®-TB Gold In-Tube Test Versus Tuberculin Skin Test across RA, PsA, and AS Patients Prior to Treatment with Golimumab, a Human Anti-TNF Antibody. Elizabeth C. Hsia[5], Neil Schluger[6], John J. Cush[1], Richard E. Chaisson[7], Eric L. Matteson[8], Anna Beutler[3], Mittie K. Doyle[2], Benjamin L. Hsu[4] and Mahboob U. Rahman[5]. [1]Baylor Research Institute, Dallas, TX, [2]Centocor Research and Development, Inc., Malvern, PA, [3]Centocor Research and Development, Inc., Collegeville, PA, [4]Centocor Research and Development, Inc./Univ. of Pennsylvania School of Medicine, Wynnewood, PA, [5]Centocor Research and Development, Inc./Univ. of Pennsylvania School of Medicine, Malvern, PA, [6]Columbia University College of Physicians & Surgeons, [7]Johns Hopkins University, [8]Mayo Clinic, Rochester, MN

Background: Screening for latent tuberculosis infection (LTBI) prior to use of tumor necrosis factor (TNF) blockers is recommended to decrease the risk of tuberculosis (TB) reactivation. The standard screening tuberculin skin test (TST) is limited by positive (+) results due to cross-reactivity with Bacillus Calmette-Guérin (BCG) vaccine and false-negative (−) results, especially in the immunocompromised. More recently developed blood tests, eg, QuantiFERON®-TB Gold test In-Tube (QFT), offer the possibility of improved LTBI detection, but performance data in patients (pts) with autoimmune inflammatory disease is limited.

Objectives: Compare QFT vs TST performance for LTBI screening prior to golimumab (GLM) use across 5 pt populations with rheumatic disease.

Methods: All pts were screened by QFT and TST in each of the 5 Phase 3 trials of subcutaneous GLM that included pts with rheumatoid arthritis, psoriatic arthritis and ankylosing spondylitis enrolled from North & South America, Europe (Western+Eastern), Australia/New Zealand, and Asia. TST (Mantoux method) was deemed + according to local country guidelines for immunosuppressed host, or if ≥5mm if no guidelines existed. Any initially indeterminate (IND) QFT results were repeated, and final results were used. IND QFT results were considered discordant with TST results. QFT and TST results were tabulated overall and by known BCG vaccination status.

Results: Of the 2294 pts in this pooled analysis, at least 1 test was + in 13.9%. Of these, 9.4% were TST +, 7.1% were QFT +, and 2.6% QFT + and TST + (Table). QFT IND rate was 1.8%. Agreement of TST and QFT results was 87.1%, and Kappa coefficient was 0.257 (95% CI: 0.192 to 0.321; p=0.021). Among QFT + tests only 36.2% were TST +; among TST + tests only 27.4% were QFT +. 784/2294 pts had prior BCG. The TST + rate was 3-fold higher in BCG + vs BCG − (15.2% vs 4.9%), which was not seen with QFT + tests (9.1% vs 6.0%), supporting the use of QFT in BCG + pts. The slightly higher QFT + rate among BCG + vs BCG − pts might be explained by the higher endemic TB rate in the regions in which this group of pts resides rather than being false +. Despite the known greater cross-reactivity of TST with non-TB mycobacteria among BCG − pts, the QFT + rate was slightly greater than the TST + rate suggesting the possibility of higher sensitivity of QFT. By repeating initially IND results, the QFT IND rate was much lower than in previous reports.

Conclusions: In the absence of a true gold-standard test for LTBI, results of this large comparison of QFT and TST in pts with rheumatic disease suggest that QFT provides greater sensitivity and specificity than TST.

Table. Screening TST results by QFT and BCG vaccination status

		Screening TST result	
	QFT result (n)	+ (n)	− (n)
All GLM Phase 3pts (n = 2294)	+(163)	59	104
	−(2089)	150	1939
	IND (42)	6	36
BCG + pts (n = 784)	+(7l)	28	43
	−(703)	91	612
	IND (10)	0	10
BCG − pts (n = 1257)	+(75)	24	51
−(1158)	32	1126	
	IND (24)	6	18

Regulatory T-Cells in Familial Mediterrnean Fever (FMF). Doron Rimar[2], Itzhak Rosner[3], Gleb Slobodin[3], Nina Boulman[3], Aharon Kessel[1], Elias Touby[1] and Michael Rozenbaum[3]. [1]Immunology Unit, Bnai-Zion Medical Center, Haifa, Israel, [2]Rheumatology Unit, Bnai-Zion Medical Center, Haifa, Israel, [3]Rheumatology Unit, Bnai-Zion Medical Center, Haifa, Israel

Introduction: The role of regulatory T cells (T-regs) in FMF is yet to be evaluated. Preliminary studies suggest a rise in the number of regulatory T cells after FMF attacks, reaching maximal level at 7 days.

Aim: To investigate the role of T-regs in FMF.

Methods: 5 patients with refractory FMF (defined as at least 1 attack per month despite colchicine therapy of at least 2 mg per day) were evaluated. Seven days after each FMF attack, the number of T-regs and expression of FOX P3 was estimated by flow cytometry after staining for CD4, CD25 bright, and FoxP3 and compared to the level after 14 or more days of remission.

Results: Three females and 2 males were included. All patients had definite FMF according to the TEL HASHOMER criteria with high severity scores, mean 2.8. The patients were of different ethnic origins: 1 Jew, 2 Arabs and 2 Druzes. Their mean age was 31.6±6.2 yrs. Mean age at onset of FMF was 9.3±9.3 yrs. Mean colchicine dose was 2.6mg ± 0.4. Six FMF attacks were assessed. The expression of FOX P3 on CD 4 CD25 bright T cells 7 days after the attacks was significantly higher than at remission, mean fluorescence intensity (MFI) of 10.68±1.6 vs. 4.26±0.9 (p = 0.0002). There was no difference between the percent of CD4, CD25 bright T cells 10.08% ± 3.18 vs. 11.23% ± 4 respectively (p>0.05).

Conclusion: The expression of FOX P3 by T-regs increases after attacks of FMF, yet the percentage of T regs remain unchanged. Anti-inflammatory cytokines interleukin-10 and TGF-β have been (paradoxically?) reported to increase in FMF attacks along with pro-inflammatory cytokines. These anti-inflammatory cytokines are known to activate T-regs, in line with the present findings. It is suggested that T-regs may have a role in terminating FMF attacks.

Safety of Arthrocentesis in Patients on Chronic Warfarin Therapy with Therapeutic INR. Imdad Ahmed[2] and Elie Gertner[1]. [1]Regions Hospital, St Paul, MN, [2]Regions Hospital

Introduction: Patients often need arthrocentesis for diagnostic and therapeutic reasons while on chronic warfarin therapy. Often the procedure is delayed or avoided because of concern about bleeding. The aim of this retrospective study was to determine the safety of arthrocentesis in patients on chronic oral warfarin therapy with INR≥2.0.

Methods: From 01/ 2001 to 11/2008, we reviewed records at Regions Hospital and HealthPartners Medical Group of 514 consecutive patients on chronic warfarin therapy who underwent 640 joint aspiration procedures. Total of 456 procedures were performed with INR ≥2.0 (Group A) and 184 procedures were performed with INR <2.0 (Group B).

The end points were: (1) clinically significant bleeding,(2) infection of the joint (3) pain in the joint needing emergency room, urgent care or physician visits. The end points were both early (within 24 hours post-procedure) and late (within 30-days). Indications for arthrocentesis were usually pain/effusion in patients with diseases such as rheumatoid arthritis, osteoarthritis, gout etc.

Results: There were no significant differences in age, sex, body mass index and concurrent use of antiplatelet agents between the two groups. Groups were also comparable among all medical co-morbidites examined (diabetes mellitus, hypercoagulability, hypertension, liver failure, renal failure and smoking status). Mean INR at the time of procedure for group A was higher than group B (2.7±0.03 vs.1.6±0.02). [Table 1] shows the early and late complications in both groups.

Table 1. Early and late complications between two groups

Complications	Group A INR > 2.0 N = 456	Group B INR < 2.0 N = 184	P Value
Clinically significant bleeding (early)	1 (0.2%)	0	NS
Clinically significant bleeding (late)	0	0	NS
Infection (early)	1 (0.2%)	0	NS
Infection (late)	1 (0.2%)	0	NS
Pain causing physician visit	3 (0.7%)	0	NS

NS = non significant.

There was no statistically significant difference in the overall complication rate between patients with INR ≥2.0 (Group A) and patients with INR<2.0 (Group B) (p=0.708). Receiver operating characteristic [Figure-2] analysis showed that INR offered modest value as a predictive instrument, with a c-statistic of 0.615.

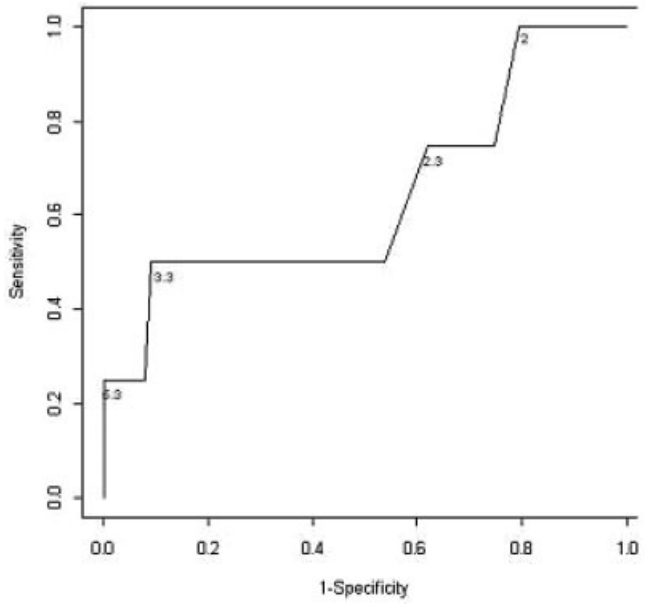

Figure 1. Receiver operating characteristic (ROC) analysis.

Conclusions: Arthrocentesis in patients on chronic warfarin therapy with therapeutic INR appears to be safe without an increased risk of bleeding complications. This approach simplifies the peri-procedural management of anticoagulation, and could lead to improved outcomes and reduced health care costs.

Standardization of Antinuclear Antibody Assessment on HEp-2 Cells by Automated Interpretation. Karl Egerer[1], Dirk Roggenbuck[4], Rico Hiemann[6], Max-Georg Weyer[5], Barbara Lehmann[3], Eugen Feist[3] and Gerd R. Burmester[2]. [1]Charite-University Medicine, Berlin, Germany, [2]Charite-University Medicine, Berlin, Germany, [3]Charite-University Medicine, [4]Medipan GmbH, Berlin Dahlewitz, Germany, [5]Medizinisches Versorgungszentrum für Laboratoriumsmedizin, Mikrobiologie, Virologie und Infektionsepidemiologie, Hygiene und Umweltmedizin, [6]University of Applied Science Lausitz

Introduction: Analysis of antinuclear antibodies (ANAs) by indirect immunofluorescence (IIF) is a basic tool for the serological diagnosis of systemic rheumatic disorders. Automation of ANA IIF interpretation including pattern recognition can improve assay reproducibility and intra- and inter-laboratory variability. Automation of ANA reading meets the demand for cost-effective assessment of large numbers of samples in routine laboratories. Comparing automated and visual interpretation of ANA patterns, the usefulness for laboratory diagnostics was investigated.

Methods: Antinuclear antibody detection by IIF on human epithelial-2 (HEp-2) cells including pattern recognition was performed in a total of 1222 consecutive sera of patients with suspected systemic rheumatic diseases from a university routine laboratory (n=924) and a private referral laboratory (n=298). IIF reading results obtained in routine diagnostics were compared with findings by a novel automated interpretation system employing mathematical pattern recognition algorithms.

Results: Visual and automated interpretation of ANA showed a very good agreement regarding positive / negative discrimination (kappa=0.828). Only 98 (8.0%) of 1222 sera demonstrated discrepant results in the differentiation of positive from negative samples. The contingency coefficient of Chi-square statistics was 0.646 for the university laboratory cohort with an agreement of 93.0% and 0.695 for the private laboratory cohort with an agreement of 90.6%, p<0.0001, respectively. According to the McNemar test, there was no significant difference in the university cohort (1.08%, p=0.25).

Comparing respective immunofluorescence patterns, 111 (15.3%) sera yielded differing results in both cohorts. Discrepant results were mainly obtained when the AKLIDES algorithms assessed cytoplasmic signals as nuclear staining due to superposition.

Conclusions: Automated interpretation of ANA by IIF on HEp-2 cells using an automated reading system is a reliable and robust method for positive/negative differentiation of IIF findings. Employing novel mathematical algorithms, automated interpretation provides reproducible detection of specific immunofluorescence patterns on HEp-2 cells. Automated interpretation can reduce drawbacks of ANA detection by IIF in routine diagnostics providing more reliable data for clinicians.

The CIRAS Study: A Case Control Study To Define the Clinical, Immunologic and Radiographic Features of the Aromatase Inhibitor Arthralgia Syndrome. Victoria K. Shanmugam[3], James McCloskey[1], Elizabeth Elston[4], Sandra J. Allison[2], Claudine Isaacs[5] and Jennifer Eng-Wong[5]. [1]Department of Internal Medicine, Georgetown University Medical Center, Washington, DC, [2]Department of Radiology, Georgetown University Medical Center, Washington, DC, [3]Division of Rheumatology, Immunology and Allergy, Georgetown University Medical Center, Washington, DC, [4]Georgetown University, [5]Lombardi Cancer Center, Georgetown University Medical Center, Washington, DC

Background: Aromatase inhibitors (AIs) reduce recurrence in postmenopausal hormone-receptor positive breast cancer. However, development of joint pains (Arthralgia Syndrome) limits compliance. The pathophysiology of this syndrome is unknown, but morning stiffness suggests an inflammatory etiology. Associations have been reported with tenosynovitis and autoimmune diseases. The CIRAS study was designed to determine the evidence for an inflammatory etiology.

Methods: Postmenopausal breast cancer patients followed at Lombardi Cancer Center with hand pain but without known autoimmune disease were recruited. Subjects receiving AIs were cases (n=25) while those not receiving AIs were controls (n=23).

Subjects were evaluated after abstaining from non-steroidal anti-inflammatory drugs for 48 hours. They completed a health assessment questionnaire (PROMIS-HAQ). The rheumatologist completed a history and physical, and disease activity score (DAS-28). Erythrocyte sedimentation rate (ESR), C-reactive protein (CRP), antinuclear antibody (ANA), rheumatoid factor (RF), anti-cyclic citrullinated peptide (CCP), vitamin D and cytokine levels were tested. Bilateral hand radiographs and ultrasound were performed. The hand ultrasound was scored for presence of flexor tenosynovitis, fluid in the metacarpophalangeal joints, tissue edema, and tendon sheath enhancement for each digit on both hands, and a total ultrasound score was computed. The rheumatologist and radiologist were blinded as to study group. Data was analyzed using t-test and Fisher's exact test.

Results: Patients in both groups were predominantly Caucasian and of similar age. Neither the DAS-28 nor the ESR was significantly different between cases and controls.

Table 1. Results of the CIRAS study

		CASE (n = 25)	CONTROL (N = 23)	p value
Symptoms:	PROMIS-HAQ (mean ± SEM)	9.700 ± 1.832	10.05 ± 2.529	0.5091
	PROMIS-HAQ Global (mean ± SEM)	51.04 ± 7.141	54.43 ± 7.714	0.7478
	Pain score (mean ± SEM)	34.88 ± 5.451	42.83 ± 5.506	0.3111
	Duration of morning stiffness/ hours (mean ± SEM)	2.400 ± 0.4203	1.435 ± 0.2937	0.0704
Inflammatory indices:	DAS-28 (mean ± SEM)	2.311 ± 0.1469	2.29 ± 0.1393	0.9182
	ESR mm hr (mean ± SEM)	17.08 ± 3.036	18.50 ± 2.936	0.7399
Vitamin D	Vitamin D ng/ml (mean ± SEM)	30.17 ± 2.537	33.35 ± 2.576	0.3848
Autoimmune features	ANA positive (n)	4	6	0.3900
	Autoimmune disease (n)	4	6	0.3900
X-ray	Degenerative joint disease (n)	15	14	0.9509
Other medication:	Bisphosphonate (n)	11	8	0.5661
	Tamoxifen (n)	7 current use	9 prior use	
Ultrasound findings:	Total ultrasound score (mean ± SEM)	6.600 ± 1.049	4.909 ± 1.040	0.2606
	Tendon nodules (n)	3	0	0.2354
	DeQuervain's tenosynovitis (n)	4	2	0.6681
	Ganglion cysts (n)	8	8	1.0000
	Flesor tenosynovitis (n)	14	10	0.5639

Hypovitaminosis D was found in 1 case and 5 controls (p 0.06).There was no significant difference in mean vitamin D. In each group two subjects had previously undiagnosed autoimmune disease (8.3%). A positive ANA was identified in 6 controls and 4 cases (20.8%). While cases experienced more prolonged morning stiffness, this did not reach statistical significance (p= 0.07). PROMIS-HAQ, global-HAQ and mean pain scores were not significantly different. There was no difference in ultrasound score or tendon nodules, Dequervain's tenosynovitis, ganglion cysts or flexor tenosynovitis. Several patients in the control arm had a similar constellation of symptoms to those receiving AIs.

Conclusions: The arthralgia syndrome may not be unique to patients receiving AIs. This syndrome warrants further investigation since development affects compliance with AI therapy.

ACR Poster Session B
Muscle Biology, Myositis and Myopathies: New Developments in the Diagnosis, Pathogenesis and Treatment of Myositis
Tuesday, November 9, 2010, 9:00 AM–6:00 PM

913

A Negative Anti-Nuclear Antibody Does Not Indicate Autoantibody Negativity. Rohit Aggarwal[2], Noreen Fertig[2], Dana P. Ascherman[3], Elaine A. Cassidy[1] and Chester V. Oddis[2]. [1]Children's Hospital Pittsburg, Pittsburgh, PA, [2]University of Pittsburgh, Pittsburgh, PA, [3]University of Pittsburgh, Pittsburgh, PA

Purpose: To evaluate the diagnostic utility of anti-cytoplasmic autoantibody (anti-cytAb) staining by indirect immunofluorescense (IIF) on Hep 2 substrate in anti-synthetase antibody positive (anti-synAb+) patients and to compare it with Anti-nuclear antibody (ANA) testing.

Methods: Using the Pittsburgh database of myositis and systemic sclerosis (SSc), anti-synAb+ patients were evaluated for ANA and anti-cytAb positivity. Anti-synAb+ patients included both Jo-1 and non-Jo-1 patients. SSc patients without anti-synAb were the control group. The following test characteristics of anti-cytAb and ANA were assessed in the anti-synAb+ patients: a) sensitivity [true positive (TP)/TP + false negative (FN)], b) specificity [true negative (TN)/ TN + false positive (FP)], c) positive predictive value (PPV; TP/TP + FP), d) negative predictive value (NPV; TN/TN + FN) and e) accuracy (TP + TN/ total number of patients tested). Anti-cytAb testing was done using the same method as ANA testing by IIF on Hep2 cell. Both were reported simultaneously on each patient sample. Anti-synAb status was not known before the ANA and anti-cytAb determination.

Results: All anti-synAb+ patients [n=202; Jo-1=122 patients; non-Jo-1=80 patients] between 1985–2009 with available serum samples were assessed. Non-Jo-1 included: anti-PL-12, anti-PL-7, anti-EJ, anti-OJ, anti-KS. Anti-cytAb showed high sensitivity (72%), specificity (91%), NPV (91%) and accuracy, but only modest PPV (44%) for anti-synAb positivity (Table 1). Similar sensitivity results were seen for Jo-1 and non-Jo-1 (PL-12, PL-7 and KS) autoAb subgroups. In contrast, the ANA showed only modest sensitivity (50%) as well as poor specificity (0.6%), PPV (5%), NPV (10%) and accuracy (5%). Positive anti-cytoplasmic staining was significantly greater in the anti-synAb+ patients than ANA positivity (72% vs. 50%, p<0.001). Moreover, 81/99 (82%) of ANA negative patients in the anti-synAb+ cohort had positive anti-cyt staining-Ab. In contrast, the control group of SSc (n=1946) showed high positive rates for ANA (1935/1946, 99%), but very low positive rates for anti-cytAb (180/1946, 9%). Combining anti-cytAb or ANA positivity to identify anti-synAb+ patients increases the sensitivity to 90% (177/196), but specificity decreases dramatically (0.4%). Finally, the combination of anti-cytAb or Jo-1 positivity shows high sensitivity (181/196, 92%) and specificity (91%) for identification of anti-synAb+ patients.

Table 1. Anti-cytAb and ANA sensitivity, specificity, NPV, PPV, and accuracy for anti-synAb+ patients

Test Statistic	ANA	Anti-cytAb	p value
Sensitivity			
All anti-synAb patients	100/199 (50%)	142/196 (72%)	p<0.001
All Jo-1	62/119 (52%)	77/116 (66%)	p=0.026
All non-Jo-1	38/80 (48%)	65/80 (81%)	p<0.001
PL-12	17/35 (49%)	30/35 (86%)	p<0.001
PL-7	13/25 (52%)	23/25 (92%)	p<0.001
EJ	3/9 (33%)	4/9 (44%)	NS
KS	2/6 (33%)	6/6 (100%)	p=0.013
OJ	3/5 (60%)	2/5 (40%)	NS
Specificity*	0.60%	91%	
NPV*	10%	91%	
PPV*	5%	44%	
Accuracy*	5%	89%	

*All anti-synAb group NS = not significant

Conclusions: Assessing patients for anti-cytAb staining using similar techniques to current ANA testing has excellent diagnostic utility for anti-synAb+ patients while ANA testing alone has poor test characteristics. Cytoplasmic staining should therefore be assessed and reported for patients suspected of having a rheumatic disease (RD), and a negative ANA should not be used to exclude a RD diagnosis.

A Novel Form of an Autosomal Dominant Vacuolar Hereditary Myopathy. Christine Castro[5], Ivona Aksentijevich[6], Elaine Remmers[6], Elisabeth Rushing[1], Simona Bianconi[3], Marjan Huizing[4], Mildred Wilson[6], Thomas Markello[2], Daniel Kastner[6] and Mark Gourley[6]. [1]Armed Forces Institute of Pathology, [2]National Institues of Health/National Human Genome Research Institute/Medical Genetics Branch, [3]National Institutes of Health, [4]National Institutes of Health, National Human Genome Research Institute, Medical Genetics Branch, [5]National Institutes of Health, National Institute of Arthritis and Musculoskeletal and Skin Diseases, Bethesda, MD, [6]National Institutes of Health, National Institute of Arthritis and Musculoskeletal and Skin Diseases

Background: Inclusion body myositis (IBM) is a slowly progressive skeletal muscle disease of unknown etiology with both sporadic and familial forms. The disease is characterized by proximal and often asymmetric distal muscle weakness, often with quadriceps atrophy. Muscle biopsy often shows degenerating and regenerating muscle fibers, perimyofiber distribution of inflammatory cells, and occasional red-rimmed vacuoles on Gomori trichrome staining. The most distinguishing feature is lack of response to immunomodulatory therapy. In familial IBM, disease onset often occurs in the late-teens to mid-20s; a Finnish form occurs in the 40s. Conversely, the sporadic form often occurs in those over age 50.

Purpose: We identify what we believe is a new familial form of IBM in one family with 3 generations demonstrating onset after age 50. In the third generation, 5 of 10 siblings are clinically affected, suggesting autosomal dominant inheritance. Results of muscle biopsy, EMG and MRI are consistent with IBM.

Methods and Materials: Subjects include 10 siblings (5 affected) ages 47 to 64, their unaffected father (age 86) and affected mother (age 70). They are of German and Dutch descent. Blood samples were obtained from all siblings and from the father. (A histology block of an endometrial biopsy from many years ago was obtained from the deceased mother.) MRI of bilateral thighs (T1-weighted and STIR images) was performed on 7 siblings. Muscle biopsy of the right quadriceps was done on 7 siblings and sent to Armed Forces Institute of Pathology for processing. DNA was extracted from blood of the 10 siblings, from their father, and the endometrial biopsy of the mother (later not used due to poor quality). Linkage analysis was performed and genotype data was analyzed via a program designed to identify the maternal haplotype transmitted to each child. Selected genes from the candidate interval were sequenced.

Results: MRI images from the 5 affected subjects showed edema, fatty replacement, muscle atrophy and/or fascial enhancement. The 2 unaffected subjects were normal. Histology revealed abnormalities including vacuoles on Gomori trichrome stain, degenerating and regenerating muscle fibers, fiber size variation, and presence of angular atrophic fibers in all 7 siblings. Through genetic analysis, a 3 megabase region of interest was found on chromosome 12. To date, no genes have been located.

Conclusion: We present a family with a seemingly autosomal dominant late onset vacuolar myopathy. Linkage analysis and gene sequencing has led us to chromosome 12 where a 3 megabase region peaks our interest. However, we have not yet isolated a gene. Characterization of this family's disease is of great interest because hereditary or familial forms of any IIM provide genetic information to further our understanding of this disease process as well as identify individuals who would be most affected by such diseases.

Anti-SRP Auto-Antibody Titers Correlate with Serum Creatine Kinase in Necrotising Myopathy. Olivier Benveniste[1], Laurent Drouot[3], Fabienne Jouen[3], Serge Herson[2], Jean-Luc Charuel[2], Coralie Bloch[2], Anthony Behin[2], Zahir Amoura[2], Isabelle Marie[4], Bruno Eymard[2], Danièle Gilbert[3], François Tron[3], Lucile Musset[2] and Olivier Boyer[3]. [1]Assistance Publique - Hôpitaux de Paris, Hôpital Pitié-Salpêtrière, Paris, France, [2]Assistance Publique - Hôpitaux de Paris, Hôpital Pitié-Salpêtrière, France, [3]Inserm, U905, Rouen University, France, [4]Rouen University Hospital, Department of Internal Medicine, France

Objective: Anti-signal recognition particle (SRP) auto-antibodies (aAbs) are associated with severe, generally treatment-resistant forms of acquired necrotising myopathies. The physiological role of the SRP complex is to guide the translocation of nascent polypeptides into the endoplasmic reticulum during protein synthesis. Since the expression of SRP is ubiquitous, the role of anti-SRP aAbs in myopathies remains elusive. Notably, clinical studies have been hampered by the lack of a quantitative assay for the longitudinal follow-up of anti-SRP aAb titers. To this end, we developed a Luminex™-based quantitative test of anti-SRP aAb, referred to as Fluorescence Microsphere Immunoassays for quantification of SRP54-specific aAb (FMI-SRP54), and asked whether there was a correlation between anti-SRP aAb titers and serum creatine kinase (CK) levels.

Methods: The diagnostic value of the test was determined by comparing serum titers from 31 anti-SRP aAb positive patients to that of 190 healthy blood donors and 167 control patients with different inflammatory/autoimmune conditions including 80 rheumatoid arthritis, systemic sclerosis or lupus, 30 anti-tRNA synthetase aAb positive myositis, 30 inclusion body myositis and 27 patients with polyclonal hypergammaglobulinemia. Among the 31 anti-SRP aAb positive patients, 8 were sampled over time for monitoring of anti-SRP aAb titers and CK levels (at least 3 times consecutively with a mean follow-up of 722 days). The date of the first sample corresponded to the initiation of treatment (for naive patients) or restart of a modified one (for relapsing patients). The relationship between anti-SRP aAb titers and CK levels was tested using a linear mixed model.

Results: The specificity of the assay was 100% with a confidence interval of [98%–100%] and the sensitivity was 100% [89%–100%]. There was a clear predominance of the IgG1 and IgG4 isotypes among anti-SRP54 aAbs. FMI-SRP54 permitted to measure the degree of aAb depletion after plasma exchanges that repeatedly reduced anti-SRP54 aAb titers by more than 2-fold in one patient studied. Importantly, the longitudinal follow-up of the 8 patients revealed a striking correlation between the degree of myolysis under therapy measured by CK levels and the anti-SRP54 aAb titers ($p<0.005$).

Conclusion: Anti-SRP aAb positive myopathy appears as one of the few human autoimmune diseases in which specific aAb titers correlate with surrogate disease activity markers. These results may also suggest a pathogenic role for anti-SRP aAbs and prompts to evaluate B-cell targeting therapies in patients with this particular form of necrotising myopathy.

Clinical Manifestation and Prognostic Factor in Anti-Melanoma Differentiation-Associated Gene 5 Antibody-Associated Interstitial Lung Disease as a Complication of Dermatomyositis. Takahisa Gono[5], Yasushi Kawaguchi[3], Takashi Satoh[2], Masataka Kuwana[1], Yasuhiro Katsumata[5], Kae Takagi[5], Ikuko Masuda[3], Sayumi Baba[5], Masanori Hanaoka[5], Yuko Okamoto[5], Yuko Ota[5], Sayuri Kataoka[5] and Hisashi Yamanaka[4]. [1]Keio University School, Tokyo, Japan, [2]Keio University School, [3]Tokyo Women's Medical University, Tokyo, Japan, [4]Tokyo Women's Medical University, Shinjuku-ku, Tokyo, Japan, [5]Tokyo Women's Medical University

Purpose: The aim of the present study is to evaluate the clinical manifestation and prognostic factors of anti-melanoma differentiation–associated gene 5 (MDA5) antibody-associated interstitial lung disease (ILD) with dermatomyositis (DM).

Methods: Fourteen patients who presented with anti-MDA5 antibody and 10 patients with anti-aminoacyl-tRNA synthetase (ARS) antibody were enrolled. All of patients were diagnosed as having DM with ILD. Clinical manifestations in the patients with anti-MDA5 antibody were compared to those in the patients with anti-ARS antibody.

Results: The age at onset was 43.6 ± 14.6 years (mean ± SD), with no significant difference between each subset. The frequency of clinically amyopathic dermatomyositis (57%) was significantly higher ($P = 0.033$) in the subset with anti-MDA5 antibody. The creatine kinase (CK) value (median, 198 IU/ml) was significantly lower ($P = 0.01$) and ferritin values (median, 680 ng/ml) were significantly higher ($P = 0.016$) in the subset with anti-MDA5 antibody. The frequencies of acute/subacute interstitial pneumonia was significantly higher ($P = 0.036$) in the subset with anti-MDA5 antibody (71%) than the subset with anti-ARS antibody (20%), although pulmonary function showed no significant differences between each subset. Significant correlations were found between A-a$DO_2$and KL-6 ($r_s = 0.73$, $P = 0.016$), and A-aDO_2 and ferritin ($r_s = 0.66$, $P = 0.013$) in the subset with anti-MDA5 antibody. Clinical manifestations were compared between the surviving and non-surviving patients who had ILD with anti-MDA5 antibody.

The followings were significantly higher in the non-surviving patients with anti-MDA5 antibody: age at onset ($P = 0.045$), A-aDO_2 ($P = 0.045$), AST ($P = 0.027$), γ-GTP ($P = 0.028$), and ferritin ($P = 0.016$). Age- and sex-adjusted Cox regression analysis was performed to identify a prognostic factor for ILD with anti-MDA5 antibody. The most significant prognostic factor was serum ferritin (Hazard ratio per unit 1.005, 95% confidential interval 1.004–1.014, $P = 0.027$). The cumulative 60-month survival rates were significantly lower ($P = 0.042$) in the subset with anti-MDA5 antibody (62.9%) than in the subset with anti-ARS antibody (100%). Additionally, the cumulative survival rate was significantly lower ($P < 0.0001$) in the subset with ferritin ≥ 1600 ng/mL than that in the subset with ferritin <1600 ng/mL in anti-MDA5 antibody-associated ILD.

Conclusion: Both serum ferritin and anti-MDA5 antibody are powerful indicators for the early diagnosis of A/SIP with DM. Serum ferritin also predicts disease severity and prognosis for patients with anti-MDA5 antibody.

Efficacy and Tolerance of Rituximab in Refractory Idiopathic Inflammatory Myopathy. Data of the AIR Registry. Marion Couderc[3], Jacques E. Gottenberg[12], Xavier Mariette[2], Eric Hachulla[9], Jean Sibilia[11], Olivier Fain[6], Arnaud Hot[8], Maxime Dougados[5], Liana E. Euller-Ziegler[7], Pierre Bourgeois[10], Claire Larroche[10], Anne Tournadre[3], Zahir Amoura[10], Bernard Mazieres[14], P. Arlet[13], Michel De Bandt[1], Thierry Schaeverbeke[4] and Martin Soubrier[3]. [1]Aulnay Hospital, Carrieres Sur Seine, France, [2]Bicetre Hospital/Paris Univ, Le Kremlin Bicetre, France, [3]Clermont-Ferrand Hospital, [4]Groupe Hospitalier Pellegrin, Bordeaux, France, [5]Hospital Cochin, Paris, France, [6]Jean Verdier Hospital, Paris University, [7]L'Archet Hospital (University), Nice, France, [8]Lyon Hospital, [9]National Scleroderma Centre, Lille Cedex, France, [10]Paris Hospital, [11]Strasbourg Hospital, Strasbourg, France, [12]Strasbourg Hospitals, Strasbourg, France, [13]Toulouse Hopsital, [14]Toulouse Hospital

Objective: To assess the efficacy and tolerance of Rituximab (RTX) in patients with refractory idiopathic inflammatory myopathies.

Methods: Adult patients from the Auto-Immunity and Rituximab (AIR) french registry treated by RTX for polymyositis (PM), dermatomyositis (DM) or antisynthetase syndrome (AS) were prospectively included. Efficacy was evaluated on the basis of CPK level, daily corticosteroid dose (CS), concomitant immunosuppressor treatment (IS) dose and physicians' opinion. A patient was considered as a responder if there was improvement in at least 2 of these 4 criteria and no aggravation in the 2 others.

Results: Thirty patients were studied (21 women (70%), mean age 52.5 years), 12 with PM, 6 with DM and 12 with AS. Mean disease duration was 6.1 years. All had received IS agents. Twenty-five patients received two doses of 1 gram of RTX 2 weeks apart and 5 patients received four weekly infusions of 375 mg/m2 of RTX. RTX was given alone to 9 patients and in combination with IS to the others. Twenty eight patients received associated CS (mean daily dose 21.4 mg/day). The mean follow up period was 17.2 months.

Twelve adverse events corresponding to 27.9 adverse events per 100 patient-years were reported: two acute infusion reactions of moderate severity, two episodes of undetermined fever, and eight infectious events (18.6 for 100 patients-year) in 7 patients of which seven were mild to moderate, and only one serious (pyelonephritis). Most of these infectious events occurred in the initial 6 months (87.5%).

Efficacy was observed in 21 patients (70%): 8 PM (66.7%), 5 DM (83.3%), 8 AS (66.7%). The mean daily corticosteroid dose (CS) decreased from 21.2 +/− 19.5 to 9.9 +/− 8.5 mg/day. Daily CS dose decreased in 20 patients, increased in 3, and remained unchanged in 7 patients. In patients with elevated CPK level (n=24), it decreased in 19 patients, increased in 5 patients and the mean CPK level decreased from 20,7 ± 29,9 to 11 ± 24,6 times the normal range. Physician opinion on RTX efficacy was favourable for 20 patients and unfavourable for 10. Three patients were considered to be in complete remission with normal CPK level, discontinuation of corticosteroids and in 2 of them discontinuation of IS therapies. Efficacy was not significantly different between patients with or without inflammatory myopathy antibodies [14/17 (82.3%)] [7/13(53.8%)] (p = 0.12)]. Mean duration of efficacy in responders was 15.5 months. Ten patients received a second course of RTX; efficacy was observed in 8 with a mean duration of 7.4 months, 1 patient was not evaluated and 1 did not respond.

Conclusions: Rituximab seems to be an effective and well-tolerated treatment in patients with idiopathic inflammatory myopathies.

Efficacy of Allogeneic Mesenchymal Stem Cells Transplantation in Patients with Drug-Resistant Polymyositis and Dermatomyositis. Lingyun Sun[1], Dandan Wang[2], Huayong Zhang[2], Jun Liang[2] and Xuebing Feng[2]. [1]Department of Rheumatology and Immunology, The Affiliated Drum Tower Hospital of Nanjing University Medical School, Nanjing, Jiangsu, China, [2]Department of Rheumatology and Immunology, The Affiliated Drum Tower Hospital of Nanjing University Medical School

Objective: To assess the safety and clinical efficacy in ten patients with drug-resistant polymyositis (PM) or dermatomyositis (DM) treated by allogeneic mesenchymal stem cells transplantation (MSCT).

Methods: A single-arm trial involved 10 DM/PM patients, 4 for DM and the other 6 for PM, aged from 19 to 44 years old, that were refractory to standard treatment and/or with severe systemic involvement. Average disease duration was 7.5 months (6 to 60 months). All the patients met the Bohan and Peter criteria for DM or PM. Three patients received bone marrow (BM) derived MSC, two of which were given a second umbilical cord (UC) derived MSC due to disease relapse. The other 7 patients were transplanted with UC-MSC only once time. BM MSC were aspirated from related healthy donors and expanded in vitro, and UC MSC were obtained from Stem Cell Center of Jiangsu Province of China. All the infused MSC were derived from passage 2 to passage 4, with rigorous purification and quality control. The clinical manifestations and laboratory parameters were compared pre- and post-MSCT, with a mean follow-up of 12 months (range, 6 to 18 months). Advert events were monitored all the time during and post-MSCT.

Results: Serum creatine kinase (CK) for all the patients decreased significantly at the first 6 months (baseline: 2380.0±673.8U/L; 1m: 1027.0±266.7U/L; 2m: 486.2±143.1U/L; 3m: 92.9±19.5U/L; 6m: 248.8±135.6U/L, all $p<0.05$ vs baseline value), and continued to decreased to 106.0±39.4U/L for 5 patients completed 1 year visit, in paralleled with the amelioration of serum CK-MB levels at the same visit. Meanwhile, patient's global assessment by VAS and detection for the Manual Muscle Test (MMT) also ameliorated with improved disease. In addition, MRI confirmed alleviated inflammation in the thigh muscles 3 months after BM MSC infusion for one patient. Six patients were complicated with moderate-to-severe ILD, shown as interstitial pneumonia. High-resolution CT scans manifested obvious amelioration in 3 patients, and at least no progression in 2 patients 6 months post-MSCT. Furthermore, for one patient with refractory skin ulcers on both knees, elbows and proximal interphalangeal joints, matter plus decreased and new granulation tissues appeared at 2 months visit, and almost healings of the ulcers 6 months after UC MSCT. Disease relapsed in 3 patients at 5, 6, 8 months post-MSCT respectively, 2 of which received second UC MSC infusion, also due to ineffective to standard treatments. Unfortunately, one patient was unresponsive to second MSCT, and the other died 5 months later due to rapid progression of disease and severe myocarditis induced by a common cold. Another patient died 7 months post-MSCT, due to uncontrolled pulmonary infection. No transplant related mortality or any significant toxicity was observed during or after MSC infusion.

Conclusion: We provide evidence that allogeneic BM or UC MSC infusion is safe and effective in drug-resistant DM/PM patients. However, further observation with more patients included and longer periods of follow-up will be needed to determine the efficacy and safety of this novel approach to the treatment of DM/PM.

ESR and CRP Do Not Correlate with Extent of Muscle Injury but Their Elevation Is Associated with Pulmonary Involvement in Idiopathic Inflammatory Myopathy. Jin Kyun Park[4], Michael George[2], Sonye K. Danoff[3], Marzouq A. Qubti[4], Allan C. Gelber[1] and Lisa Christopher-Stine[5]. [1]Baltimore, MD, [2]Department of Medicine, University of Pennsylvania, [3]Division of Pulmonary and Critical Care Medicine, Johns Hopkins University School of Medicine, [4]Division of Rheumatology, Department of Medicine, Johns Hopkins University School of Medicine, Baltimore, MD, [5]Johns Hopkins University, Baltimore, MD

Background: Although Idiopathic Inflammatory myopathies (IIM) are systemic autoimmune diseases with muscle as the main target, the clinical implication of Erythrocyte Sedimentation Rate (ESR) is not well defined to date. From our clinical experience, we hypothesized that ESR is elevated in IIM subsets with interstitial lung disease (ILD).

Methods: Clinical and laboratory data from 50 patients with IIM who visited our Center between March 2007 and April 2009 were collected. All patients underwent routine CT scanning in a standard protocol to assess malignancy and ILD status. ESR (normal<30mm/hr), C-reactive protein (CRP; normal <0.5 mg/dL), creatine phosphokinase (CPK) and aldolase level were measured at the time of diagnosis. ILD was defined by presence of typical radiographic changes. Mann-Whitney test for continuous variables and 2 sided Fisher's exact test for dichotomous variables were performed. Rho and P values were generated using Spearman's correlation analysis. These associations were also examined in analyses stratified by the presence (vs. absence) of ILD. P-values of <0.05 were considered statistically significant.

Results: ESR and CRP did not correlate significantly with CPK (ESR, r_s= 0.106, p=0.465; CRP, r_s =0.031, p=0.878) or aldolase (ESR, r_s= 0.034, p= 0.827; CRP, r_s=0.076, p=0.719), while CPK and aldolase showed high correlation with each other (r_s=0.784, p<0.001) as expected. Notably, there were 21 patients with 29 without ILD. Age, gender and race did not differ significantly between both groups. CPK and aldolase did not differ between IIM without versus with ILD (CPK 1028 +/− 2567 IU/L vs. 1227 +/−2804 IU/L, p=0.723; aldolase 16.9 +/− 22.2 IU/L vs. 22.7 +/− 35.6 IU/L, p=0.914). However, within the IIM stratum with ILD, ESR was significantly higher (18.3 +/−15.7 mm/hr vs. 44.9 +/− 36 mm/hr, P= 0.001). CRP was similarly higher in ILD groups (0.71 +/− 0.57 mg/dL vs. 0.23 +/− 0.185 mg/dL, p=0.045). Further, 5 (17.2 %) out of 29 patients without ILD had elevated ESR as compared to 12 (57.1 %) out of 21 with ILD (p= 0.0059). CRP was elevated in 1 (7.7 %) of 13 IIM without ILD, and in 7 (50 %) of 14 IIM with ILD (p=0.035).

Conclusion: Here, we provide evidence that: i.) ESR and CRP do not correlate with biochemical muscle injury and ii.) elevation of ESR or CRP is associated with the presence of ILD. Therefore, any elevation of systemic inflammatory markers should prompt clinicians to evaluate for the presence of an ILD.

Evaluation of Reliability, Validity, and Responsiveness of the CDASI and CAT-BM. Renato Goreshi[8], Joyce Okawa[8], Matt Rose[8], Rui Feng[1], Lela Lee[6], Christopher Hansen[10], Carolyn Bangert[9], Kari Connolly[5], Mark Davis[2], Jeff Callen[7], Nicole Fett[8], Steven Fakharzadeh[4], Jennie Clarke[3] and Victoria Werth[8]. [1]Center for Clinical Epidemiology and Biostatistics, University of Pennsylvania, [2]Mayo Clinic- Rochester, [3]Penn State Hershey, School of Medicine, [4]Philadelphia VA Medical Center, [5]University of California-San Francisco, School of Medicine, [6]University of Colorado, School of Medicine, [7]University of Louisville, School of Medicine, [8]University of Pennsylvania, School of Medicine, [9]University of Texas, School of Medicine, [10]University of Utah, School of Medicine

To properly evaluate therapies for cutaneous dermatomyositis (DM) it is essential to administer an outcome instrument that is reliable, valid, and responsive, particularly when measuring disease activity. The purpose of this study is to compare two skin-severity DM outcome measures, the Cutaneous Disease and Activity Severity Index (CDASI) and the Cutaneous Assessment Tool-Binary Method (CAT-BM), with the Physician Global Assessment (PGA) as the 'gold standard'. In a one-day session, ten dermatologists evaluated fourteen patients with DM using the CDASI, CAT-BM, and PGA scales, which were used as the 'gold standard' for comparison. Inter- and intra-rater reliability was assessed by intraclass correlation coefficients (ICC) and paired t-tests. Construct validity was determined by using a linear mixed model. Content validity was determined by administering a Physician Exit Questionnaire, specifically asking if any outcome instrument was missing an appropriate measure for the evaluation of DM. Responsiveness was assessed from a different study population, where one physician determined CDASI, CAT-BM, and PGA scale scores, including a qualitative perception from the physician if the patient had improved, worsened, or had no change from their previous visit. A standard response mean (SRM), or mean change:standard deviation of change between visits, of the activity scores of each outcome instrument was determined by choosing the largest change in PGA scale scores between two visits, when the physician noted a change between visits. Difference in completion time of each instrument was assessed by a paired t-test. The CDASI was found to have a higher inter-rater reliability (ICC: CDASI Activity 0.748, CAT-BM Activity 0.546) and a higher intra-rater reliability (ICC: CDASI Activity 0.868; CAT-BM Activity 0.714). To assess construct validity, both the CDASI and the CAT-BM were found to be significant predictors of the the PGA scales (p<0.001). All physicians felt that the CDASI was not missing any measure to sufficiently assess DM. 90% of physicians felt the same with the CAT-BM, with one physician feeling that the CAT-BM did not adequately assess the scalp. The CDASI had the highest SRM among all outcome instruments (CDASI: 1.25, CAT-BM: 0.93, PGA-Activity: 1.03, PGA-Activity Likert: 0.61). The CDASI had a statistically longer completion time than the CAT-BM (Completion Time: CDASI 4.76 minutes; CAT-BM 3.19 minutes; p<0.001) with a mean time difference of 1.58 minutes. We conclude that the CDASI is a better clinical tool to assess skin severity in DM, especially in regards to responsiveness.

Fasciitis Is a Common Lesion of Dermatomyositis Demonstrable Early after Disease Onset by *En Bloc* Biopsy Combined with Magnetic Resonance Imaging. Ken Yoshida[2], Daitaro Kurosaka[2], Kensuke Joh[1], Eigo Takahashi[2], Kenichiro Hirai[2], Kentaro Noda[2], Taro Ukichi[2], Kazuhiro Furuya[2], Maimi Yanagimachi[2], Isamu Kingetsu[2] and Akio Yamada[2]. [1]Division of Pathology, Sendai Shakai Hoken Hospital, [2]Division of Rheumatology, Department of Internal Medicine, Jikei University School of Medicine, Tokyo, Japan

Purpose: To investigate the incidence of fasciitis in dermatomyositis (DM), and to analyze the process of myositis progression.

Methods: *En bloc* biopsy combined with Short tau inversion recovery or fat-suppressed T2-weighted magnetic resonance imaging (MRI) was performed on fourteen patients with newly diagnosed adult-onset DM. Vascular inflammation score (VIS) was defined as the number of aggregates of ≥50 inflammatory cells infiltrating around a small blood vessel or vessels per 4 mm^2 area of tissue. Total vascular inflammation score (TVIS) was defined as the summation of VIS in three fields with the most remarkable perivascular infiltrates. Fasciitis was defined as TVIS of the fascia ≥3 to exclude very mild inflammation. The grade and distribution of perivascular inflammatory changes were evaluated in the fascia and muscle using TVIS. *En bloc* biopsy was also performed on six patients with other rheumatic diseases including three patients with polymyositis (PM). These subjects constituted a comparison group. Immunohistochemistry was performed to identify T lymphocytes (CD3), CD4+ cells, CD8+ cells, B cells (CD20, CD79a), and macrophages (CD68).

Results: In all patients with DM, MRI revealed abnormal hyperintensity in the fascia and in marginal sites of the muscle predominantly over central sites. In Case 11, abnormal hyperintense areas were detected on the first MRI in the fascias, and on the second MRI two months later, the hyperintense areas had progressed from the fascias to marginal sites of the muscles. *En bloc* biopsy revealed fasciitis evidenced by inflammatory infiltrates around the fascial small blood vessels in most of the patients with DM. However, inflammatory infiltrates around the intramuscular small blood vessels were not detected in four patients with DM. In those who underwent *en bloc* biopsy earlier than two months after the appearance of muscle symptoms, TVIS of the fascia was significantly higher than TVIS of the muscle. In contrast, in those who underwent *en bloc* biopsy at two months or later, TVIS of the

fascia did not differ significantly from TVIS of the muscle. Immunohistochemistry showed that CD3+ T lymphocytes, CD4+ cells and CD20+ B cells were mainly present among inflammatory cells. The CD4/CD8 cell ratio was >1 in almost all specimens from the patients with DM. In any one of the patients with other rheumatic diseases, MRI revealed no significant hyperintense areas in the fascias and none of specimens from other rheumatic diseases histopathologically revealed fasciitis.

Conclusions: Fasciitis was histopathologically confirmed in most of the patients with adult-onset DM and recognized as a common lesion that appears early after the onset of muscle symptoms in DM. Our results suggest that the fascial microvasculature is the primary site of inflammatory cell infiltration in DM. The results of MRI suggest that inflammation in myopathy accompanying DM progresses from the fascia into the muscle. Muscle symptoms such as myagia in DM may be attributed to fasciitis if muscle biopsy reveals no myositis. Fasciitis may be a lesion specific to DM rather than to PM.

Immunosuppressive Treatments Do Not Alter Natural History of Sporadic Inclusion Body Myositis: The Paris/Oxford Study on 136 Patients. Benveniste Olivier[2], Guiguet Marguerite[5], Jane Freebody[4], Serge Herson[2], Odile Dubourg[3], Waney Squier[4], Pascal Laforet[1], Isabel Leite[4], Bruno Eymard[1] and David Hilton-Jones[4]. [1]Assistance Publique-Hôpitaux de Paris, Hôpital Pitié-Salpêtrière, Institut de Myologie, France, [2]Assistance Publique-Hôpitaux de Paris, Hôpital Pitié-Salpêtrière, Médecine Interne, France, [3]Assistance Publique-Hôpitaux de Paris, Hôpital Pitié-Salpêtrière, Neuropathologie, France, [4]Department of Neurology, West Wing, John Radcliffe Hospital, Oxford, United Kingdom, [5]INSERM–UPMC UMR S 943, Biostatistique, Paris, France

Objective: Sporadic inclusion body myositis (sIBM) is characterized by slowly progressive, asymmetric atrophy and weakness of both proximal and distal muscles, most prominently affecting the finger and wrist flexors and quadriceps. Although drugs such as corticosteroids, methotrexate, cyclophosphamide, and IVIg may reduce the degree of inflammation on biopsy and lower serum creatine kinase levels, clear clinical improvement has not been demonstrated. The aim of the study was to evaluate whether immunosuppression alters the course of progression of sIBM.

Methods: Two cohorts of patients, one from Paris and the other from Oxford were included. The same clinical-research form was used in both centers for data collection and was completed either during a clinic visit (52%), or by extraction from previous medical records (48%).

Results: 136 patients (57% males, 61 [55–69] years at onset) were included. sIBM was diagnosed on the basis of accepted clinical and pathological criteria; 97 patients (72%) were considered to have definite sIBM, 39 patients (28%) had probable sIBM. At the last visit all patients had muscle weakness (proximal MRC $\leq$ 3/5 in 47%, distal MRC $\leq$ 3/5 in 38%) and half of them reported swallowing problems. During their follow-up, 75% of patients had significant walking difficulties and 37% used a wheelchair (after a median duration from onset of 14 years). The risk of death was only influenced by older age at onset of first symptoms. 71 (52%) patients received immunosuppressive treatments (prednisone in 91.5% associated (in 64.8%) with other immunomodulatory drugs (intravenous immunoglobulins, methotrexate or azathioprine) for a median duration of 41 months). At the last assessment, patients who had been treated were more severely affected on a sIBM weakness composite index ($p=0.03$) and disability scales (Walton $p=0.007$, RMI $p=0.004$).

Conclusion: This study showed that in our population, sIBM started on average in the 6th decade of life and is then slowly progressed. It took a median of 14 years to get from first symptoms to the need to use a wheelchair, but also, that this disease is not usually the cause of death. Furthermore, it could not be excluded that conventional immunosuppressant treatment is not only ineffective but might also hasten progression. The findings of this study include important messages for the design of the future trials.

Interleukin-18 Is a Key Mediator in Dermatomyositis: Contribution to Development of Interstitial Lung Disease. Takahisa Gono[2], Yasushi Kawaguchi[1], Tomoko Sugiura[2], Kae Takagi[2], Ikuko Masuda[1], Hisae Ichida[2], Yasuhiro Katsumata[2], Akiko Tochimoto[2], Sayumi Baba[2], Masanori Hanaoka[2], Yuko Okamoto[2], Yuko Ota[2], Sayuri Kataoka[2] and Hisashi Yamanaka[3]. [1]Tokyo Women's Medical University, Tokyo, Japan, [2]Tokyo Women's Medical University, [3]Tokyo Womens Med Univ, Shinjuku-ku, Tokyo, Japan

Purpose: The aim of the present study is to determine whether interleukin (IL)-18 is involved in the inflammation of dermatomyositis (DM) and polymyositis (PM).

Methods: Thirty-three patients with DM were enrolled in this study, including 25 with interstitial lung disease (ILD). In addition, 16 patients with PM were enrolled, including 6 with ILD. All patients were admitted to our hospital as a result of their condition requiring treatment, and clinical laboratory data including serum creatine kinase (CK), ferritin and IL-18 were recorded on admission.

Results: The level of CK was significantly ($P = 0.01$) higher in PM patients (median, 2174 IU/ml) than in DM patients (median, 375 IU/ml). Although CRP levels were not significantly different, ferritin was significantly ($P = 0.003$) higher in DM patients (median, 236 ng/ml) than in PM patients (median, 55 ng/ml). The median levels (range) of serum IL-18 were 552 pg/mL (141–4850), 256.5 pg/mL (119–2190), and 50.5 pg/mL (18–121) in DM patients, PM patients, and healthy controls (n = 30), respectively. The levels of IL-18 were significantly higher in DM and PM patients than in healthy controls ($P < 0.0001$ for both comparisons), and were significantly ($P = 0.0044$) higher in DM than in PM patients. Additionally, ferritin and IL-18 were significantly ($P = 0.023$ and 0.034, respectively) higher in DM patients with ILD (median, 320 ng/ml and 625 pg/ml, respectively) than in DM patients without ILD (median, 82 ng/ml and 328 pg/ml, respectively), but the CK and CRP levels were not significantly different. By contrast, the median values of IL-18 were 382.5 pg/mL and 234.5 pg/mL in PM with ILD and PM without ILD patients, respectively. There were no significant differences between PM with and without ILD for the measured parameters. Significant positive correlations were found between CK and ferritin ($r_s = 0.39$, $P = 0.024$), CK and IL-18 ($r_s = 0.48$, $P = 0.005$), and IL-18 and ferritin ($r_s = 0.54$, $P = 0.0012$) in the DM group as a whole, although correlations between CRP and CK, CRP and IL-18, and CRP and ferritin were not found. These findings were especially notable in the DM with ILD subset. Significant positive correlations were found between CK and ferritin ($r_s = 0.40$, $P = 0.047$), CK and IL-18 ($r_s = 0.63$, $P = 0.0008$), and IL-18 and ferritin ($r_s = 0.41$, $P = 0.042$) in the DM with ILD subset. By contrast, there was no significant correlation with PM.

Conclusion: Serum IL-18 was strikingly elevated in patients with DM, and was associated particularly with disease activity and ILD complication in DM.

KL-6: A Serological Biomarker for Interstitial Lung Disease and Pulmonary Function in Patients with Polymyositis and Dermatomyositis. Sevim Barbasso Helmers[3], Maryam Fathi[1] and Ingrid E. Lundberg[2]. [1]Department of Respiratory Medicine and Allergy, Karolinska Institutet, Stockholm, Sweden, [2]Karolinska Institutet, Stockholm, Sweden, [3]Rheumatology Unit, Dpt. of Medicine, Karolinska University Hospital, Solna, Karolinska Institutet, Stockholm, Sweden

Background: Interstitial lung disease (ILD) is reported in up to 78% of polymyositis (PM) and dermatomyositis (DM) patients, but pulmonary function tests are not always easily available and repeated radiological examinations are restricted by the irradiation. One interesting biomarker for ILD is Krebs von den Lungen-6 (KL-6), a glycoprotein secreted by type II alveolar pneumocytes and bronchiolar epithelial cells. A few studies with a limited number of patients have reported elevated serum levels of KL-6 in patients with myositis associated ILD. These need replication and it is unknown whether KL-6 serum levels vary over time in PM/DM patients.

Objectives: To investigate whether Caucasian patients with PM/DM and ILD have elevated serum levels of KL-6 compared to healthy controls and

whether KL-6 could be used as a marker for disease activity and prognosis of ILD in PM/DM.

Methods: Thirty PM/DM patients (19 women, 11 men; median 54 years, range 22–74,) and 17 age- and gender matched healthy controls were included in a cross-sectional analysis. Twelve patients with less than one month in between multiple serum samples and lung function tests were included for longitudinal evaluation. KL-6 serum levels were analyzed using a sandwich enzyme immunoassay kit (Sanko Junyaku Co., Ltd, Tokyo, Japan). ILD was defined as restrictive lung function impairment, total lung capacity (TLC) and diffusing capacity for carbon monoxide (DLco) l<80% of predicted, with radiographic signs of ILD on chest X-ray /or high resolution computerized tomography. Groups were compared by Mann Whitney test. Spearman's correlation r-value > 0.5 or < -0.5, and p-values ≤ 0.05 were considered significant.

Summary of Results: Patients with PM or DM had significantly higher KL-6 serum levels compared to healthy controls (median, range; 400, 132–2318 U/ml versus 225, 136–519 U/ml, p=0.01). The patients with ILD (n=7) had significantly higher median serum concentrations of KL-6 compared to those without (n=23) (995, 533–2318 U/ml versus 322, 132–1225 U/ml, p=0.0002). At KL-6 cut-off level of 549 U/ml (mean ±2.5 SD of controls) we found a sensitivity and specificity of 84% and 80% respectively for diagnosis of ILD. A significant inverse correlation between KL-6 serum levels and results of pulmonary function tests was demonstrated in the cross sectional part: forced expiratory volume in one second (FEV1)% (r=−0.60), vital capacity (VC)% (r=−0.54), TLC% (r=−0.59), Forced VC (FVC)% (r=−0.64) and DLco% (r=−0.52). In the patients with longitudinal follow up, this inverse correlation increased: FEV1% (r=−0.801), VC% (r=−0.788), TLC% (r=−0.788), FVC% (r=−0.784) and DLco% (r=−0.653). The changes of KL-6 serum levels showed a significant inverse correlation with changes of the pulmonary function tests: FEV1% (r=−0.570), TLC% (r=−0.530), DLco% (r=−0.530) and RV (r=−0.525). There was no significant correlation between serum levels of KL-6 and CRP or creatine kinase (CK) levels.

Conclusion: These results support the usefulness of serum measurements of KL-6 in the diagnostic evaluation and establishment of severity, as well as in evaluation of response to therapy in patients with ILD and myositis.

Longitudinal Assessment of Activity and Damage in a Synthetase Positive Cohort. Elaine A. Cassidy[1], Rohit Aggarwal[3], Noreen Fertig[4], Dana P. Ascherman[3] and Chester V. Oddis[2]. [1]Children's Hospital Pittsburgh Division of Rheumatology, Pittsburgh, PA, [2]University of Pittsburgh, Pittsburgh, PA, [3]University of Pittsburgh School of Medicine Division of Rheumatology and Clinical Immunology, Pittsburgh, PA, [4]University of Pittsburgh School of Medicine Division of Rheumatology and Clinical Immunology

Purpose: To compare disease activity and damage in a longitudinal cohort of Jo-1 and non Jo-1 anti-tRNA synthetase autoantibody (anti-synAb) positive patients (pts).

Methods: Since 2002 one investigator (CVO) has prospectively completed the Myositis Disease Activity Assessment Tool (MDAAT) and Myositis Damage Index (MDI) on pts with the data entered into the Myositis Data Management System (MDMS). All anti-synAb+ pts in MDMS were included in this analysis. The MDAAT includes an intention to treat component but only the visual analog scale (VAS) assessing disease activity at last visit in constitutional, cutaneous, skeletal, pulmonary, extramuscular global, muscle and overall global categories were used in this study. VAS activity scores were designated as: none=0; minimal (0<VAS≤1); mild (1<VAS≤3); moderate (3<VAS≤7) and severe (VAS>7). The groups were compared using Kruskal Wallis test for VAS scores, and the Chi-square test for ordinal VAS values. The MDI assesses organ system damage using a VAS and a dichotomous variable, and the 2 groups were compared using the last recorded organ system VAS score (Kruskal Wallis) and the presence or absence of organ damage using Chi-square test for skeletal, muscle, pulmonary, and global categories. Regression analysis was used to control for time from diagnosis and first visit to assessment of activity or damage.

Results: Activity was assessed in 59 anti-synAb+ pts (41 Jo-1; 18 non-Jo-1) having at least 2 MDAATs in 1 year, or >3 over any time period. Damage was assessed in 71 pts (50 Jo-1; 21 non-Jo-1) that had >1 MDI. The Jo-1 and non-Jo-1 groups were similar in terms of gender and ethnicity. Median time in yrs (IQR) from diagnosis to last completed MDAAT was 5.8 (2.2–3.9) vs. 4.2 (2.0–8.7) for Jo-1 and non-Jo-1 pts (p=NS). The skeletal activity at last assessment was worse in Jo-1 pts as 71% had VAS = 0 compared to 95% of non Jo-1 pts (p=0.03). This remained significant after controlling for time from diagnosis or first visit to assessment (p=0.03). There were no differences in disease activity at last visit between Jo-1 and non Jo-1 pts in the other categories. Regarding damage, non-Jo-1 patients had significantly more damage from pulmonary hypertension (PHT) at last MDI (40% non-Jo 1 vs. 11% Jo-1 pts; p=0.005) which remained significant after controlling for time from diagnosis or first visit (p=0.006). Forty-two of 71 anti-synAb+ pts had pulmonary function tests at last MDI and %predicted FEV-1 (75 +/− 16 vs. 74 +/− 25) and %predicted DLCO (57 +/− 23 vs. 52 +/− 25) were similar for Jo-1 and non-Jo-1 pts (p=NS). There was no difference between groups in global disease damage at last visit [median VAS (IQR): 1.8 (0.65–3.25) and 2.2 (1.4–3.8), respectively]. No differences in damage between Jo-1 and non Jo-1 pts were noted in the other categories.

Conclusions: Jo-1 and non-Jo-1 anti-synAb+ pts have similar activity and damage scores at last follow-up for multiple organ systems. Jo-1 pts have increased arthritis activity while non-Jo-1 pts have increased PHT-related damage. Comparing these results to other autoantibody and myositis subsets will further validate the usefulness of these activity and damage indices.

Longitudinally Followed Serum Levels of B-Cell Activating Factor of the TNF Family Correlate with Disease Activity in Anti-Jo-1 Positive Patients with Myositis. Olga Krystufkova[1], Marta Mitterwald-Modra[2], Herman Mann[2], Louise Ekholm[5], Hana Hulejova[2], Ingrid E. Lundberg[4] and Jiri Vencovsky[3]. [1]Institute of Rheumatology, Prague, Czech Republic, [2]Institute of Rheumatology, [3]Institute of Rheumatology and Dept of Rheumatology of the 1st Faculty of Medicine, Charles University, Prague, Prague, Czech Republic, [4]Karolinska Institutet, Stockholm, Sweden, [5]Karolinska Institutet, Sweden

Purpose: A role of B cells in pathogenesis of myositis is supported by common occurrence of autoantibodies. Anti-histidyl-tRNA synthetase (anti-Jo-1) is the most frequent myositis specific autoantibody, associated with a distinct clinical phenotype. Its observation before onset of clinical symptoms suggests a role in the pathogenesis of this subset of myositis. B-cell activating factor of the TNF Family (BAFF) plays a role in autoantibody production. In a previous cross-sectional study we found elevated serum levels of BAFF in patients with anti-Jo-1 positive polymyositis (PM) and in dermatomyositis (DM) and there was a correlation with serum creatine kinase (CK) levels.

The aim of the study was to investigate if serum levels of BAFF change over time and if there is a relation to disease activity measures in anti-Jo-1 positive myositis.

Methods: Sixty-seven anti-Jo-1 autoantibody positive patients from two centers were included. Paired serum samples from two time points (mean interval 28 months) in 50 patients (21 DM and 29 PM) were evaluated. Anti Jo-1 positivity was confirmed by line-blot and western blot assays. BAFF levels in serum were measured by ELISA. Serum levels of CK, myoglobin, aminotransferases (ALT, AST) and C-reactive protein (CRP) were retrieved from patients' records or measured in the same sera. Clinical disease activity was assessed by the score of the core set tool according to the IMACS Group, including both extramuscular, muscular and the physician's score of overall disease activity.

Results: The baseline BAFF levels correlated positively with serum levels of CK (rs=0.49, p<0.0001), myoglobin, (rs=0.37, p=0.005), AST (rs=0.46, p=0.0001) and CRP (rs=0.42, p=0.0006) and with cutaneous disease activity (rs=0.26, p=0.04). Levels of BAFF and myoglobin had decreased significantly at the second visit (paired test p<0.05), while p value for CK was 0.09. A significant improvement of cutaneous, skeletal, pulmonary, muscle and global disease activities was also recorded (p<0.05 for all). A positive correlation between changes of serum BAFF levels and changes of CK (rs=0.7, p=0.0001), myoglobin (rs=0.6, p<0.0001), ALT (rs=0.52, p=0.0001), AST (rs=0.62, p<0.0001) and CRP (rs=0.29, p=0.049) levels in serum or skeletal (rs=0.45, p=0.003), muscle (rs=0.32, p=0.04) and global (rs=0.37, p=0.02) disease activities was also recorded.

Conclusions: The correlation between serum levels of BAFF and markers of muscle involvement or clinical measures of disease activity as well as a correlation of their changes over time might indicate a role of BAFF in the pathogenesis of myositis with anti-Jo-1 autoantibodies. BAFF could thereby be a novel potential target of intervention in this subset of myositis.

MHC Classes I and II Expressions in Membrane and Cytoplasm of Muscle Fibers in Untreated Juvenile and Adult Dermatomyositis. Adriana Maluf Elias Sallum, Samuel Katsuyuki Shinjo, Mary Souza Carvalho, Clóvis Artur Almeida da Silva, Maurício Levy-Neto and Suely Kazue Nagahashi Marie. Hospital das Clínicas da Faculdade de Medicina da Universidade de São Paulo, São Paulo, Brazil

Background: Recently, we have shown that MHC I expression in muscle fibers is a premature and late marker of treated and untreated juvenile dermatomyositis (JDM). However this alteration was not systematically studied in adult DM (ADM). Moreover, simultaneous assessment of MHC I and II expressions in fibers membrane and cytoplasm in both untreated diseases has not been performed.

Objectives: To assess the MHC I and II expressions in fibers membrane and cytoplasm in untreated ADM and JDM and to correlate to clinical, laboratorial, and treatment outcome features.

Patients and Methods: Twenty-seven ADM and 34 JDM patients, fulfilling Bohan and Peter criteria diagnosed from 1990 to 2010, were included in this study. Routine histochemistry and immunohistochemistry (StreptABComplex/HRP) for MHC I and II (Dakopatts) were performed on serial frozen muscle sections. Each biopsy specimen was coded and analyzed concomitantly by two investigators (AMES and SKS). The pathology readers were blinded to diagnosis, clinical status and therapy when the biopsies were evaluated. Expressions of MHC I and II were assessed as negative or positive stained fibers.

Results: The mean age at disease onset was significantly higher in ADM than in JDM (42.7±18.3 vs. 8.2±3.8 years, $p<0.001$), whereas the symptoms duration before muscle biopsy were similar in both groups (9.8±13.3 vs. 7.1±10.7 months; $p=0.388$). No statistical differences were observed regarding gender, ethnicity, frequency of constitutional symptoms, disease severity, organ involvement (articular, pulmonary, cardiac or gastrointestinal), comorbidities, laboratorial (CK and aldolase levels) and treatment (prednisone, intravenous methylprednisolone and immunosuppressive drugs) ($p=0.050$), except for the lower frequency of Gottron signal in ADM compared to JDM patients (85.2 vs. 100.0%, $p=0.034$). Regarding the immunohistochemical analysis, the frequency of MHC I expression in fibers membrane (85.2 vs. 100.0%, $p=0.034$) and cytoplasm (74.1 vs. 97.1%, $p=0.017$) was significantly lower in ADM than JDM. In contrast, the MHC II expressions in fibers membrane (70.4 vs. 35.3%; $p=0.010$) and the cytoplasm (44.5% vs. 17.7%, $p=0.028$) were higher in ADM than JDM. Additionally, the MHC I and II expressions were not correlated to demographic data, clinical and laboratorial features, including CK levels and disease duration before muscle biopsy.

Conclusions: The MHC I and II expressions differ in muscle fiber in JDM and ADM. These diagnostic tools can be routinely used independent of period of time until muscle biopsy.

MicroRNA Expression in Juvenile Dermatomyositis (JDM): Clues to Disease Pathogenesis and Chronicity. Simone Sredni, Peter Hendrickson, Sheela Shrestha and Lauren M. Pachman. Children's Memorial Research Center, Chicago, IL

Background: Juvenile dermatomyositis (JDM) is an autoimmune vasculopathy targeting small blood vessels. We found that: (1) untreated chronic inflammation lasting >2 mos has a strong influence on disease prognosis and molecular pathophysiology, (2) proinflammatory cytokines, IFN-α and TNF-α are increased in JDM sera and tissue damaging endothelial cells and (3) JDM patients have immune activation of VCAM-1, a soluble gatekeeper for leukocyte migration localized in high concentration on endothelial cells. It is also known that the A polymorphism of TNF-α-308 promoter region contributes to the inflammatory microenvironment in JDM, but the mechanism is not well understood. Moreover, due to absence of inflammatory process biomarkers and disease severity prognostic indicators, there are no surrogate indicators of immune activation that can guide effective treatment for JDM, as muscle enzymes normalize rapidly.

MicroRNAs (miRNAs) are non-coding RNAs usually 18–25bp long that regulate several messenger RNAs simultaneously by mechanisms such as incomplete base pairing and post-transcriptional gene silencing. Modulation of levels of key miRNAs can affect regulation of several physiological and pathological functions offering a new prototype for therapeutic intervention.

Methods: After obtaining informed consent, miRNA expression profiles in diagnostic muscle biopsies (MBx) from 2 groups of children with definite/probable JDM and age/gender-matched controls were tested: (1) short duration of untreated disease (SDD), <2 mos prior to MBx; (2) long disease duration (LDD), ≥2 mos of symptoms, using microarrays with locked nucleic acid technology (miRCURY LNA™ microRNA Array Exiqon, Vedbaek, Denmark). Selected dysregulated genes were confirmed by qRT-PCR and immunohistochemistry.

Results: We found significant differential expression of: (1) miR-10b ($p=0.03$) in JDM vs. controls, (2) miR-146b ($p=0.02$), miR-126 ($p=0.014$) and miR-23a ($p=0.04$) when comparing SDD and LDD and (3) miR-34a ($p=0.02$) when comparing SDD vs LDD patients with TNF-α-308 G allele. Expression of miRNAs (23a, 126 and 146b) and of possible interactive targets (IL1B, TNF-α, VCAM-1) was verified by qRT-PCR and immunohistochemistry.

Discussion: MiR-10b, down regulated in JDM vs. controls, modulates HOXD10 expression. HOXD10 controls OPN, which is important in T cell regulation/regeneration and is present in dystrophic calcifications associated with chronic cutaneous inflammation. When comparing JDM MBx of SDD vs LDD miR-23a, miR-126 and miR146b were differentially expressed. MiR-126 regulates VCAM-1 (increased in SDD) and might be a key component of vascular damage. Increase in miR-146b expression by cytokines IL-1B and TNF-α may be important in molding the phenotype of children who have had untreated chronic inflammation for a longer period.

Conclusion: In JDM, critical processes affecting vascular system formation/function and inflammation are modulated by miRNAs. Identification of key miRNAs will give us clues not only to JDM pathogenesis and chronicity but may reveal new potential therapeutic targets.

Non-Jo-1 Anti-Synthetase Autoantibodies Are Not Specific for Myositis and Are Associated with Poor Survival. Elaine A. Cassidy[1], Rohit Aggarwal[3], Noreen Fertig[3], Mary Lucas[3], Dana P. Ascherman[3] and Chester V. Oddis[2]. [1]Children's Hospital of Pittsburgh Division of Rheumatology, Pittsburgh, PA, [2]University of Pittsburgh, Pittsburgh, PA, [3]University of Pittsburgh School of Medicine Division of Rheumatology and Clinical Immunology, Pittsburgh, PA

Purpose: To compare clinical features and outcome in patients (pts) with Jo-1 vs. non-Jo-1 anti-tRNA synthetase autoantibodies (anti-synAb).

Methods: All anti-synAb positive pts in a Connective Tissue Disease (CTD) Registry were included regardless of initial or subsequent CTD diagnosis. Demographic and clinical data were collected from the medical record and registry. Current status and cause of death was determined by query of the National Death Index or Social Security Death Index, and medical record. For lung survival an endpoint of lung transplant or death was used. Survival was compared by Kaplan-Meier and log rank test. Cox proportional hazards ratios were calculated to compare survival after controlling for co-variates.

Results: 202 of 3880 (5.2%) CTD pts were anti-synAb positive [122 Jo-1; 80 non-Jo-1 (35 PL-12; 25 PL-7; 9 EJ; 6 KS; 5 OJ]. Both groups had similar demographic features (Table 1), but non-Jo-1 pts had a greater delay in diagnosis, and a diagnosis at 1st visit in 60% that did not include PM or DM.

Table 1. Demographic and Clinical Features of Synthetase Cohort

	Mean Age at Symptom Onset (yrs)	% Female	% Caucasian	Myositis (%)	Diagnoses at First Visit Overlap or UCTD (%)	SSc (%)	Median Delay in Dx from 1st CTD Symptom (mths; IQR)
Jo-1 (n = 122)	45	67	82	83	PM 58 DM 25	17 0	6 (2–13)
non-Jo-1 (n = 80)	46	70	75	40	PM 23 DM 17	49 11	9 (3–24)
p value	NS	NS	NS	p < 0.0002			p = 0.03

NS = not significant; IQR-interquartile ratio; UCTD = undifferentiated connective tissue disease

Sixty-six pts are deceased with pulmonary fibrosis and pulmonary hypertension the most common causes. Twelve pts (7 Jo-1; 5 non-Jo-1) underwent lung transplantation. Although a pulmonary cause of death was similar between Jo-1 and non-Jo-1 cohorts, the 5 and 10 yr unadjusted cumulative and median survival was significantly different.

Table 2. Outcome and Survival of Synthetase Cohort

	Deceased (%)	Mean Age at Death (yrs)	Pulmonary Cause of Death: Fibrosis PHT	Cumulative Survival: 5 year (%)	Cumulative Survival: 10 year (%)	Median Survival (yrs; IQR)
Jo-1 (n = 122)	36 (30%)	58 +/−14	19/36 16/36 3/36	90	74	15 (7.9–21.3)
non-Jo-1 (n = 80)	30 (38%)	62 +/−14	20/30 16/30 4/30	70	48	9 (4.3–18)
p value	NS		NS	P <0.01		P <0.01

PHT = pulmonary hypertension

After adjusting for gender, ethnicity and age at diagnosis, non-Jo-1 pts had decreased survival (HR 1.86; p=0.02; 95% CI 1.10–3.14) and lung survival (HR 1.96; p= 0.008; 95% CI 1.19–3.23) compared to Jo-1 pts. After adjusting for diagnosis delay, non-Jo-1 pts had decreased lung survival (HR 1.77; p= 0.03; 95% CI 1.06–2.97), and a trend toward decreased cumulative survival (HR 1.71; p =0.051; 95% CI 1.00– 2.96). Non-Jo-1 PM pts had the worst cumulative survival (HR 3.75; p=0.02; 95% CI 1.21– 11.68) and lung survival (HR 2.84; p=0.01; 95% CI 1.23–6.52).

Conclusions: In the largest reported anti-synAb+ cohort to date, the previously described myositis specificity of non-Jo-1 anti-synAb was not supported. Non-Jo-1 pts have decreased cumulative survival and lung survival compared to Jo-1 pts, with non-Jo-1 pts with PM having the worst cumulative and lung survival. The difference in survival may be attributable to a delay in diagnosis in the non-Jo-1 group due to nonspecific symptoms at presentation and negative commercial antibody testing. Increased awareness of this CTD subset among rheumatologists and pulmonologists is emphasized.

Predictors of Survival in Patients with Anti-Synthetase Autoantibodies.

Rohit Aggarwal[5], Elaine A. Cassidy[1], Noreen Fertig[4], Mary Lucas[4], Dana P. Ascherman[2] and Chester V. Oddis[3]. [1]Children's Hospital Pittsburg, Pittsburgh, PA, [2]University of Pittsburgh, Pittsburgh, PA, [3]University of Pittsburgh, Pittsburgh, PA, [4]University of Pittsburgh, [5]University of Pittsburgh Medical Center, Pittsburgh, PA

Purpose: To evaluate baseline clinical, laboratory, serologic, radiographic and functional predictors of survival in patients (pts) with anti-synthetase autantibodies (anti-synAb) from a single tertiary care center.

Methods: All anti-synAb+ pts from a single referral center between1985–2009 were included regardless of their initial or subsequent connective tissue disease (CTD) diagnosis. All data were collected from the registry database and medical record. Current status and cause of death was determined by query of the National Death Index or Social Security Death Index, and record review. For lung survival an endpoint of lung transplant or death was used. Each baseline characteristic was evaluated for prediction of overall and lung survival using Cox-proportional hazard in a univariate fashion. Only clinical data available at first visit was used in the model.

Results: Of the 3880 CTD pts in the registry from 1985–2009, 202 (5.2%) were anti-synAb+ [122 Jo-1; 80 non Jo-1 (35 PL-12; 25 PL-7; 9 EJ; 6 KS; 5 OJ)]. Eighty-nine (44%) had PM, 44 (22%) DM, and 69 (34%) had undifferentiated or overlap CTD. Demographic features predicting survival included age at diagnosis and symptom onset, and a diagnosis delay (Table 1). PM pts had worse survival. Among other variables only arthralgia, pleurisy, dermatomyositis V neck or trunk rash, and telangiectasia had worse survival while Gottron papules had better survival. Raynaud, sicca symptoms, dyspnea, fever, muscle weakness, dysphagia, puffy fingers, mechanic hands, heliotrope rash, physician global assessment of active disease, capillary microscopy, digital abnormality, and calcinosis did not predict survival. Among lab and serologic parameters only non-Jo1 anti-synAb positivity, particularly anti-PL-7 and anti-EJ predicted worse survival, while SSA antibody was protective. ANA positivity, muscle enzymes, hemoglobin, platelet and ESR had no impact on survival. The % predicted FVC and DLCO along with pulmonary hypertension (PHT) by echocardiography and secondary PHT at baseline predicted survival. High resolution CT (HRCT) evidence of pulmonary fibrosis did not predict survival as most pts had some evidence of fibrosis by routine chest radiography or HRCT.

Table 1. Univariate predictors of overall and lung survival in a synthetase cohort

	Overall survival Hazzard ratio (C.I.)	p value	Lung survival Hazard ratio (C.I.)	p value
Demographic				
Gender (male)	0.82 (0.47–1.44)	0.57	0.82 (0.48–1.43)	0.47
Ethnicity (AA)	0.92 (0.43–1.96)	0.87	1.0 (0.49–2.04)	0.98
Age at diagnosis (yrs)	1.03 (101–1.05)	<0.001	1.03 (1.01–1.05)	<0.001
Age at symptoms (yrs)	1.02 (1.0–1.04)	0.07	1.02 (1.0–1.03)	0.01
Diagnosis delay (yrs)	1.03 (1.0–1.06)	0.04	1.01 (1.0–1.01)	0.008
Clinically history				
Clinical diagnosis	PM: 2.4 (1.08–5.53)	0.032	PM: 2.73 (1.21–6.15) UCTD 2.54 (1.11–5.84)	PM: 0.015 UCTD 0.27
Inflammatory arthralgia	1.84 (1.08–3.15	0.02	1.78 (1.08–2.95)	0.02
V neck trunk rash	2.9 (1.14–7.32)	0.02	2.64 (1.05–.6.65)	0.04
Gottron papules	0.33 (0.14–0.78)	0.01	0.32 (0.14–0.71)	0.005
Telangiectasia	2.6 (1.4–4.8)	0.003	2.93 (1.64–5.25)	<0.001
Pleurisy	1.88 (1.02–3.48)	0.04	1.97 (1.06–3.63)	0.03
All non-Jo1	1.67 (1.05–2.68)	0.03	1.64 (1.03–2.63)	0.04
Anti-PL-7	2.45 (1.31–4.56)	0.005	2.55 (1.37–4.73)	0.003
Anti-EJ	3.29 (1.27–8.49)	0.01	3.14 (1.22–8.09)	0.01
SSA (n = 81)	0.11 (0.15–0.85)	0.04	0.10 (0.13–0.76)	0.03
Pulmonary Function Testing Other				
%FVC 1	0.97 (0.96–0.99)	0.03	0.97 (0.95–0.98)	0.001
%DLCO	0.96 (0.94–0.98)	0.006	0.96 (0.94–0.99)	0.006
Elevated PAP	3.1 (1.3–70)	0.006	3.2 (1.53–6.74)	0.002
Secondary PHT	3.46 (1.65–7.27)	0.001	3.34 (1.59–7.0)	0.001
O_2 requirement at baseline	2.43 (1.38–4.26)	0.002	2.42 (1.37–4.21)	0.002

CI = confidence interval, AA = African American, PAP = Pulmonary artery pressure

Conclusion: The myositis clinical subset (i.e. PM), anti-synAb positivity, pulmonary function parameters, secondary PAH, joint involvement, pleurisy, various DM rashes and telangiectasia help predict overall survival and lung survival in anti-synAb+ pts. Some findings can be explained on the basis of their known myositis subset associations, such as Gottron papules in DM (which has a better prognosis than PM) and telangiectasias in UCTD (worse survival due to non-Jo-1 association). However, others require further study to confirm their association with survival (e.g. SSA positivity).

Pulmonary Manifestations of Polymyositis and Long-Term Outcomes—A Retrospective Study.

Catherine Bakewell[1], James Hotaling[1], Michael Huck[3], Dale Wilson[3], Jennifer Hayes[1], Carolyn Spada[1], Gurpreet Rawat[1] and Ganesh Raghu[2]. [1]University of Washington Medical Center, Seattle, WA, [2]University of Washington Medical Center, Seattle, [3]University of Washington School of Medicine, Seattle, WA

Background: Polymyositis (PM) is a systemic inflammatory disorder which primarily affects striated muscles; however, other organ systems, including the lungs, may be involved. While the interstitial lung disease (ILD) associated with polymyositis (ILD-PM) carries significant morbidity and mortality, the clinical factors impacting outcome of patients with ILD-PM are unclear.

Methods: A single-center retrospective study of well-defined patients with PM (Peter and Bohan criteria) and ILD evaluated and followed by an ILD expert (GR). Baseline demographics, serial pulmonary function tests (PFTs), estimates of pulmonary arterial hypertension (PAH) based on echocardiogram results, high resolution computed scan (HRCT) images of the chest, and treatment regimen were assessed to determine long term outcome of patients. Statistical analyses were performed using STATA v.11.

Results: 25 patients met inclusion criteria; baseline demographics are shown.

Table 1. Baseline Patient Demographics and Follow-Up Data

Women: n (%)	15 (60%)	
Men: n (%)	10 (40%)	
Mean Age (range)	59 (39–82)	
ILD/IIP as initial presentation (prior to PM)	12 (48%)	
Current smoker	2/25	
Past smoker	11/25	
Never smoker	12/25	
Jo - 1 Ab positivity	6/17 (35%)	
ANA positivity	5/15 (33%)	
Pulmonary Function Testing	Baseline	Last Recorded
Mean DLCO	39% (+/−16)	38% (+/−17)
Mean FVC	58% (+/−16)	61% (+/−20)
Mean FEV1	57% (+/−14)	55% (+/−18)
Mean FEV1/FVC	.77 (+/−.13)	.76 (+/−.15)

(+/−) denotes standard deviation. IIP: Idiopathic Interstitial Pneumonia

Twelve of the 25 patients (48%) manifested ILD/idiopathic interstitial pneumonia (IIP) before the overt manifestation of PM, and an average of 18.2 months elapsed prior to diagnosis of PM. Mean duration of follow up was 7.2 years; 4 patients died during this period (16% mortality rate). HRCT images confirmed ILD/IIP in all patients; ground glass opacification was the most common pattern (n=7), followed by honeycombing (n=4). Estimated systolic pulmonary artery pressure > 35mm Hg was observed in three of six patients subjected to echocardiogram. Microscopic features of nonspecific interstitial pneumonia (n=2), usual interstitial pneumonia (n=1), organizing pneumonia (n=1), and unclassifiable fibrotic pattern (n=2) were present in six patients subjected to surgical lung biopsy. Although history of cigarette smoking did not influence the baseline PFTs, ever smokers had a lower last recorded DLCO (p=0.045, adjusted for age and gender). Treatment regimens included methotrexate (MTX) (n=11), azathioprine (n=17), mycophenolate (n=2), and prednisone in all of the patients. The means of the last recorded DLCO and FVC for patients treated with MTX were 29.9% and 47.8% of predicted values respectively, compared with 43.7% and 68% for those who were never treated with MTX. The last recorded DLCO was more frequently <30% of predicted values in patients treated with MTX compared to those treated with azathioprine or mycophenolate (logistic regression; p< 0.001), even when controlled for age, gender, and smoking status.

Conclusions: 1) 48% of patients with ILD-PM present with ILD/IIP prior to overt manifestation of PM.

2) History of cigarette smoking confers a poor prognosis based upon worsening of DLCO measurements during the course of ILD-PM.

3) 16% of patients with ILD-PM died during follow up (mean duration=7.2 yrs).

4) Patients treated with MTX had a poor outcome based on the worsening of DLCO to < 30% predicted at last follow up.

Skin Ulcer Is a Prognostic Factor of Respiratory Failure in Interstitial Lung Disease in Patients with Polymyositis or Dermatomyositis. Kazuyoshi Ishigaki[3], Yasunobu Takizawa[4], Junko Maruyama[4], Ran Nakashima[1], Tsuneyo Mimori[2] and Keigo Setoguchi[4]. [1]Department of Rheumatology and Clinical Immunology, Kyoto University Graduate School of Medicine, Japan, [2]Department of Rheumatology and Clinical Immunology, Kyoto University Graduate School of Medicine, Japan [3]Tokyo Metropolitan Komagome Hospital, Bunkyo-ku, Tokyo, Japan, [4]Tokyo Metropolitan Komagome Hospital

Objective: To elucidate prognostic factors of interstitial lung disease (ILD) in Japanese patients with polymyositis or dermatomyositis including clinically amyopathic dermatomyositis (CADM).

Methods: We reviewed the medical records of 59 consecutive polymyositis and dermatomyositis patients who were seen at Tokyo Metropolitan Komagome Hospital from January 2000 to December 2009.

Results: Eighteen patients had polymyositis; 41 patients had dermatomyositis, of whom 15 had CADM. Thirty-one patients (53%) developed ILD; 13 cases were indolent, 18 were acutely progressive, and 6 led to respiratory failure (demographic data in Table 1). Univariate analysis identified associations between respiratory failure and normal muscle strength, skin ulcers, pneumomediastinum, CRP level at or above 2.0 mg/dl, ferritin level at or above 200 ng/ml, and LDH/CPK ratio at or above 2.0. Multivariate analysis identified associations only between respiratory failure and skin ulcers (odds ratio (OR) 12.1, 95% confidence interval (CI) 1.42–104, p=0.022) and elevated CRP level at or above 2.0 mg/dl (OR 14.9, 95%CI 1.34–167, p=0.028) (Table 2). Ferritin level was excluded from multivariate analysis because 33 values were missing. Four of 7 serum samples from CADM patients were positive for anti-CADM 140 antibody, which is reportedly associated with CADM. Three of the 4 antibody-positive patients subsequently underwent respiratory failure (p=0.371, not significant). Skin biopsy was done in 7 of the 10 patients with skin ulcers, but no signs of vasculitis were detected in any.

Conclusion: Skin ulcers and high CRP level are independent prognostic factors of respiratory failure in ILD in patients with polymyositis or dermatomyositis. Although we found no pathological evidence linking skin ulcers to vasculitis, we suspect systemic vasculopathy may contribute to the poor prognosis. Aggressive immunosuppressive therapy should be considered to prevent respiratory failure in patients with skin ulcers and high inflammatory marker levels.

Table 1. Categorical data are n (%) and age data are mean ± SD

Classification	PM (n = 18)	DM (n = 26)	CADM (n = 15)	Total (n = 59)
Age at onset (years)	59.8 ± 14.3	61.5 ± 11.4	54 ± 16.5	59.1 ± 14.1

The Anti-Oxidant Function of High Density Lipoprotein and Paraoxanase-1 Are Abnormal in Patients with Dermatomyositis. Christina Charles-Schoeman[2], Yuen Yin Lee[3], John D. FitzGerald[4], Veena K. Ranganath[1] and Srinivasa T. Reddy[3]. [1]UCLA School of Med Rehab 32–59, Los Angeles, CA, [2]UCLA School of Medicine, Los Angeles, CA, [3]UCLA School of Medicine, [4]UCLA School of Medicine Rehabilitation, Los Angeles, CA

Purpose: Damage to the vascular endothelium is implicated in the pathogenesis of dermatomyositis (DM) and to a lesser degree in other idiopathic inflammatory myopathies (IIM). Normal high density lipoprotein (HDL) protects the vascular endothelium from damage due to oxidized phospholipids, which accumulate under conditions of oxidative stress. During acute and chronic inflammatory states, enzymes such as myeloperoxidase (MPO) produce increased amounts of oxidized phospholipids, which impair this function of HDL. The current work evaluates the function of HDL and its associated protein, paraoxanase 1 (PON-1), in patients with IIM.

Methods: Plasma samples were collected from 26 patients with DM, 20 patients with polymyositis (PM), and 23 healthy controls. HDL's anti-oxidant function was measured by a cell free assay which assesses the ability of patient HDL to inhibit oxidation of a stock LDL. PON-1 activity was measured by the arylesterase assay and MPO activity was assessed using a commercial kit. HDL and LDL cholesterol levels were measured by standard methods and apolipoprotein A-1 (apoA-1) levels were assessed by ELISA.

Results: The anti-oxidant function of HDL as measured by its ability to inhibit oxidation of LDL was significantly worse in patients with DM when compared to age and sex matched healthy controls (see table). Plasma MPO activity was significantly higher in DM patients compared to controls and was correlated with HDL function, ($r = 0.43$, $p=0.0003$ all patients; $r= 0.44$, $p=0.02$ DM only); higher plasma MPO activity was associated with worse HDL function. PON-1 activity was significantly lower in both DM and PM patients compared to controls and there was a trend for an association with HDL function ($r= -0.20$, $p=0.11$); lower PON-1 activity associated with worse HDL function.

Group	HII	Age (yrs)	F (%)	HSCRP (mg/L)	ESR (mm/h)	HDL (mg/dL)	LDL (mg/dL)	ApoA-1 (ug/ml)	MPO (ng/ml)	PON (mOD/min)
DM n = 26	0.73 ± 0.55*	46 ± 14	92†	7.3 ± 10.6*	30 ± 29*	53 ± 16	101 ± 32	305 ± 141	31 ± 17*	3.3 ± 1.3*
PM n = 20	0.61 ± 0.73	54 ± 12*	60	6.4 ± 9.4*	31 ± 25*	62 ± 33	117 ± 49	239 ± 143	27 ± 22	3.5 ± 1.1*
Controls n = 23	0.34 ± 0.14	45 ± 13†	73	1.3 ± 1.7†	11 ± 9†	55 ± 13	101 ± 31	259 ± 64	22 ± 18	4.4 ± 1.3†

HII = HDL Inflammatory Index; F = Female; HSCRP = High Sensitivity C Reactive Protein, ESR = Erythrocyte Sedimentation Rate; *p value < 0.05 compared to controls; †p value < 0.05 compared to PM.

Conclusions: The anti-oxidant function of HDL and its associated protein PON-1 are abnormal in patients with DM compared to healthy controls. Because HDL normally protects the vascular endothelium from oxidative damage, these findings may warrant further investigation of therapies that remove oxidized phospholipids and improve the function of HDL, such as apoA-1 mimetic peptides, for the treatment of DM and other IIM associated with vascular injury.

The Interferon Signature in Myositis Is Associated with RNA-Binding Protein Autoantibodies. Hatice Bilgic[4], Joseph Wilson[4], Thearith Koeuth[4], Kelly T. McNallan[2], Steven R. Ytterberg[1], Erik J. Peterson[3], Ann M. Reed[1] and Emily C. Baechler[4]. [1]Mayo Clinic, Rochester, MN, [2]Mayo Clinic, Rheumatology, Rochester, MN, [3]University of Minnesota Department of Medicine, Minneapolis, MN, [4]University of Minnesota Department of Medicine, Minneapolis, MN

Background: Several autoimmune diseases are characterized by elevated expression of type I interferon (IFN)-regulated transcripts and proteins in peripheral blood. This IFN signature' is a marker for disease activity in patients with dermatomyositis (DM), and IFN pathway activation is proposed to play a role in the pathogenesis of this disease. The IFN signature in systemic lupus erythematosus is associated with the presence of autoantibodies against RNA binding proteins (RBP), which are commonly observed in lupus patients. However, anti-RBP antibodies are found less frequently in patients with DM.

Methods: We compared blood IFN signatures and autoantibody profiles in 126 patients with inflammatory idiopathic myopathies (IIM), including 76 DM patients (46 adult and 30 pediatric) and 50 patients with other types of IIM (24 polymyositis (PM), 9 inclusion body myositis (IBM), and 17 with uncharacterized myositis). IFN gene signatures were measured from whole blood RNA using TaqMan quantitative real-time RT-PCR to detect the levels of 3 IFN-regulated transcripts (G1P2, IFIT1, and IRF7). For each subject, an IFN gene score' was calculated from the levels of these 3 transcripts. Serum levels of IFN-regulated chemokines (IP-10, I-TAC, and MCP-1) were measured using a multiplexed ELISA (SearchLight, Aushon Bioscience), and a chemokine score' was calculated for each patient using the normalized levels of the 3 chemokines. A bead-based immunoassay (Luminex) was used to detect anti-Sm, -RNP, -SS-A 60, -SS-A 52, -SS-B, -Scl-70, -Jo-1, -Ribosome P and -Chromatin antibodies in serum. Spearman's rank method was used to for correlation and the Mann-Whitney test was used for group comparisons.

Results: Out of 126 myositis patients, 33 were positive for at least one RBP antibody (anti-Sm, -RNP, -SS-A, or –SS-B). Both chemokine scores ($p=0.04$) and IFN gene scores ($p=0.003$) were significantly higher in RBP+ patients compared to RBP- patients. The IFN gene score was significantly correlated with the number of RBP antibodies ($r=0.31$, $p=0.002$), and with the levels of individual autoantibodies (anti-RNP, $r=0.28$, $p=0.004$; SS-A 60, $r=0.23$, $p=0.02$; and SS-A 52, $r=0.35$, $p=0.0004$). The chemokine score was positively correlated with anti-SS-A ($r=0.20$, $p=0.02$) but negatively correlated with anti-Sm ($r = -0.18$, $p=0.04$). When the analysis was repeated in the DM and other myositis' (PM, IBM, uncharacterized IIM) groups separately, IFN gene scores of RBP+ and RBP- groups were significantly different in both the DM and other myositis' subgroups ($p=0.01$ for both). IFN gene and chemokine scores were significantly correlated in the DM subgroup ($r=0.61$, $p<0.001$) but not in the others ($r=0.11$, $p=0.59$).

Conclusions: These results suggest that the IFN gene signature is associated with the presence of anti-RBP antibodies in patients with myositis. The presence of these autoantibodies, together with elevated IFN signatures, may promote identification of patients with myositis overlap syndromes.

The Role of Innate Immunity in a Model of HRS-Induced Myositis. Makoto Soejima[4], Eun Ha Kang[1], Yasuhiro Katsumata[2], Xinyan Gu[3], Paula Clemens[3] and Dana Ascherman[3]. [1]Seoul National University College of Medicine, [2]Tokyo Women's Medical University, [3]University of Pittsburgh, [4]University of Pittsburgh, Pittsburgh, PA

Aim: The aim of this study was to clarify the contribution of innate immunity in a model of histidyl-tRNA synthetase (HRS)-induced myositis.

Background: Previous studies have suggested an important role for the autoantigen HRS in the pathogenesis of myositis. While most investigations have focused on the ability of HRS to trigger adaptive immune responses, *in vitro* studies clearly indicate that HRS possesses intrinsic immunostimulatory properties that may operate through the innate immune system.

Methods: We immunized different strains of mice (C57BL/6, B6.G7, NOD.*Idd3/5*, DO11.10/Rag2$^{-/-}$, and C3H/HeJ) with soluble HRS (Jo-1) or appropriate control proteins (maltose binding protein; MBP) via the intramuscular (IM) route. To evaluate the resulting immune response, we determined IgG anti-Jo-1 and anti-MBP antibody levels in the sera of mice immunized with different proteins using standard solid phase ELISA. As a measure of *in vitro* T cell proliferation, we CFSE labeled splenocytes or LN cells derived from these mice and then co-cultured cells with various antigens for 96 hours before flow cytometric assessment of CFSE dilution. Immunohistochemical staining of cell surface markers (CD3, CD4, CD8, CD44, CD11c, F4/80, B220, CCR5) permitted characterization of inflammatory infiltrates resulting from our IM immunization protocol. Quantification of antigen-induced muscle inflammation was based on a scoring system combining the relative intensity and distribution of lymphocytic infiltrates in multiple fields viewed under high power magnification, where 0=no inflammation, 1=minimal inflammation, 2=moderate inflammation, and 3=severe inflammation. Severity scores for muscle inflammation were compared using the Mann-Whitney *U*-test.

Results: IM immunization with a murine HRS fusion protein induced significant muscle inflammation (relative to MBP control protein) in multiple congenic strains of C57BL/6 and NOD mice. Infiltrates occurred as early as 7 days post immunization and persisted as long as 7 weeks following a single administration of soluble HRS protein. Immunohistochemical staining indicated that these infiltrates were composed primarily of CD3+CD44+CCR5+ lymphocytes admixed with smaller numbers of B cells and macrophages. Corresponding to these histopathologic findings, ELISAs demonstrated class-switched antibody responses to HRS at each of these time points. Measurement of T cell responses to immunizing antigens through CFSE proliferation assays also revealed a level of antigen-specific priming. Parallel experiments in DO11.10/Rag2$^{-/-}$ (OVA-specific TCR transgene) and C3H/HeJ (TLR4$^{-/-}$) mice showed that HRS could induce exuberant muscle inflammation in the absence of TCR or TLR4 signaling, further implicating alternative components of the innate immune response.

Conclusion: Based on IM immunization with a soluble derivative of murine HRS, the reported experiments demonstrate that this putative autoantigen can trigger innate immune responses which bypass BCR and TCR signaling to generate significant muscle inflammation in a novel model of idiopathic inflammatory myopathy.

13-Week Efficacy and Safety Evaluation of Naproxcinod, a Cyclooxygenase Inhibiting Nitric Oxide Donator (CINOD), in Patients with Osteoarthritis of the Hip. Christoph Baerwald[3], Hayet Frayssinet[1], Thierry Ferreira[1], Brigitte Duquesroix[1] and Thomas Schnitzer[2]. [1]NicOx, SA, [2]Northwestern University, [3]Universitätsklinikum Leipzig

Purpose: Naproxcinod is a Cyclooxygenase Inhibiting Nitric Oxide Donator (CINOD) under development for the relief of signs and symptoms of osteoarthritis (OA).

Methods: 810 patients with primary hip OA experiencing pain flare at baseline were randomized to naproxcinod 750mg, placebo or naproxen 500mg (all *bid*) in a 2:2:1 ratio. 3 co-primary efficacy endpoints: change from baseline in WOMAC™ pain and function subscales, and patients' overall rating of disease status at Week 13. The primary efficacy variables were analyzed using an ANCOVA model with treatment group and site as factors, and baseline value as a covariate. Non-inferiority naproxcinod versus naproxen was tested post-hoc. Safety assessments included adverse events (AEs) and office blood pressure (BP) monitoring (2 to 4 hours post-dose).

Results: 810 patients randomized. Naproxcinod was statistically superior to placebo for all 3 co-primary endpoints ($p<0.0001$), while similar to naproxen. Treatments were well tolerated. Most AEs were mild or moderate and SAEs were low and similar between groups. The mean change (SD) from Baseline at Week 13 in Systolic BP was −2.60 (11.33) mm Hg in the naproxcinod 750 mg bid group, −2.49 (11.64) mm Hg in the placebo bid group, and −0.49 (12.32) mm Hg in the naproxen 500 mg bid group.

Conclusion: Naproxcinod efficacy was statistically superior to placebo in all 3 co-primary efficacy variables. Naproxcinod was well tolerated with a BP profile that tended to be different from that of naproxen.

A Fixed-Dose Combination of Naproxen and Esomeprazole Magnesium (VIMOVO™) Has Comparable Efficacy and Tolerability to Celecoxib in Patients with Osteoarthritis (OA) of the Knee: Results from Two Randomized, Controlled Trials. Marc C. Hochberg[4], Byron Cryer[5], John G. Fort[3], Clara Hwang[1], Ola Svensson[2] and Mark B. Sostek[1]. [1]AstraZeneca, Wilmington, DE, [2]AstraZeneca, Sodertalje, Sweden, [3]POZEN, Inc, Chapel Hill, NC, [4]University of Maryland, Baltimore, MD, [5]University of Texas Southwestern Medical Center, Dallas, TX

Background: It is recommended that patients (pts) at risk for serious NSAID-associated upper gastrointestinal (UGI) toxicity should receive a COX-2 selective inhibitor, or a nonselective NSAID plus gastroprotection. The efficacy and tolerability of a fixed-dose combination (FDC) of enteric-coated naproxen 500mg and immediate-release esomeprazole magnesium 20mg was compared with celecoxib 200mg in 2 identical, non-inferiority studies in pts with OA.

Methods: Two double-blind, double-dummy, placebo-controlled, multicenter Phase 3 studies (307/309) enrolled pts aged ≥50 years with symptomatic OA of the knee. Following an OA flare, pts were randomized 2:2:1 to receive FDC naproxen/esomeprazole BID, celecoxib 200 mg QD, or placebo for 12 weeks. The primary endpoints were mean change from baseline to Week 12 in WOMAC pain, WOMAC function, and Patient Global Assessment (PGA) of OA using a visual analog scale (VAS, 0–100mm); each endpoint had prespecified non-inferiority margin of 10mm between active treatments. Tolerability endpoints included the modified Severity Of Dyspepsia Assessment (mSODA), heartburn severity, and predefined NSAID-associated UGI adverse events (AEs).

Results: Study 307: 619 pts were randomized, 614 were treated, and 521 completed; Study 309: 615 pts were randomized, 610 were treated, and 489 completed. Baseline demographics were similar between treatment groups in both studies; mean age was 62 years and >60% were women. Improvements in WOMAC pain and function, and PGA were seen with naproxen/esomeprazole and celecoxib in both studies. Naproxen/esomeprazole was non-inferior to celecoxib for each primary endpoint; upper/lower limits of 95% CI of treatment differences were <5mm (table). Both active treatments showed significantly greater efficacy vs placebo in Study 307 ($p<0.05$), while only naproxen/esomeprazole was significantly superior to placebo in Study 309 ($p<0.05$). The incidence of UGI AEs was 17.3% in Study 307 and 20.3% in Study 309, and was similar between treatment groups. UGI AEs reported by ≥3% of pts were dyspepsia, nausea, and upper abdominal pain. In Study 307, 1.2%, 1.6%, and 2.4% of pts discontinued due to UGI AEs in the naproxen/esomeprazole, celecoxib, and placebo groups, respectively; in Study 309, 0.8%, 3.7%, and 2.5% withdrew, respectively. Improvements in mSODA scores were similar across treatment groups in both studies, with no significant differences between active treatments (table). Pts treated with naproxen/esomeprazole had significantly more heartburn-free days vs those treated with celecoxib (95% CIs: Study 307: 2.1, 12.7; Study 309: 2.5, 13.4) and placebo (95% CIs: Study 307: 6.4, 19.2; Study 309: 1.1, 14.4).

	Study 307			Study 309		
	Naproxen/ esomeprazole (N=246)	Celecoxib (N=243)	Naproxen/ esomeprazole – celecoxib	Naproxen/ esomeprazole (N=241)	Celecoxib (N=244)	Naproxen/ esomeprazole – celecoxib
WOMAC pain,[a] n	226	221		213	220	
LS mean change from baseline to Week 12	-42.0	-41.8	-0.2	-44.2	-42.9	-1.3

LS mean change from baseline to Week 12	-36.4	-36.3	-0.1	-38.9	-36.8	-2.1
95% CI			-4.6, 4.4			-6.8, 2.6
PGA-VAS,[a] n	242	230		235	234	
LS mean change from baseline to Week 12	21.2	21.6	-0.5	29.0	25.6	3.5
95% CI			-5.1, 4.1			-1.4, 8.3
mSODA, n	245	237		238	241	
LS mean change from baseline to Week 12	-3.8	-4.6	0.8	-4.0	-3.4	-0.6
95% CI			-0.4, 1.9			-1.8, 0.6

ITT population analysis with last observation carried forward. [a]Non-inferiority was established if the upper bound of a 95% CI was ≤10 mm for WOMAC pain and function, and if the lower bound was ≥-10 mm for PGA-VAS. CI, confidence interval; ITT, intent-to-treat; LS, least squares.

Conclusions: With non-inferior efficacy and comparable UGI tolerability to celecoxib, naproxen/esomeprazole may offer an effective and well-tolerated treatment option for pts with knee OA at risk for serious UGI AEs.

Chondroitin Sulfate Treatment Is Effective at Reducing Cartilage Loss in the Tibiofemoral Compartment in Knee OA as Assessed by Magnetic Resonance Imaging (MRI). Jean-Pierre Pelletier[8], Lukas M. Wildi[5], Jean-Pierre Raynauld[5], André Beaulieu[3], Louis Bessette[4], Frédéric Morin[1], François Abram[6], Marc Dorais[7] and Johanne Martel-Pelletier[2]. [1]Centre de Recherche Musculo-squelettique, Trois-Rivières, [2]CR-CHUM, Notre-Dame Hospital, Montreal, QC, Canada, [3]Faculty of Medicine, University of Laval, QC, [4]Groupe de Recherche en Rhumatologie et Maladies Osseuses, Sainte-Foy, [5]Osteoarthritis Research Unit, University of Montreal Hospital Research Centre (CRCHUM), Notre-Dame Hospital, [6]Research and Development, ArthroVision Inc., Montreal, [7]StatSciences Inc., Notre-Dame de l'Ile-Perrot, [8]University of Montreal Hospital Research Centre (CRCHUM), Notre-Dame Hospital, Montreal, QC, Canada

Background: The osteoarthritis (OA) disease-modifying effect of chondroitin sulfate (CS) has been demonstrated by X-ray in knee OA after two years of treatment [1,2]. We further explored by performing a randomized, double-blind, placebo-controlled study using a more sensitive imaging technique, quantitative MRI, the effect of CS treatment on cartilage volume loss in knee OA. We also investigated, for the first time, the effect of CS on bone marrow lesion (BML) size and the severity of synovitis.

Methods: Knee OA patients were treated with CS (800 mg once daily) or placebo for 6 months, followed by an open-label period of 6 months in which patients from both groups received CS. Patients with primary knee OA, Kellgren-Lawrence grades 2–3, and clinical as well as MRI signs of synovitis were included. MRI was performed at baseline, 6, and 12 months. Global cartilage volume and sub-regions were quantified using a specially developed computer program. The BML size was assessed using a semi-quantitative scoring system. Synovial membrane thickness (synovitis) was measured in mm, and joint swelling incidence was evaluated. Statistical analyses were assessed by ANCOVA for the cartilage volume, Wilcoxon Mann-Whitney

tests for BML, ANOVA for synovitis, and Fisher's exact test for joint swelling.

Results: Knee OA patients were treated with CS (n=35) or placebo (n=34). Patients on CS treatment (12 months CS) compared to the patients in the placebo group (6 months placebo followed by 6 months CS) experienced a significant reduction in global cartilage volume loss at 6 (p=0.064 for a trend) and 12 (p=0.025) months, in the lateral tibiofemoral compartment (p=0.015; p=0.004), as well as in the tibial plateau (p=0.002; p=0.017). Interestingly, there was also a reduction in BML score in the global knee and lateral tibiofemoral compartment at 12 months (p=0.060; p=0.035, respectively). Although there was no statistically significant difference in synovial thickness between the 2 treatment groups at 6 months, discrimination between patients showed that those who received concomitant NSAID treatment demonstrated a statistically significant reduction in the CS group compared to the placebo group (p=0.029), as well as lower incidence of joint swelling (p=0.092).

Conclusion: Data showed that CS treatment can rapidly and significantly reduce the cartilage loss in symptomatic knee OA patients. This protective effect was associated with a decrease in BML size, supporting their role in cartilage loss. Moreover, data revealed that CS in combination with NSAIDs exerts an additional clinically relevant anti-inflammatory activity.

Chronic Pain Associated with Obesity in the Elderly Is in Part Explained by the Presence of Osteoarthritis. Irene Blanco[2], Richard B. Lipton[2], Chaim Putterman[1] and Carol A. Derby[2]. [1]Albert Einstein College of Med, Bronx, NY, [2]Albert Einstein College of Medicine, Bronx, NY

Background: Up to 60% of the elderly report chronic pain. Our group has shown a significant association between chronic pain and obesity in the elderly. It is unclear if this association is due to being overweight or comorbidities associated with obesity such as diabetes and osteoarthritis. Therefore, we conducted a cross-sectional study to investigate if the link between obesity and chronic pain is mediated by other factors.

Methods: The Einstein Aging Study (EAS) is a longitudinal study of community residing elderly. Participants are recruited using Medicare beneficiary lists and voter registration records. Demographics and medical history are collected as well as the Geriatric Depression Scale (GDS), SF-36, and the Total Pain Index (TPI) which measures pain severity, location, duration and frequency over 3 months prior to the visit. Chronic pain is defined as pain intensity of ≥4/10 (moderate to severe intensity) in at least 1 body location. To investigate the role of osteoarthritis (OA) and several comorbidities in the relationship between chronic pain (CP) and obesity, unweighted logistic regressions were performed. Overweight was defined as a BMI ≥ 25.0 and obese as a BMI ≥ 30.0

Results: 423 participants screened between 2005–2009 were included. The median age of the group was 78.9y (IQR: 74.7–83.3) and 63.8% were female (270/423). Of these participants, 209/423 (49.4%) report having chronic pain. More women than men reported CP (55.2% v 44.8%, p<0.01). There was no association of CP with either age (p=0.32), race (p=0.47), education (p=0.187), depression (p=0.42) or a history of a hip replacement (p=0.37) or hip/femur/pelvis fracture (p=0.41). On univariate analyses, being obese conferred an increased risk of CP (OR=1.76, p=0.025). CP was also associated with a history of diabetes (OR=1.92, p=0.01) and a osteoarthritis (OR=3.27, p<0.01)

When adjusted for age, race, gender, education and the following comorbidities: diabetes, stroke, heart attack, COPD, hip replacement and hip/femur/pelvis fracture, being overweight or obese significantly increased the risk for chronic pain. (OR=1.57, p=0.038) However when the model was adjusted for a history of osteoarthritis, BMI was no longer significantly associated with CP (OR= 1.45, p=0.09). OA was associated with the presence of CP with a significantly increased odds ratio of 3.03 (p<0.01, 95%CI: 1.90, 4.84). When we stratified the model by OA status, being overweight or obese increased the risk of CP in those with OA, but it was not significant (OR=1.39, p=0.22). In the stratified model, females with OA continued to have a higher risk of CP (OR=2.05, p=0.01) and diabetes did confer a higher risk that trended towards significance (OR=1.86, p=0.063)

Conclusions: We continue to see a link between chronic pain and obesity in this population. It is likely secondary to the effects of obesity, particularly osteoarthritis. New research has linked adipokines to the pathogenesis of OA. It is unknown if these molecules are correlated with increased pain from OA. More studies are needed to elucidate the origins of pain in the elderly so that targeted interventions can be designed.

Clinical Evaluation of Chondroitin 4&6 Sulfate (Condrosulf®) in the Treatment of Symptomatic Hand Osteoarthritis. A 6-Month Randomized Double-Blind, Placebo Controlled Study. Cem Gabay, Carole Medinger, Danielle Gascon and Axel Finckh. Univ Hosp of Geneva, Geneva, Switzerland

Background: Symptomatic hand osteoarthritis (OA) is a common cause of consultation for both primary care physicians and in rheumatologists. Severe forms may lead to advanced structural changes, joint deformity and disability. Despite its frequency and severity there are currently only a limited number of therapeutic options.

Objective: To examine the effect of chondroitin 4&6 sulfate (CS) 800 mg daily on pain and function in patients with hand OA.

Patients and Methods: This is an investigator initiated, randomized, placebo-controlled, single center, trial. Patients older than 40 years, with hand OA as defined by the ACR clinical and radiological criteria, suffering from regular joint pain (VAS ≥ 40/100 mm), and substantial functional impairment (functional index of hand OA (FIHAO): Dreiser score ≥ 6) were randomized to CS or placebo. Patients with other rheumatic conditions were excluded. The use of paracetamol, but not nonsteroidal anti-inflammatory drugs, was allowed during the study period. Primary end points included global spontaneous pain (VAS) and functional impairment (FIHOA). Secondary endpoints included global improvement (VAS improvement), grip strength, duration of morning stiffness, consumption of paracetamol, and drug safety. The investigators, independently from the pharmaceutical study sponsor, replicated both the data transcription and the statistical analysis.

Results: 163 patients were randomized, 81 in the CS and 82 in the placebo groups. One patient in the CS group was excluded from the ITT analysis for protocol violation. Demographic data including age, sex, BMI, blood pressure were perfectly matched in the two groups. Mean ± SD global pain VAS and Dreiser scores in the CS and placebo groups were 54.9 ± 14.2 and 11.0 ± 4.1 and 53.6 ± 14.2 and 10.3 ± 3.8, respectively. Other clinical characteristics including grip strength, number of days of painful flares, duration of morning stiffness was also balanced between the two groups. At six months, the improvement of global pain (VAS) and FIHOA were significantly more important in the CS group (−20 ± 26.6 mm and −2.9 ± 5.3) than in the placebo group (−11.3 ± 24.0 and −0.7 ± 4.8, significance P=0.03 and P=0.008, respectively). The evaluation of global improvement (VAS improvement) and duration of morning stiffness were also significantly better in the CS group (P=0.04), whereas grip strength and rescue medication were not significantly different. There was also no difference regarding the frequency of adverse events.

Conclusion: CS 800 mg daily is effective and safe in the treatment of symptomatic hand OA.

Controversies in the Use of Acupuncture for Osteoarthritis (OA). A Systematic Review of the Quality and Treatment Features of Randomized Clinical Trials (RCT). Maria F. Marengo[2], Christian A. Waimann[2], Maria A. Lopez-Olivo[2], Carol Looney[1] and Maria E. Suarez-Almazor[3]. [1]The University of Texas M. D. Anderson Cancer Center, [2]The University of Texas M. D. Anderson Cancer Center, Houston, TX, [3]University of Texas, MD Anderson Cancer Center, Houston, TX

Background: Acupuncture is one of the most frequently used non-pharmacological therapies for musculoskeletal disorders. There is conflicting evidence on its efficacy for the management of knee OA, which could potentially be attributable to the quality and variability of methodologies used

across RCTs. We conducted a systematic review of the evidence reported for acupuncture in the treatment of knee OA.

Methods: We electronically searched Embase, Medline, Web of Science and Cochrane Library up to June 9 2010, and manually searched the bibliography included in the identified systematic reviews and meta-analyses. We selected all RCTs which included patients with knee OA, compared needle acupuncture with a sham procedure, and reported pain outcomes. We excluded articles were the control group did not receive a sham intervention. We evaluated the quality of the trials using the Cochrane methods to assess risk of bias (0-worst to 11-best), and we also identified the characteristics of the trials, and specifically the modalities used for the acupuncture and sham treatments. Two authors independently agreed on eligibility and assessed the quality and methods.

Summary of the Results: We identified 6 systematic reviews. Of 14 RCTs, 9 included a sham intervention. Eight of the trials included the WOMAC as an outcome. A total of 1034 patients received acupuncture and 1127 sham intervention. Five of the 9 RCT reported statistically significant results with respect to pain. Six RCTs had a quality score of at least 7 points. The 3 with lower quality did not report statistically significant findings. Marked differences were observed with respect to trial characteristics, acupuncture treatment and sham procedures, with respect to use and number of points, duration and frequency of treatments and sham pricedures (penetrating versus non-penetrating needles). Negative trials were more likely to have used fewer acupuncture points, shorter duration and number of treatments, electric stimulation in the sham group. Very few studies controlled for the potential placebo effects of the interaction between acupuncturists and research staff with participants.

Conclusions: RCTs of acupuncture in the treatment of knee OA show variability in the results that does not appear to be related to quality of the trial, but is associated with the characteristics of the acupuncture treatment and the procedures used for the sham intervention.

Disease Modifying Activity of Celecoxib on Articular Cartilage in Osteoarthritis?—A Randomized Clinical Trial. T. N. de Boer[2], S. C. Mastbergen[2], A. M. Huisman[3], A. A. Polak[1], J. W. J. Bijlsma[2] and F. P. J. G. Lafeber[2]. [1]Orthopedics, Sint Franciscus Gasthuis Rotterdam, Rotterdam, The Netherlands, [2]Rheumatology & Clinical Immunology, University Medical Center Utrecht, Utrecht, The Netherlands, [3]Rheumatology, Sint Franciscus Gasthuis Rotterdam, Rotterdam, The Netherlands

Background: Selective COX-2 inhibitors are frequently used in the treatment of osteoarthritis (OA) to control inflammation and relieve pain. *In vitro* and *ex vivo* research using human articular cartilage, demonstrated an inflammation independent chondroprotective effect of celecoxib. Such effects are difficult to verify in clinical trials because changes in OA cartilage are slow and evaluation by imaging and biomarker techniques are still hampered by their limited sensitivity. Therefore, patients were treated *in vivo* prior to joint replacement surgery. At the moment of surgery, cartilage was obtained and analyzed in detail *ex vivo*. Three recent studies using this approach demonstrated a beneficial effect of celecoxib at chondrocyte mRNA and protein level, and at the level of matrix integrity suggesting disease modifying characteristics of celecoxib. These positive results tempted us to perform a well designed and powered RCT to evaluate the disease modifying properties of celecoxib in treatment of end-stage OA.

Methods: Patients (n=172) with end-stage knee OA on the waiting list for knee replacement surgery were randomized to 4 groups and treated for at least 4 weeks prior to surgery: celecoxib 2dd200mg, naproxen 2dd250mg stopped 3 days prior to surgery (because of its platelet-inhibiting effect), celecoxib 2dd200mg also stopped 3 days prior to surgery, or no treatment. Cartilage and synovial tissue were collected during surgery and analyzed *ex vivo* fully blinded to the treatment until all data were obtained. The study was conducted according to the declaration of Helsinki and registered EudraCT nr 2007-004862-41.

Results: 4 patients withdrew their consent, 10 changed medications within 2 weeks, and of 20 patients insufficient tissue was obtained. Drop-outs were equally distributed over the 4 treatment arms. Data were analyzed by intention to treat as well as per protocol of the remaining 138 patients. At inclusion, age, gender, weight (BMI), and cartilage damage (X-ray, macroscopic or histological) did not differ between the 4 randomized groups. Unexpectedly, cartilage proteoglycan release was not different between the 4 treatments. Also the other biochemical cartilage parameters did not differ between the 4 groups. Furthermore, prostaglandin-E_2 and nitric oxide (NO) levels produced by the cartilage remained unchanged compared to the no-treatment group. The *ex vivo* release of inflammatory mediators IL-1β, TNFα, PGE_2 and NO by the synovial tissue only showed a statistical significant decrease in NO levels in the celecoxib treated group compared to the no-treatment group. Celecoxib treatment showed a slight improvement in WOMAC pain ($p<0.01$), function and total score compared to the no-treatment group.

Conclusions: No clear effect of celecoxib treatment on cartilage was evident in the present study. Also the effects on synovial inflammatory mediators were limited. Only a small beneficial effect on WOMAC scores was found. As such the reported *in vivo* disease modifying effects of celecoxib could not be confirmed in a sufficiently powered single blinded RCT.

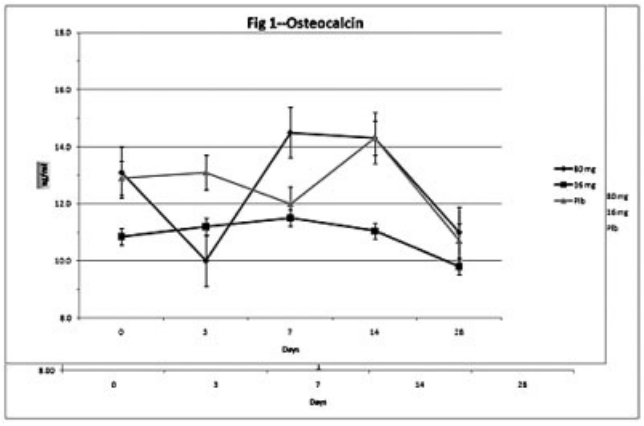
Effects of Intraarticular (IA) Corticosteroid Injections on Bone Markers and Endogenous Cortisol in Patients with Knee Osteoarthritis (OA), a Pilot Study. Aruna Baratham[3], Barbara P. Lukert[1] and Herbert B. Lindsley[2]. [1]Kansas City, KS, [2]Kansas University Med Ctr, Kansas City, KS, [3]KU Medical Ctr, Kansas City, KS

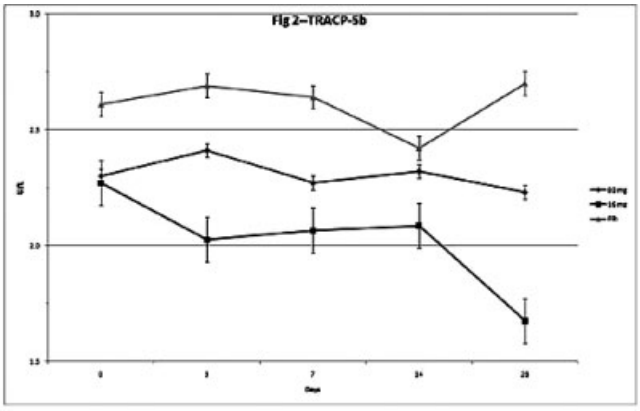
Purpose: IA steroids are used to treat knee OA. Little is known about the systemic effect of intraarticular steroid injections on bone or the pituitary-adrenal axis. There are some studies describing transient decreases in cortisol levels after IA injections in rheumatoid arthritis patients, but no data are published regarding IA steroid injections and their effect on bone turnover markers in OA patients.

Method: We describe a randomized, double blind, placebo controlled study to determine the effects of IA corticosteroid injections on bone turnover markers and endogenous cortisol. 25 subjects (20 females, 5 males) with knee OA, age range 40–80 years were identified from our clinical practice. They were not on any bisphosphonates for at least three years, no systemic illness, and not on oral glucocorticoids; their last IA glucocorticoid injection was given more than 3 months ago. They were randomized to one of three different groups injected in the more symptomatic knee on Day 0. Ten subjects (Group 1) were injected with Depo-methylprednisolone 80 mg plus lidocaine 20 mg, 10 additional subjects (Group 2) were injected with Depo-methylprednisolone 16 mg plus lidocaine 20 mg and 5 subjects (Group 3) was given normal saline with lidocaine 20 mg. Blood draws were performed five times (Days 0, 2–3, 7, 14 and 28).

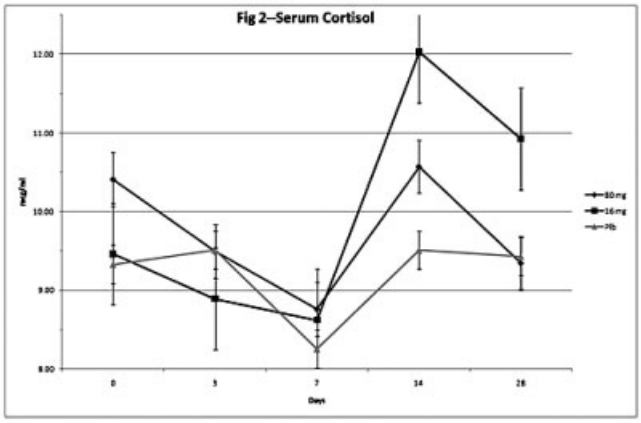
Results: Median levels of serum osteocalcin a bone formation marker, reached a nadir (10 ng/ml from baseline of 16 ng/ml) by Days 2–3 with recovery by Day 7 (15 ng/ml) after IA corticosteroids only for Group 1 ($p=0.003$). No change was seen in Groups 2,3.



In contrast the bone catabolic marker Tartrate-resistant Acid Phosphatase Form 5b (TRACP-5b) showed no consistent change for any of the three groups over 28 days (range 1.7–2.7 U/L).



Median baseline endogenous cortisol level was 9.5 mcg/dL, reached a nadir by Day and returned at least to baseline by day 14 (p=NS).



Conclusions: IA corticosteroids have a transient adverse effect on bone formation with significant recovery of osteocalcin levels by one week and no change in bone catabolism. Cortisol levels decrease slightly at one week of IA administration and rebound above baseline by two weeks. In contrast to daily oral corticosteroids, single doses of IA steroids have no persistent adverse effect on bone or the HPA axis.

Efficacy and Safety of the Lidocaine Patch 5% (Lidoderm®) When Used as Adjunct Treatment in Patients with Osteoarthritis of the Knee. Alan Kivitz[1], Ernest A. Kopecky[3], Yusong Chen[2], Steve Xiang[2], Matthew Wieman[2] and Errol M. Gould[2]. [1]Altoona Center for Clinical Research, Duncansville, PA, [2]Endo Pharmaceuticals Inc., Chadds Ford, PA, [3]Endo Pharmaceuticals Inc.

Purpose: To explore the sensitivity of a dual sequence, crossover design to estimate the treatment effect and safety of the lidocaine patch 5%, relative to placebo, as adjunctive therapy for knee osteoarthritis (OA).

Methods: This pilot study was a randomized, double-blind, placebo-controlled, 2-sequence, dual crossover, 3-period, multicenter trial in patients with moderate-to-severe pain from OA of the knee. Following an open-label, active run-in phase of up to 28 days (to achieve adequate, stable pain control without the use of rescue medication), patients were randomized to 1 of 2 treatment sequences: Sequence LPP (lidocaine patch 5%, placebo patch, placebo patch) or Sequence PLL (placebo patch, lidocaine patch 5%, lidocaine patch 5%). Two full patches were applied once daily to the knee, 1 on the front and 1 on the back of the knee. Patients maintained their existing OA analgesic regimen. Each treatment period was 4 weeks. The primary efficacy endpoint was time-to-exit from current study treatment; secondary efficacy measures included a Pain Intensity-Numerical Rating Scale (PI-NRS; 0 = no pain to 10 = worst possible pain) and Pain Relief Scale (PRS; 0 = completely worse to 8 = complete pain relief). Adverse events (AEs) were recorded.

Results: A total of 169 patients participated in the run-in phase; 93 patients aged 39 to 85 years were randomized. Correction of operational issues necessitated a modified intent-to-treat (MITT) population (n = 42). In the MITT population, the hazard ratio (95% confidence interval [CI]) for time-to-exit was 1.78 (0.89, 3.55), indicating that a patient on the lidocaine patch 5% has a 78% greater chance of remaining on treatment relative to the placebo patch at any time point during any 4-week treatment period. The odds ratio (95% CI) for exit status was 1.86 (0.86, 4.02), indicating that a patient on lidocaine patch 5% has an 86% greater likelihood of remaining on treatment relative to placebo. The LS means of the average of the last 2 daily PI-NRS or PRS scores favored the lidocaine patch 5% compared with placebo for all populations. PI-NRS scores were significantly improved for lidocaine patch 5% patients only in the MITT population (0.54-point difference compared with placebo [P = 0.02]). General disorders and administration site conditions were the largest group of treatment-related AEs in the run-in phase and double-blind treatment periods. Cutaneous AEs were mostly mild or moderate in severity and self-limited.

Conclusions: The small size of the MITT population did not allow for robust hypothesis testing, however the results suggest a beneficial treatment effect of the lidocaine patch 5% as add-on therapy in patients with OA of the knee. The lidocaine patch 5% was generally well tolerated in this population. Use of a dual sequence, crossover design may be a sensitive model for studying the effects of the lidocaine patch 5%.

945

Efficacy, Safety and Tolerability of HZT-501, Including Users of Low-Dose Aspirin, a Single-Tablet Combination of Ibuprofen-Famotidine: Results of Two Phase 3 Trials. Michael E. Weinblatt[2], Mark C. Genovese[5], Alan J. Kivitz[1], Alfonso E. Bello[4], Amy Grahn[3], Jeffrey W. Sherman[3] and Michael H. Schiff[6]. [1]Altoona Arthritis & Osteo Ctr, Duncansville, PA, [2]Brigham & Womens Hospital, Boston, MA, [3]Horizon Pharma, Inc., Northbrook, IL, [4]Illinois Bone & Joint Inst, Glenview, IL, [5]Stanford University, Stanford, Sunnyvale, CA, [6]University of Colorado, Denver, Greenwood Village, CO

Background: Gastrointestinal (GI) toxicity remains a major concern with non-steroidal anti-inflammatory drugs (NSAIDs) used in the treatment of OA, RA, and pain. Low-dose aspirin (LDA) is prescribed for prevention of cardiovascular events. LDA is a risk factor for upper GI (UGI) ulcers and UGI bleeding, with the risk increased when LDA is taken in combination with NSAIDs. Randomized trials have demonstrated that high-dose H_2 receptor antagonists (H_2RAs) reduce the incidence of ulcers in NSAID users and in LDA users, but their benefit in patients taking concomitant NSAIDs and LDA is uncertain. A combination tablet of a NSAID plus a high-dose H_2RA may both decrease ulcer disease in NSAID plus LDA users and improve compliance.

Methods: Two 24-wk double-blind, randomized trials of HZT-501, a single-tablet combination of ibuprofen (IBU; 800mg) and famotidine (FAM; 26.6mg) given three times daily were undertaken (REDUCE-1 and REDUCE-2). Patients 40–80 yrs expected to require daily NSAID therapy >= 6 mos with no history of ulcer complications, negative H. pylori stool test and baseline endoscopy (EGD) showing no ulcers and <5 erosions in the UGI tract were randomly assigned in a 2:1 ratio to HZT-501 or IBU 800 mg tablets. Concomitant LDA (<=325 mg daily) and oral anticoagulants (OAC) therapies were permitted. Randomization was stratified based on LDA/OAC therapy and prior ulcer history. Study EGDs were done at 8, 16 and 24 wks of therapy. The predefined population for primary analyses of ulcers was all patients with at least one on-study EGD. Additional safety data included treatment emergent adverse events (TEAEs), clinical laboratory assessments and physical exams.

Results: The studies included 906 and 627 patients. Total patients were1533, of which 1022 received HZT-501 and 511 received IBU. They included 121 of 812 and 79 of 570 LDA users in their primary analysis populations, respectively. A combined sub-group analysis of the LDA

users demonstrated a reduction in UGI ulcers (HZT-501: 14.0% vs. IBU: 34.5%; difference 20.5% [95% CI: 6.5, 34.6]). The Table shows the differences for HZT-501 vs. IBU in the life table estimates and crude proportions for all patients and for the LDA users developing UGI ulcers as well as discontinuation, serious adverse events (SAE) and TEAEs of interest over 24 wks. There were no clinically relevant differences between treatment groups in vital signs, hematology, biochemistry values or physical exams.

Table

	REDUCE 1 & 2		
	HZT-501 (N=1022)	**IBU (N=511)**	**p-value**
Discontinuation	31.0%	42.9%	<0.0001
TEAE	6.7%	7.6%	0.478
Dyspepsia[1]	0.6%	1.8%	0.014
SAEs	3.2%	3.3%	NA
TEAEs	55.0%	58.7%	0.162
GI Disorders	26.0%	28.4%	0.329
Dyspepsia[1]	4.7%	8.0%	0.009
Infections and Infestations	20.6%	20.7%	0.960
Cardiac Disorders	0.4%	1.0%	NA
UGI Ulcer: All	**HZT-501 (N = 930)**	**IBU (N = 452)**	**p-value**
Life table	14.1%	26.5%	<0.0001
Crude rate	11.0%	21.9%	<0.0001
UGI Ulcer: LDA Users	**HZT-501 (N=149)**	**IBU (N=58)**	**p-value**
Life table	14.0%	34.5%	0.004
Crude rate	12.8%	32.8%	0.002

[1]Preferred term for patient reported adverse event

Conclusion: HZT-501 reduces NSAID-associated UGI ulcers overall and in the subset of NSAID users taking LDA. TEAEs were balanced across both treatment groups except dyspepsia which was statistically lower for HZT-501 vs. IBU in line with known activity of FAM. Combination therapy may improve adherence and compliance in patients taking NSAIDs plus LDA who require gastroprotection.

946

Long Term Safety of an NSAID with Built-in Gastroprotection for Treatment of Pain and Inflammation Related to OA and RA: Results from a One Year Safety Trial of a Single-Tablet Combination of Ibuprofen-Famotidine vs. Ibuprofen Alone. Michael H. Schiff[6], Mark C. Genovese[5], Alan J. Kivitz[1], Alfonso E. Bello[4], Jeffrey W. Sherman[3], Amy Grahn[3] and Michael E. Weinblatt[2]. [1]Altoona Arthritis & Osteo Ctr, Duncansville, PA, [2]Brigham & Womens Hospital, Boston, MA, [3]Horizon Pharma, Inc., Northbrook, IL, [4]Illinois Bone & Joint Inst, Glenview, IL, [5]Stanford University, Stanford, Sunnyvale, CA, [6]University of Colorado, Denver, Greenwood Village, CO

Background: Gastrointestinal (GI) toxicity remains a major concern with NSAIDs used in the treatment of OA, RA, and pain. Proton pump inhibitors (PPI) and other gastroprotective agents are recommended to decrease NSAID-associated GI injury. Concerns exist regarding the potential for PPIs to adversely interact with antiplatelet agents as well as increase the risk of fractures. High-dose H_2 receptor antagonists provide significant benefit in decreasing NSAID-associated GI injury (Cochrane review). Most NSAID users at increased risk for GI events do not receive or adhere to gastroprotective co-therapy. HZT-501 [single-tablet combination of ibuprofen (IBU; 800 mg) and famotidine (FAM; 26.6 mg)] has been shown to significantly reduce upper GI ulcers as compared to IBU (800 mg) alone given thrice daily (REDUCE-1 and REDUCE-2).

Methods: Assessment of long term safety of HZT-501 or IBU tablets for up to 52 wks of treatment for patients with OA, RA or moderate pain. Patients who completed one of two large 24-week double-blind prospective trials of identical design (REDUCE-1 or REDUCE-2) were eligible for an additional 28 weeks of treatment; enrollment goal was at least 150 patients. Patients 40–80 yrs expected to require daily NSAID therapy ≥ 6 months with no history of ulcer complications, a negative H. pylori stool antigen test and baseline EGD showing no ulcers and <5 erosions in the upper GI tract were randomly assigned in a 2:1 ratio either to HZT-501 or IBU tablets. Randomization was stratified based on concomitant low-dose aspirin/anticoagulant therapy and prior ulcer history. Patients completing 24 weeks of blinded treatment (no ulcer development; expected to continue requiring daily NSAID therapy) were eligible to enroll into a follow-on study for an additional 28 weeks on the same double-blind treatment assignment. Crossover between treatments was not allowed. Safety data included serious adverse events (SAEs), treatment emergent adverse events (TEAEs), clinical laboratory assessments, vital signs, and physical exams.

Results: A total of 179 subjects were enrolled into the follow-on study, 132 received HZT-501 (112 completed) and 47 received ibuprofen (38 completed). The incidence of TEAEs was comparable in both groups for the overall 52-week period. The Table shows the differences for HZT-501 vs. IBU for discontinuation, serious adverse events (SAE) and TEAEs of interest over 52 wks. There were no clinically relevant differences between treatment groups in vital signs, hematology, biochemistry values or physical exams.

Table.

	REDUCE 1 & 2 Follow-on Population		
	HZT-501 (N = 132)	**IBU (N = 47)**	**p-value**
Discontinuation	15.2%	19.1%	0.505
SAEs	6.1%	6.4%	
TEAEs	68.2%	68.1%	0.988
Infections and Infestations	34.8%	36.2%	0.878
GI Disorders	26.5%	23.4%	0.703
Dyspepsia[1]	3.8%	8.5%	0.184
Cardiac Disorders	0.8%	0	

[1]Preferred term for patient reported adverse event

Conclusion: These results show the safety of long-term use of HZT-501, together with the significant decrease in upper GI ulcers, demonstrate that HZT-501 offers a potential new option for OA, RA and pain patients.

Modified Bent Knee Approach for Highly Accurate Injection of the Knee. Suzanne Delea[1], Wilmer L. Sibbitt[3], Philip Band, Natalia Chavez-Chiang[2], Hillary Norton[2] and Arthur D. Bankhurst[4]. [1]University of New Mexico, Albuquerque, NM, [2]University of New Mexico, [3]University of New Mexico HSC, Albuquerque, NM, [4]University of NM Med Ctr, Albuquerque, NM

Background: The extended knee lateral midpatellar portal for 1 intraarticular injection of the knee is accurate but is not practical for all patients.

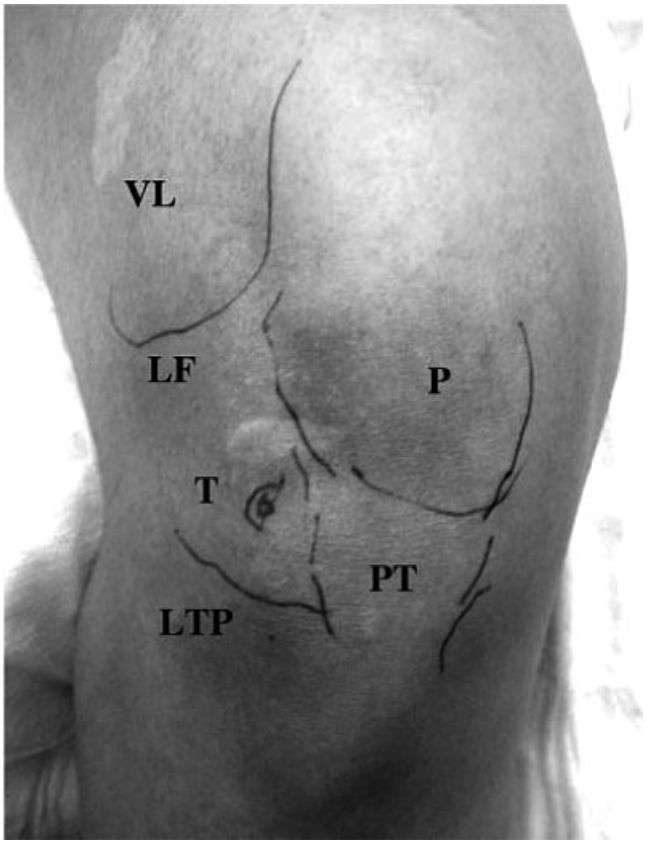
Hypothesis/Purpose: We hypothesized that a highly accurate modified anteriolateral portal where the synovial membrane of the medial femoral condyle is the target would be effective for intraarticular injection of the knee.

Study Design: Randomized controlled clinical trial. Level 1.

Methods: 83 subjects with "dry" non-effusive osteoarthritis of the knee were randomized to intraarticular injection using the modified anteriolateral bent knee versus the standard lateral midpatellar portal. 80 mg of triamcinolone acetonide was injected into the knee using a 2.0-in (5.1-cm) 21-gauge needle on a RPD procedure syringe (reciprocating procedure device) using the one-needle two-syringe technique. Baseline pain, procedural pain, and pain at outcome (2 weeks and 6 months) were determined with the 0–10 cm Visual Analogue Pain Score (VAS).The

accuracy of needle placement was determined by sonographic imaging with provocative testing.

Results: The lateral midpatellar and modified anteriolateral portals resulted in similar levels of procedural pain (VAS midpatellar: 4.6±3.1 cm; anteriolateral: 4.8±3.2 cm; p =0.77), pain at 2 weeks (VAS midpatellar: 2.6±2.8 cm; anteriolateral: 1.7±2.3 cm; p= 0.11), pain at 6 months (VAS midpatellar: 4.9±3.1 cm; anteriolateral: 4.8±3.2 cm; p =0.89), responders (midpatellar: 45.0%; anteriolateral: 55.8%; p=0.33), non-responders (midpatellar: 55.0%; anteriolateral: 44.2%; p =0.33), duration of therapeutic effect (midpatellar: 3.9±2.4 months; anteriolateral: 4.1±2.2 months; p=0.69), time to next procedure (midpatellar: 7.3±3.3 months; anteriolateral: 7.7±3.7 months; p=0.71), and cost per year (midpatellar: $243±110; anteriolateral: $231±111; p= 0.61). The bent knee anteriolateral portal was 97.4% accurate.



Conclusions and Clinical Relevance: The modified anteriolateral 1 bent knee portal is an effective and accurate alternative to the standard lateral midpatellar portal for intraarticular injection of the knee, and results in equivalent levels of responders, pain reduction, costs, and duration of therapeutic effect.

OARSI-OMERACT Virtual Joint Replacement in Disease Modifying Osteoarthritis Drug (DMOAD) Randomized Clinical Trials (RCTs) for Knee and Hip Osteoarthritis (OA): Selection of Optimal Thresholds for Symptomatic Severity.

Rebecca L. Manno[5], Clifton O. Bingham[6], Simon Paternotte[1], Philippe Coste, Giampaolo Giacovelli[9], Lucio C. Rovati[8], Kenneth D. Brandt[7], Steven A. Mazzuca[4], Daniel O. Clegg[10], Helen Shi, Eleonora Tajana Messi[3], Arturo Lanzarotti[3] and Maxime Dougados[2]. [1]AP-HP Cochin Hospital, René Descartes University, Paris, France, [2]Hospital Cochin, Paris, France, [3]IBSA Institut Biochimique SA, [4]Indiana Univ Schl of Medicine, Indianapolis, IN, [5]Johns Hopkins University, Baltimore, MD, [6]Johns Hopkins University, Baltimore, MD, [7]Kansas Univ Medical Center, Fairway, KS, [8]Rottapharm, Monza Milan, Italy, [9]Rottapharm, [10]University of Utah Med Ctr, Salt Lake City, UT

Background: DMOAD development has been limited by few patients (pts) fulfilling xray (XR) progression criteria. Joint arthroplasty (AP) has been proposed as an optimal outcome in DMOAD RCTs; however, disparities by race, gender, socioeconomic status, access to care, surgeon preference, and health care systems have generated concerns regarding biased outcomes. Moreover, a trial using AP outcomes would require a large sample size and long duration to capture sufficient event numbers. A combined OARSI/OMERACT initiative to develop "virtual total joint replacement" (VJR) criteria for DMOAD RCTs has proposed several thresholds of sustained pain, reduced function, or XR change as AP indications. Our objective is to evaluate the prevalence of pts fulfilling different clinical/XR progresson scenarios from existing DMOAD RCTs. We evaluated the prevalence of multiple cutoffs that could potentially be used as future criteria for VJR in DMOAD RCTs.

Methods: We analyzed data from placebo arms of 8 RCTs of putative DMOADS for hip or knee OA. XR progression was defined as decrease in joint space width (JSW) by the study's smallest detectable difference (SDD) for XR Δ or 0.5mm. The proportion of pts fulfilling 9 VJR scenarios with combined pain + function scores ≥80 or 100, or [(pain ≥50 + function ≥30) OR (function ≥50 and pain ≥30)] at 2, 3, or 4 consecutive visits with/without XR progression was assessed for each trial. Effect sizes of clinical scenarios were modeled in regression analyses using XR pro-

gression as a continuous (JSW Δ) and dichotomous (cutoff 0.5mm) variable.

Results: 8 OA RCTs between 1–3 yrs duration representing 1379 pts were included. Pain was assessed by WOMAC and/or VAS and function assessed by WOMAC and/or Lequesne. Radiographic SDD was evaluated in 4 trials (range 0.20–0.50). Weighted mean baseline measures demonstrated: JSW 3.18 mm (range: 2.39–4.05), pain 37.78, function 37.97, pain+function 76.78. Among 6 knee and 2 hip studies, 248 (22%) and 132 (51%) pts respectively had XR progression by JSW Δ ≥0.5mm and 366 (37%) by JSW Δ ≥SDD. Among the 9 clinical scenarios, the highest prevalence (n=486, 36%) was in the least stringent scenario (pain+function≥80 at ≥2 visits); the fewest pts fulfilled criteria (n=101, 7%) in the most stringent scenario (pain+function≥80 at ≥4 visits). When XR progression was added, the prevalence of pts fulfilling a VJR scenario ranged from 2.16% to 12.14% for JSW Δ ≥0.5mm; 3.4% to 16.7% for JSW Δ ≥ SDD. Although individual studies demonstrated associations between a clinical scenario and XR progression, in pooled regression analyses of all RCTs there was no relationship. Using the prevalence of 9 scenarios among all 8 RCTS a sample size of 545–3532 per group would be needed to demonstrate a 30% Δ.

Conclusions: The prevalence of pts with sustained symptomatic OA of at least a moderate degree with XR progression is low. Even using the most lenient criteria to define a "VJR," large numbers of pts would be required to detect differences between groups in DMOAD RCTs. RCT heterogeneity with a range of baseline JSW, symptoms, study duration and assessments may have contributed to the lack of association between XR progression and clinical symptoms in these post hoc analyses.

Patient Global Impression of Change Results from a 1-Year Open-Label Extension Study of Tapentadol Extended Release in Patients with Chronic Osteoarthritis or Low Back Pain. Bettyanne McCann[2], Robert Lange[1], Bertil Wagner[2], Achim Steup[1], Bernd Lange[1] and Mila Etrolpolski[2]. [1]Global Development, Grünenthal GmbH, Aachen, Germany, [2]Johnson & Johnson Pharmaceutical Research & Development, L.L.C., Raritan, NJ

Background: Tapentadol is a centrally acting analgesic with 2 mechanisms of action, μ-opioid receptor agonism and norepinephrine reuptake inhibition. The safety and tolerability of tapentadol extended release (ER) were assessed in a 1-year open-label extension study (ClinicalTrials.gov Identifier: NCT00487435); efficacy was evaluated using the patient global impression of change (PGIC).

Methods: Patients were eligible for enrollment in this study if they completed 1 of 4 phase 3 studies: two 15-week studies that evaluated the efficacy of tapentadol ER and oxycodone controlled release (CR) compared with placebo for chronic osteoarthritis knee pain (NCT00421928) or low back pain (NCT00449176), a crossover study (two 2-week periods following a 3-week titration with tapentadol immediate release) to assess dose conversion between the immediate-release and extended-release formulations of tapentadol in patients with chronic low back pain (NCT00594516), or a 1-year controlled long-term safety study of tapentadol ER and oxycodone CR in patients with chronic osteoarthritis hip or knee pain or low back pain (NCT00361504). Patients who completed 1 of the efficacy studies or the crossover study or who received oxycodone CR in the 1-year safety study were titrated to their optimal therapeutic dose of tapentadol ER (100–250 mg bid) during a titration period of up to 4 weeks; patients then continued on that optimal dose during a maintenance period of up to 48 weeks. Patients who received tapentadol ER during the 1-year safety study continued on their optimal dose determined in the parent study. Dose adjustments within the therapeutic range were permitted under the supervision of a physician throughout the current study. The PGIC, which was completed at baseline of this trial, at Weeks 24 and 48 of maintenance, and at the end of treatment, was used to assess patient's subjective changes in their overall status from baseline to endpoint. Patients indicated their perceived change by completing the statement "Since I began study treatment, my overall status is:" using a 7-point scale (1 = "very much improved," 2 = "much improved," 3 = "minimally improved," 4 = "no change," 5 = "minimally worse," 6 = "much worse," 7 = "very much worse"). Adverse events (AEs) were monitored throughout the study.

Results: The safety population included 1,154 patients, the intent-to-treat population included 1,149 patients, and PGIC data at endpoint were available for 1,059 patients. The majority (61.4% [650/1,059]) of patients reported a change in overall status at endpoint of "very much improved" or "much improved," and an additional 25.7% (272/1,059) of patients reported that their overall status was "minimally improved." The most commonly reported (>10%) TEAEs included headache (13.1% [151/1,154]), nausea (11.8% [136/1,154]), and constipation (11.1% [128/1,154]).

Conclusion: Long-term treatment with tapentadol ER (100–250 mg bid) for up to 1 year (and up to 2 years for some patients) was associated with an improvement in overall status for the majority of patients in this open-label extension study of patients with moderate to severe chronic osteoarthritis pain or low back pain.

Analysis of the Multicenter Osteoarthritis (MOST) Study. Jasvinder Singh[1], Tuhina Neogi[2], David T. Felson[3], James Torner[7], Kristin Baker[4], Michael C. Nevitt[5], Irina Tolstykh[5] and Cora E. Lewis[6]. [1]Birmigham VA Medical Center and University of Alabama, Minneapolis, MN, [2]Boston Univ Schl of Med, Boston, MA, [3]Boston University School of Medicine, Boston, MA, [4]Boston University School of Medicine, [5]UCSF, San Francisco, CA, [6]University of Alabama, [7]University of Iowa

Objective: OA has been labeled an inflammatory disorder but studies have examined only a limited repertoire of inflammatory markers with disease and have reported inconsistent findings. We assessed whether inflammation biomarkers and those representing adipokines are associated with synovitis and knee pain in participants in a cohort study of knee OA.

Methods: A subgroup of 100 Caucasian women were included from the NIH-funded Multicenter Osteoarthritis (MOST) Study. MOST participants were age 50 to 79 years at baseline and either with symptomatic knee OA or at high risk of disease. At baseline and 30 month follow-up, subjects were queried about the presence of knee pain on most days, completed a knee-specific Western Ontario McMaster Osteoarthritis Index (WOMAC), and had weight-bearing PA and lateral knee x-rays. New knee pain was present if a subject did not have knee pain on most days at baseline but did at follow-up irrespective of x-ray OA. At 30 months, participants underwent a gadolinium contrast-enhanced MRI using a 1.5 Tesla scanner to detect synovitis, categorized as none/questionable, mild, or a lot/extensive. WORMS readings of MRI's were used to score bone marrow lesions (BML's) and size of effusion. We assessed the multivariable-adjusted association of 1 standard deviation change in each biomarker level at baseline (blood or urine) with synovitis, prevalent pain and incident pain on most days on WOMAC scale at 30 months: TNF-alpha, MCP-1, leptin, adiponectin, PAI-1, CRP, MMP3, TIMP3, ICAM-1, IGF-1, IGF-BP3, oxidized LDL, TGF-beta 1, estradiol (total), DHEA-S, sex hormone binding globulin (SHBG) and cartilage oligomeric matrix protein (COMP).

Results: Mean age (standard deviation) was 59.5 years (7.2), body mass index (BMI) was 29 (4.8) kg/m^2, 57% had no radiographic OA at baseline, 20% with unilateral OA and 23% with bilateral OA and 68% were using an pain medications at baseline. Adjusted for site, age, BMI, baseline K/L grade, BML score (>0) and effusion score (>0), the following associations were significant for presence of a lot/extensive synovitis at 30-month visit: baseline adiponectin, OR 2.6 (95% CI:1.3, 4.9) and baseline TGF-beta 1, OR 0.3 (95% CI: 0.2, 0.7).

Significant predictors of outcomes in Multivariable adjusted Odds per 1 Standard deviation increase in each biomarker

	A lot /extensive Synovitis (ref: none/mild)		Prevalent knee pain on WOMAC (ref: none)		Incident knee pain on WOMAC (ref: none)	
	OR (95% CI)	p-value	OR (95% CI)	p-value	OR (95% CI)	p-value
Adiponectin	**2.6 (1.3, 4.9)**	**0.005**	1.4 (0.9, 2.4)	0.16	0.9 (0.4, 2.2)	0.84
TGF-B1	0.3 (2.0, 0.7)	**0.002**	1.2 (0.7, 2.1)	0.43	1.2 (0.5, 2.9)	0.71
TNF-alpha	1.2 (0.7, 2.1)	0.44	**1.9 (1.1, 3.2)**	**0.015**	2.4 (0.8, 6.6)	0.10
ICAM-1	1.1 (0.7, 1.8)	0.71	1.1 (0.7, 1.8)	0.57	**0.3 (0.1, 0.97)**	**0.044**

Similarly, in multivariable-adjusted analyses, the following associations were significant for any synovitis (versus none) at 30-month: baseline ICAM-1, OR 1.9 (1.1, 3.4) and baseline IGF-1, OR 1.9 (1.1, 4.1). Adjusted for all the variables above and use of pain medications, baseline TNF-alpha was significantly associated with prevalent knee pain at 30-months, OR 2.0 (1.2, 3.4) and ICAM-1 was associated with incident knee pain, OR 0.3 (0.1, 0.97).

Conclusions: In this hypothesis-generating study using a longitudinal cohort of Caucasian women, we found several biomarkers predictive of synovitis, prevalent and incident knee pain at 30-month follow-up.

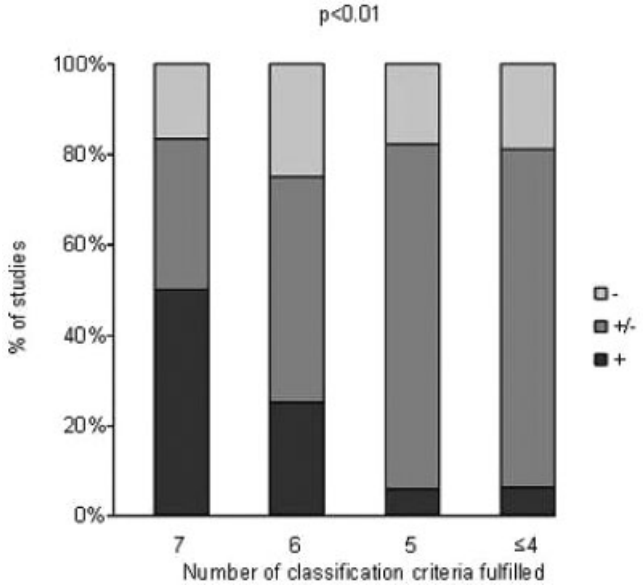
952

The Importance of Methodological Quality for the Association between Radiographic and Clinical Features of Hip and Knee Osteoarthritis: A Systematic Review. M. B. Kinds[2], E. P. Vignon[5], J. W. J. Bijlsma[4], M. A. Viergever[1], A. C. A. Marijnissen[4], F. P. J. G. Lafeber[4] and P. M. J. Welsing[3]. [1]Image Sciences Institute, University Medical Center Utrecht, The Netherlands, [2]Rheumatology & Clinical Immunology, Image Sciences Institute, University Medical Center Utrecht, The Netherlands, [3]Rheumatology & Clinical Immunology, Julius Center for Health Sciences & Primary Care, University Medical Center Utrecht, The Netherlands, [4]Rheumatology & Clinical Immunology, University Medical Center Utrecht, The Netherlands, [5]Rheumatology, University Hospital Lyon-Sud Pierre-Benite, France

Background: Still there is debate on the presumed association between radiographic and clinical features of osteoarthritis (OA). Inconsistency in reported associations might be caused by different definitions of clinical OA, and by different protocols and scoring methods for radiographic damage. Objective of this review was to evaluate whether there is an association between radiographic OA and clinical OA of hip and knee, accounting for the importance of disease definition, radiographic protocol, and standardized outcome measures.

Methods: A systematic literature search was performed with the keywords 'OA', 'hip', 'knee', 'radiographic', and 'clinical'. For comparison of study results, seven classification criteria for general study quality and methodological quality were developed. All studies were evaluated for an association between radiographic and clinical OA. Associations were classified as 'present' when statistically significant, as 'absent' when not statistically significant, and as 'non-evident' when not all performed comparisons were statistically significant. The influence of classification criteria on the association was investigated, by classifying both the number and the specific criteria fulfilled.

Results: The literature search resulted in 47 studies describing associations between radiographic and clinical OA. When all studies were evaluated, associations were present in 15%, absent in 19%, and non-evident in 66%. Associations were strongest in the six studies fulfilling all classification criteria; present in 50%, absent in 17%, and non-evident in 33% of studies. The frequency of studies with present associations significantly ($p<0.01$) diminished when the number of fulfilled criteria decreased.



Frequency of associations: + (association), +/− (non-evident association), and − (no association) in 6, 8, 17, and 16 studies fulfilling 7 (all), 6, 5, and ≤4 classification criteria respectively. Linear regression analysis with number of criteria as independent variable and association + vs association +/− and − as dependent variable: $p<0.01$.

Specifically the criteria for radiographic protocol, and standardized outcome measures were important. Associations were present in 35%, absent in 12%, and non-evident in 53% of the 17 studies in which the radiographic protocol was adequate. In the 30 studies not fulfilling this criterion, associations were significantly less present ($p=0.012$): associations were non-evident in 74% of studies, present in only 3%, and absent in 23% of studies. Considering standardized outcomes, associations were present in 26%, absent in 37%, and non-evident in 37% of studies when the criterion was fulfilled. When the criterion was not fulfilled, associations were significantly less present ($p=0.002$): associations were non-evident in 86%, present in only 7%, and absent in 7% of studies.

Conclusion: Radiographic OA and clinical OA were more commonly associated when studies fulfilled criteria for study quality and methodological quality. Specifically the radiographic protocol and standardized outcome measures are important for future research regarding the association between radiographic and clinical OA.

Time to Onset of Gastrointestinal Adverse Events of Naproxcinod vs. Naproxen and Placebo in Patients with Osteoarthritis. Byron Cryer[2], Angel Lanas[1], Rosanna Fleming[4], Fabrizio Dolphi[3], Diana Aguirre[3] and Brigitte Duquesroix[3]. [1]Aragon Health Sciences Institute, University of Zaragoza, [2]Department of Veterans Affairs Medical Center, [3]NicOx SA, [4]NicOx, Inc

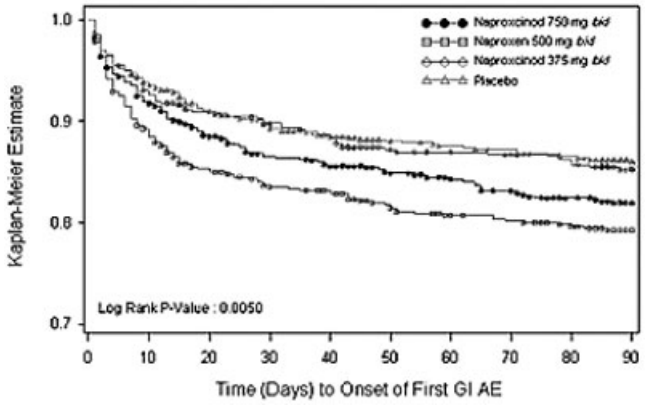
Background: Naproxcinod is a first-in-class COX-Inhibiting Nitric Oxide Donator (CINOD). Previous studies showed naproxcinod was effective compared to placebo in osteoarthritis (OA) patients.

Objectives: To evaluate the time to onset of GI adverse events (AEs) of naproxcinod 750 mg bid and naproxcinod 375 mg bid vs naproxen 500 mg bid and placebo bid in OA patients.

Methods: The safety populations were pooled from three Phase 3 OA studies (13 weeks of treatment) including two dose regimens of naproxcinod, naproxen and placebo. GI AEs and discontinuations due to GI AEs were part of a pre-planned descriptive statistical analysis. A post-hoc analysis of time to onset of GI AEs and discontinuations due to GI AEs among the different treatment groups was performed by estimating the distributions of the times to onset using Kaplan-Meier methods and comparing the distributions among the treatment groups using log rank test.

Results: A total of 2741 patients were included in the analysis: 801 on naproxcinod 750 mg, 489 on naproxcinod 375 mg, 638 on naproxen 500 mg and 813 on placebo. Demography and baseline characteristics were well balanced among groups and reflected those of the general OA population. At least one GI AE was reported by 138 (17.2%) patients on naproxcinod 750 mg bid, 69 (14.1%) on naproxcinod 375 mg bid, 128 (20.1%) on naproxen and 109 (13.4%) on placebo. Few patients discontinued due to at least one GI AE: 27 (3.4%) on naproxcinod 750 mg bid, 9 (1.8%) on naproxcinod 375 mg bid, 29 (4.5%) on naproxen and 27 (3.3%) on placebo.

Time to onset of GI AEs for the different treatment groups is presented below.



Overall, the difference among the treatment groups was significant (log Rank p-value=0.0050). Time to onset of discontinuations due to GI AEs showed a similar trend but the difference was not significant among treatment groups.

Conclusions: This analysis showed that over the 13 weeks of treatment the onset of GI AEs was less likely to have occurred for naproxcinod-treated patients than for naproxen-treated patients. A similar trend was observed for discontinuations due to GI AEs.

Topical Diclofenac Solution (PENNSAID®) Compared with Oral Diclofenac in Osteoarthritis of the Knee: Pooled Analysis from 2 Controlled Clinical Trials. Sanford H. Roth[1] and Philip Fuller[2]. [1]Arizona Research and Education, Arthritis Research Laboratory, Arizona State University, Phoenix, AZ, [2]Covidien

Background: The use of topical nonsteroidal anti-inflammatory drug (NSAID) formulations, which produce less systemic exposure to NSAIDs compared with oral formulations, is recommended in current guidelines for the management of osteoarthritis (OA). Several randomized clinical trials have shown that topical diclofenac solution (TDiclo) with penetration enhancer dimethyl sulfoxide (DMSO) is effective and well tolerated in the treatment of OA. Results of a pooled analysis of data from 2 trials comparing the safety and efficacy of TDiclo with that of oral diclofenac (ODiclo) are presented here.

Methods: Pooled analysis was performed for two 12-week, double-blind, double-dummy, randomized, controlled, multicenter studies comparing the safety and efficacy of TDiclo with ODiclo in patients with radiologically confirmed symptomatic OA of the knee. Safety and tolerability assessments in both studies included recording of vital signs and adverse events (AEs), dermatologic evaluation of the knee, and clinical laboratory measurements. Primary efficacy variables were pain and physical function as measured by the Western Ontario and McMaster Universities Arthritis (WOMAC) Index and a patient global assessment.

Results: A total of 927 patients (randomized population) were included in pooled safety analysis, and 909 patients (intent-to-treat population) were included in the pooled efficacy analysis. AEs occurred in 312 (67.1%) of patients using TDiclo vs 298 (64.5%) of those taking ODiclo. The most common AE with TDiclo was dry skin at the application site, reported in 24.3% of patients (vs 1.9% with ODiclo; $P<.0001$). Fewer gastrointestinal-related AEs (25.2% vs 39.0%; $P<.0001$) and fewer cardiovascular AEs (1.5% vs 3.7%; $P=.037$) occurred with TDiclo compared with ODiclo. Efficacy as measured by WOMAC scales and patient global assessment was similar between treatment groups.

Conclusions: Although minor skin irritation at the application site was more common in patients using TDiclo, the incidence of gastrointestinal and cardiovascular AEs was significantly lower with TDiclo compared with ODiclo.

Topical Diclofenac Solution with the Absorption Enhancer Dimethyl Sulfoxide (PENNSAID®) for the Treatment of Osteoarthritis of the Knee: Integrated Summary of Safety. Sanford H. Roth[1] and Philip Fuller[2]. [1]Arizona Research and Education, Arthritis Research Laboratory, Arizona State University, Phoenix, AZ, [2]Covidien

Background: Several randomized clinical trials have shown that topical diclofenac solution (TDiclo) with the penetration enhancer dimethyl sulfoxide (DMSO) is effective and well tolerated in the treatment of osteoarthritis (OA) of the knee. Because topical nonsteroidal anti-inflammatory drugs (NSAIDs) are associated with less systemic exposure to the active molecule, TDiclo may present a safer treatment alternative to oral NSAIDs. To further characterize the safety and tolerability profile of TDiclo, data were analyzed across clinical studies conducted in patients with OA of the knee.

Methods: Adverse events (AEs) with TDiclo therapy were analyzed for seven phase 3 controlled trials and one open-label study conducted in patients

with primary OA of the knee. The data reflect TDiclo exposure in 911 patients treated for 4 to 12 weeks (mean duration, 49 d) in the phase 3 controlled trials and 793 patients from the open-label study. In the open-label study, 463 patients were treated for at least 6 months, and 144 patients were treated for at least 12 months.

Results: Mean age of the study participants was approximately 60 years. Of the evaluated patients, 89% were white and 64% were female. The most common AEs with TDiclo were application site reactions, including dry skin (32%), contact dermatitis characterized by skin erythema and induration (9%), contact dermatitis with vesicles (2%), and pruritus (4%). Application site reactions were the most common cause of patient withdrawal from studies. In controlled trials, gastrointestinal-related AEs occurring with TDiclo at a rate at least twice that with placebo included constipation (3% vs <1%), diarrhea (4% vs 2%), dyspepsia (8% vs 4%), nausea (4% vs 1%), flatulence (4% vs <1%), abdominal pain (6% vs 3%), and edema (3% vs 0%).

Conclusions: TDiclo offers a well-tolerated potential alternative to oral NSAID therapy in patients with OA. There was a low incidence of gastrointestinal-related AEs in patients treated with TDiclo. The most common AEs across controlled and uncontrolled clinical trials were application site reactions.

Adenosine A2A Antagonist ZM241385 Increases Osteoblast Differentiation and Function In Vitro. Louisa Ziglar[2] and Bruce N. Cronstein[1]. [1]New York Univ Med Ctr, New York, NY, [2]NYU Medical Center, New York, NY

Introduction: Adenosine, a potent endogenous physiological mediator, regulates a wide variety of physiological processes via interaction with one or more of four G protein-coupled receptors (A1, A2a, A2b, and A3), expressed on many cell types. Because we have reported that adenosine receptors affect bone mineral density (BMD), we determined whether adenosine, acting through one or another of these receptors, regulated the formation of osteoblasts and their function in vitro.

Methods: Murine MC3T3-E1 Osteoblast precursor cells were cultured for 12 or 21 days in alpha-MEM media with vitamin C and beta-glycerolphosphate enrichment. Adenosine receptor A1 and A2a agonist and antagonist were added individually at a concentration of 10^{-6} mg/ml. To evaluate osteoblast differentiation, alkaline phosphatase (ALP) assay activity was performed on day 12. Alizarin red activity was measured on day 21 to evaluate osteoblast function. Experiment was performed in triplicate.

Results: Our preliminary results report no significant difference in osteoblast differentiation using A1 receptor treatment and increased differentiation and function under the presence of adenosine A2A antagonist ZM241385. Alizarin red activity showed no significant difference from control in the presence of A1 receptor agonist or antagonist where the A2A antagonist showed increased activity by 71% ($p<0.001$ n=1). Cells treated with ZM241385 showed an increase in ALP activity by 53% ($p=0.19$ n=1).

Discussion: Adenosine receptors are targets for a variety of drugs, including anti-inflammatory drugs (e.g. adenosine mediates the anti-inflammatory effects of low-dose methotrexate in the treatment of Rheumatoid Arthritis). Other indications are currently under study in pre-clinical and clinical studies. Our results suggest that adenosine A2A receptors may be potential targets for the treatment of bone disease as well.

Algorithm for Using a Bone Formation Marker PINP To Monitor the Response to Teriparatide (TPTD) in Patients with Glucocorticoid-Induced Osteoporosis (GIO). Nancy E. Lane[2], Kyoungah See[1], Margaret Warner[1] and John H. Krege[1]. [1]Eli Lilly, Indianapolis, IN, [2]Univ of California at Davis, Hillsborough, CA

Biochemical markers of bone turnover may provide useful information about response to a treatment. A least-significant change algorithm using the serum concentration of N-terminal type I procollagen propeptide (PINP), has been proposed to aid in the management of patients with postmenopausal osteoporosis treated with TPTD (Eastell et al. Curr Med Res Opin 2006;22: 61-6). The purpose of this post-hoc analysis was to assess this approach in GIO patients treated with teriparatide (TPTD). Patients who took at least 5 mg of prednisone or equivalent for at least 3 months were treated for up to 36 months with TPTD 20 g/day. Patients with a baseline and postbaseline (1 and 6 months) PINP were included in this analysis. Responders were defined as patients with an increase in PINP of >10 g/L (least significant change) at 1 or 6 months. At 1 month, the signal-to-noise ratio for PINP was 3.0 compared with 1.2 for bone-specific alkaline phosphatase (bone ALP), 1.4 for C-terminal telopeptide of type I collagen (CTX), 3.2 for osteocalcin (OC), and 2.0 for C-terminal type I procollagen propeptide (PICP). Of the TPTD-treated patients, 88% were responders. PINP responders had significantly greater increases in bone ALP, PICP, and OC ($p<0.03$) at 1 month, compared with nonresponders. In summary, PINP responders had greater than two-fold larger mean percentage increases from baseline in lumbar spine (LS) bone mineral density (BMD) at 12, 24, and 36 months versus non-responders. In patients with GIO, PINP had a high signal-to-noise ratio and most patients treated with teriparatide had a significant increase in PINP. Patients who had a significant increase in PINP had a significantly greater increase in BMD than the small number of patients who did not have a significant increase in PINP. The PINP findings in patients with GIO treated with TPTD in this study were similar to previously reported results in postmenopausal women with osteoporosis.

Lumber Spine BMD gain [mean ± SE (n)]**

PINP	12 months	24 months	36 months
> 10ug/L	8.2% ± 0.73 (n=70)	11.4% ± 1.00 (n=60)	13.3% ± 1.21 (n=55)
< 10 ug/L	3.6% ± 1.13 (n=10)	5.1% ± 1.37 (n= 9)	4.6% ± 3.19 (n= 7)
p-value*	0.023	0.021	0.018

Anti-Hypertensive Therapy and Bone Mineral Density: Analysis in a Population-Based U.S. Sample. Mitsuyo Kinjo[3], Soko Setoguchi[1] and Daniel Hal Solomon[2]. [1]Brigham and Women's Hospital, [2]Brigham and Womens Hospital, Boston, MA, [3]Okinawa Chubu Hospital, Japan

Background: Several prior studies suggest that beta-blockers and anigiotensin converting enzyme inhibitors (ACE-I) may increase bone mineral density (BMD) in humans. Many studies have examined fracture risks associated with anti-hypertensive treatments. We examined BMD in subjects using beta-blockers, ACE-Is, angiotensin receptor blockers (ARBs), calcium, thiazide diuretics and calcium channel blockers (CCBs), and BMD in a representative U.S. population-based sample from the National Health and Nutrition Examination Survey 1988–1994 (NHANES III) and 1999–2004.

Methods: We identified adult subjects 20 years and older using beta blockers, ACE-Is, ARBs, thiazide diuretics, or CCBs who underwent dual energy X-ray absorptiometry scanning in NHANES. Femoral neck BMD available in NHANES III and lumbar spine BMD in NHANES1999–2004 were examined. Subjects on beta blockers, ACE-I or thiazide monotherapy were compared to CCB users in adjusted linear regression models that included known demographic, anthropometric, and medical risk factors for osteoporosis.

Results: The mean age of study subjects was 65 years old. Among subjects with BMD measured, 2,532 used these medications in NHANES III and 1,224 used them in NHANES 1999–2004. In multiple regression analyses (see Table), ACEI use was associated with higher lumbar spine BMD in both women ($P = 0.03$) and men ($P = 0.037$). Thiazide use was

associated with higher BMD at femoral neck BMD in women, although statistically not significant. Beta-blocker use was only significantly associated at the lumbar spine BMD (P = 0.027) in women. BMD did not differ between ARB and CCB users.

Table 2-1. Adjusted BMD (least square mean) among female subjects in NHANES 1999–2004 and NHANES III

	BB	P-value	ACEI	P-value	Thiazide	P-value	ARB	P-value	CCB
NHANES 1999–2004 (Female)	151		99		68		41		132
Lumbar spine BMD	1.02 (1.00, 1.05)	0.027	1.03 (1.00, 1.03)	0.03	0.98 (0.91, 1.03)	0.5	1.00 (0.94, 1.06)	0.3	0.95 (0.92, 0.97)
NHANES III (Female)	257		195		110		n/a		389
Femoral Neck BMD	0.71 (0.70, 0.71)	0.2	0.73 (0.72, 0.74)	0.3	0.74 (0.73, 0.75)	0.082			0.72 (0.71, 0.73)

*age, race, bmi, smoking, and estrogen use only for female

Table 2-2. Adjusted BMD (least square mean) among male subjects in NHANES 1999–2004 and NHANES III

	BB	P-value	ACEI	P-value	Thiazide	P-value	ARB	P-value	CCB
NHANES 1999–2004 (Male)	158		104		48		40		94
Lumbar spine BMD	1.03 (1.01, 1.05)	0.7	1.11 (1.09, 1.14)	0.037	1.08 (1.00, 1.15)	0.7	1.04 (1.00, 1.09)	0.6	1.05 (1.02, 1.07)
NHANES III (Male)	211		186		63		n/a		279
Femoral Neck BMD	0.82 (0.81, 0.83)	0.5	0.81 (0.80, 0.82)	0.6	0.83 (0.82, 0.85)	0.2			0.81 (0.80, 0.82)

Conclusions: Bone mineral density appears higher in users of ACE-I and thiazides than CCB users among adults, but a causal relationship is not clear.

Bone Density Following Long-Duration Spaceflight and Recovery. Shreyasee Amin[1], Sara Achenbach[1], Elizabeth Atkinson[1], L. Joseph Melton[1], Sundeep Khosla[1] and Jean Sibonga[2]. [1]Mayo Clinic, [2]NASA-Johnson Space Center

Background: Rapid bone loss in the weight-bearing skeleton is well recognized during microgravity exposure in long-duration spaceflight, but the implications on long-term bone health remain unclear. How bone mineral density [BMD] in US crew members serving on long-duration missions in space [US crew] compare with what would be expected had they not been exposed to microgravity, is unknown.

Methods: We therefore examined the observed changes in BMD (g/cm^2) among 28 US crew (immediately post-flight and following ~12 months recovery) relative to comparable age- and gender-expected changes derived from 348 men (age range at baseline: 22–90 yrs) and 351 women (range: 21–93 yrs) representing an age-stratified, random sample of the adult community population. BMD measurements (Hologic QDR 2000) were made at the total hip, lumbar spine, ultradistal and midshaft radius, and total body (sites also measured in US crew). Men were measured at baseline, 2, and 4 yrs; women were measured at baseline, 1, 2, and 4 yrs. Linear mixed effects models were used to predict follow-up BMD using baseline BMD, age, gender, and follow-up time, adjusting for the fact that most people were measured more than once. Models including body mass index (BMI) or lean mass were also considered. In US crew (24 men, age range at pre-flight scan: 36–53 yrs; 4 women, age: 41–53 yrs), BMD was measured pre-flight, immediately post flight and at ~12 months post-flight using Hologic QDR 2000, QDR 4500 and Discovery scanners. The majority had pre- and post-flight BMD on similar machines. Immediate post-flight BMD was performed a median of 6 (range: 3–33) days after return, with a median flight duration of 167 (range: 95–215) days. 22 men and 4 women had a scan within 6–18 months post-flight; median days from landing to ~12 months scan was 376 (range: 184–534) days.

Results: Using their age, gender, pre-flight BMD and follow-up time, post-flight BMD values for US crew were predicted based on the model developed from the community sample. The predicted and observed BMD and rates of change immediately and ~12 month post-flight for US crew are presented (see Table). Findings were similar using prediction models which included BMI or lean mass. Due to microgravity exposure, the observed immediate post-flight BMD at all sites was significantly lower than predicted. However, at ~12 months post-flight, BMD values at most sites in US crew were still lower than would be expected had they not been exposed to microgravity.

BMD Site	Mean BMD (g/cm^2) (% change in BMD per month) [95% Confidence Interval]					
	Immediate Post Flight			~12 Month Post Flight		
	Predicted	Observed	p-value	Predicted	Observed	p-value
Total Hip	1.082 (−0.00) [−0.05, 0.04]	1.012 (−0.87) [−1.04, −0.71]	<0.001	1.086 (0.01) [−0.01, 0.02]	1.062 (−0.10) [−0.15, −0.06]	<0.001
Spine	1.078 (0.12) [0.10, 0.13]	1.028 (−0.48) [−0.61, −0.34]	<0.001	1.086 (0.05) [0.05, 0.06]	1.068 (−0.03) [−0.01, 0.03]	0.004
Ultradistal Radius	0.519 (−0.02) [−0.05, −0.00]	0.511 (−0.21) [−0.34, −0.09]	0.01	0.512 (−0.07) [−0.07, −0.06]	0.517 (−0.002) [−0.07, 0.02]	0.03
Mid Shaft Radius	0.710 (0.17) [0.11, 0.23]	0.695 (−0.06) [−0.17, 0.04]	0.001	0.705 (0.06) [0.03, 0.09]	0.694 (−0.01) [−0.06, 0.04]	0.02
Total Body	1.264 (−0.05) [−0.05, −0.04]	1.240 (−0.26) [−0.37, −.0.16]	0.002	1.264 (−0.02) [−0.03, −0.02]	1.248 (−0.08) [−0.15, −0.01]	0.08

Conclusion: These findings have implications on potential long-term adverse effects to bone health of US crew serving on long-duration spaceflight missions.

Bone Geometry Parameters among Black and White Women with SLE. Jimmy D. Alele[2], Diane L. Kamen[2], Kelly J. Hunt[2], Gary S. Gilkeson[1] and Rosalind Ramsey-Goldman[3]. [1]Med Univ of South Carolina, Charleston, SC, [2]Medical University of South Carolina, Charleston, SC, [3]Northwestern University, Chicago, IL

Purpose: Recent studies reported an increased prevalence of osteoporotic fractures among patients with systemic lupus erythematosus (SLE). While the prevalence of low bone mineral density (BMD) is higher among these subjects than the general population, this finding does not fully account for increased fracture rate. The purpose of this study was to determine if SLE status was associated with bone geometry parameters that predict increased skeletal fragility among black and white women.

Methods: Study subjects included 153 women who had participated in the Study of Lupus Vascular and bone Long Term Endpoints (SOLVABLE) (69% white, 31% black) and 4920 controls from the third National Health and Nutrition Examination Survey (NHANES III) (59% white, 41% black). Dual energy x-ray absorptiometry (DXA) scans from SOLVABLE (Hologic DQR-4500), and NHANES III (Hologic DQR-1000) were analyzed using the Hip Structure Analysis (HAS) program to derive BMD and bone geometry parameters (section modulus, buckling ratio, outer diameter and cross-sectional area) at the femoral neck, intertrochanter and proximal femoral shaft. Linear regression was used to examine differences (SLE vs. NHANES) in bone density and geometry in blacks and whites after adjusting for age and body mass index.

Results: NHANES participants were older than SLE subjects, and were more likely to smoke. We detected significant BMD and bone geometry differences (SLE vs. non-SLE, black and white subjects) at the intertrochanter as follows and per table below:

1) BMD (g/cm^2) was lower among both black and white SLE subjects (0.80 vs. 0.94, $p<0.0001$ and 0.82 vs. 0.86, $p<0.01$ respectively).

2) BMD reduction was associated with reductions of cross sectional area (cm^2) among black and white SLE subjects (3.76 vs. 4.61 and 4.05 vs. 4.35 respectively, $p<0.0001$), suggesting that low BMD among SLE patients was a result of reduced total bone quantity.

3) Section modulus (cm^3) was also reduced among SLE subjects in both races (3.03 vs. 3.81, $p<0.0001$ and 3.54 vs. 3.76, $p<0.01$ respectively), suggesting reductions in bending resistance among SLE patients.

4) Reductions in section modulus were accompanied by reductions in outer skeletal diameter (cm) among both black and white SLE subjects (4.98 vs. 5.20, $p<0.0001$ and 5.19 vs. 5.31, $p<0.001$, respectively), suggesting reduced subperiosteal apposition.

5) Finally, buckling ratio was increased among black patients vs. NHANES (9.49 vs. 8.58, $p<0.01$), suggesting increased tendency for local cortical buckling among black patients at this location. Similar findings were detected at the narrow neck and proximal shaft.

Table. Age and BMI-adjusted mean (95% CI) bone mineral density and bone geometry parameters stratified by race and SLE status.

	Whites		Blacks	
	NHANES (n = 2916)	SLE (n = 105)	NHANES (n = 2004)	SLE (n = 48)
Intertrochanter Region				
BMD (g/cm^2)	0.86 (0.86, 0.87)	0.82 (0.79, 0.85)*	0.94 (0.93, 0.94)	0.80 (0.75, 0.84)‡
Section Modulus (cm^3)	3.76 (3.74, 3.79)	3.54 (3.40, 3.68)*	3.81 (3.78, 3.85)	3.03 (2.81, 3.24)‡
Cross Sectional Area (cm^2)	4.35 (4.32, 4.37)	4.05 (3.91, 4.20)‡	4.61 (4.58, 4.65)	3.76 (3.55, 3.97)‡
Width (cm)	5.31 (5.30, 5.32)	5.19 (5.13, 5.26)†	5.20 (5.18, 5.22)	4.98 (4.89, 5.08)‡
Bucking Ratio	9.25 (9.17, 9.32)	9.27 (8.88, 9.66)	8.58 (8.49, 8.67)	9.49 (8.90, 10.1)*

P-values are for comparisons within racial group between NHANES participants and individuals with SLE: *, p-value < 0.01; †, p-value < 0.001; ‡, p-value < 0.0001.

Conclusion: Our study suggests that SLE is associated with BMD and bone geometry profiles that predict increased skeletal fragility among both black and white women. These skeletal differences probably result from the inflammatory nature of SLE and common therapies, especially steroids.

Cardiovascular Disease Is Associated with Increased Bone Loss and Fracture Risk; a Systematic Review of the Association between Cardiovascular Disease and Osteoporosis. Debby den Uyl[2], Mike T. Nurmohamed[1], Lilian H. D. van Tuyl[2], Hennie G. Raterman[2] and Willem F. Lems[2]. [1]Department Rheumatology/Jan van Breemen Institute, Amsterdam, The Netherlands, [2]Department Rheumatology/VU University Medical Centre, Amsterdam, The Netherlands

Background: Both cardiovascular disease and osteoporosis are important causes of morbidity and mortality in the elderly. The co-occurrence of cardiovascular disease and osteoporosis prompted us to review the evidence of an association between cardiovascular (CV) disease and osteoporosis and potential shared common pathophysiological mechanisms.

Methods: A systemic literature search (Medline-Pubmed and Embase) was conducted to identify all clinical studies that investigated the association between cardiovascular disease and osteoporosis. Relevant studies were screened for quality according to guidelines as proposed by Dutch Cochrane Centre (1) and evidence was summarized.

Results: Seventy-one studies were included in this review. Due to a large heterogeneity in study population, design and outcome measures a formal meta-analysis was not possible. Six of the highest ranked studies (mean n=2000) showed that individuals with prevalent CV disease had higher risk for increased bone loss and fractures during follow-up compared to persons without CV disease (range of reported risk: HR 1.5; OR 2.3–3.0). The largest study (n=31936) reported an over 4 times higher risk in women and over 6 times higher risk in men. There is moderate evidence that individuals with low bone mass had higher CV mortality rates and incident CV events than subject with normal bone mass (risk rates 1.2–1.4). Although the shared common pathophysiological mechanisms are not fully elucidated, the most important factors that might explain this association appear to be age, estrogen deficiency and inflammation.

Conclusions: The current evidence indicates that individuals with prevalent CV disease are at increased risk for bone loss and subsequent fractures. Hence, evaluation of bone mass could be considered in patients with prevalent CV disease. Presently no firm conclusions can be drawn to which extent low bone mineral density might be associated with increased cardiovascular risk.

Cholecalciferol High Dose Supplementation Should Be Preferred in Rheumatic Patients Independently to the Presence of an Autoimmune Disease. Mattia Bellan[3], Pier Paolo Sainaghi[1] and Mario Pirisi[2]. [1]Immuno-Rheumatology Outpatient Unit, DMCS, "A. Avogadro" University and IRCAD (Interdisciplinary Reseach Center of Autoimmune Diseases), Novara, Italy, [2]Immuno-Rheumatology Outpatient Unit, DMCS, "A. Avogadro" University and IRCAD (Interdisciplinary Reseach Center of Autoimmune Diseases), Novara, Italy, [3]Immuno-Rheumatology Outpatient Unit, DMCS, "A. Avogadro" University, Novara, Italy

Introduction: Hypovitaminosis D is common in rheumatic patients, but the response to different supplementation regimens in this setting has not been fully investigated. We aimed to compare two different supplementation regimens of cholecalciferol in patients with rheumatic diseases.

Methods: The clinical records of 832 consecutive adult patients attending a tertiary level immuno-rheumatology clinic from June 2007 to May 2010 were evaluated retrospectively. We included all patients diagnosed to have either an autoimmune rheumatic disease (ARD: rheumatoid arthritis, spondyloarthritis, polymyalgia rheumatica and other connective tissue diseases) or a non-autoimmune rheumatic disease (NARD: osteoarthritis, osteoporosis), who received a) a single 100.000 IU oral dose followed by a 800–1000 IU daily dose of cholecalciferol (loading treatment-LT) or b) standard oral supplementation (ST: 800–1000 IU daily), both regimens maintained for ≥6 months. We excluded patients with renal failure, primary hyperparathyroidism, liver failure and those already receiving vitamin D supplementation. Plasma 25(OH)vitamin D (VITD) concentration together with other clinical data were recorded at baseline and after 6 months of treatment; due to its non-normal distribution (test Shapiro-Wilk, $p<0.05$), a non parametric statistic analysis was chosen.

Results: The study population included 116 patients, 81 with ARD and 35 with NARD; 86 received the ST, and 32 the LT (2 of them after ST). Plasma VITD concentrations were suboptimal both in NARD (median [IQR], 27.2 [12.7–47.4] nmol/L) and ARD (30.0 [17.2–43.4]) (Mann-Whitney U test, p=ns). After receiving ST, plasma VITD increased similarly in the two groups (ARD: 56.4 [40.7–79.4], and NARD: 60.4 [48.9–75.1], p=ns), with only 27.9% [19.5–38.2 95%CI] of patients able to reach the reference value of 75 nmol/L. Among patients who received LT, VITD concentrations also increased similarly in ARD (71.6 [55.4–81.4]) and NARD (72.9 [60.4–79.4]), but a higher proportion of patients (43.8% [28.1–60.8]) reached a plasma VITD concentration ≥75 nmol/L. Indeed, plasma VITD increments from baseline were significantly higher after LT (40.2 [27.5–58.4]) than following ST (22.5 [3.7–45.9], $p<0.009$), again without differences between ARD and NARD (ST: ARD 22.7 [3.7–52.2] vs NARD 22.2 [4.2–44.7] p=ns; LT ARD 37.2 [29.5–56.7] vs NARD 46.7 [13.0–64.9] p=ns).

Conclusions: Hypovitaminosis D is common in patients with rheumatic diseases with and without autoimmune features. A LT supplementation regimen is more efficient than ST in increasing VITD plasma levels, with higher rates of VITD normalization. Finally, following Vitamin D supplementation plasma VITD normalization is achieved similarly in ARD and NARD patients.

Differences in the Observed Rate of Hip Fracture in Male and Female Patients Diagnosed with Osteoarthritis or Ankylosing Spondylitis Compared with the Expected Based on the General Population Seeking Health Care. Martin Englund[2], Jonas Franklin[3] and Ingemar F. Petersson[1]. [1]Lund University Hosp, Lund, Sweden, [2]Musculoskeletal Sciences, Department of Orthopedics, Clinical Sciences Lund, Lund University, Lund, Sweden, [3]University Hospital, Akureyri, Iceland

Background: There are conflicting reports of the association between hip osteoarthritis (OA) and hip fracture, and little is known of the association between knee OA or ankylosing spondylitis (AS) and hip fracture.

Objective: To study the rate of hip fracture in male and female OA and AS patients compared with the general population seeking health care.

Methods: Cohort design; Sweden has publicly funded health care with all in- and outpatient health care consultations registered by the patient's personal identifier. We studied residents aged ≥20 yrs of southern Sweden by 1 Jan 2004 who consulted a physician at least once the following 4 calendar years (n=761,210 of total adult population n=879,624), thus being captured with diagnostic codes in the Skane Health Care Register (SHCR). We identified all residents with an ICD-10 code given by a physician for: hip OA (M16), n=11,901, mean age 69.6 yrs, 57.1% women; knee OA (M17), n=23,866, mean age 66.3 yrs, 58.8% women; AS (M45), n=1374, mean age 53.1 yrs, 39.8% women. To obtain observed hip fracture rates we calculated the person-time for each individual, from the day of his/her first OA or AS diagnosis within the study period until the day of first hip fracture (ICD-10 codes: S72.0, S72.1, or S72.2) or until another censoring event (death, relocation, or end of study period by cross-referencing with the population register). The person-time for each subject in the general population aged ≥20 yrs seeking health care (n=761,210, the background population) started to count by his/her first diagnostic code (any ICD-10 code) in the SHCR within the period until first hip fracture or another censoring event (in an

identical fashion as for OA and AS patients). We then calculated the standardized fracture-rate ratio (SFR) by dividing the observed rate of hip fracture in OA or AS patients by their expected rate (based on the age- and gender-specific rates in the background population). Thus, a SFR >1 equals an increased rate of hip fracture and <1 equals a reduced rate of hip fracture compared with the background population. In a sensitivity analysis for estimates in OA patients, we excluded all residents (in both the OA cohort and the background population) being registered with total hip replacement within the study period.

Results: In female knee OA patients the hip fracture rate was significantly reduced by about 20%, but not in men. No significant SFRs were found for hip OA patients, neither men nor women (figure). In AS we found the SFR increased by about 70% for both men an women. However, due to the relatively rare AS diagnosis and low number of fractures observed, the 95% CIs were large and included one (the SFR for men and women combined was 1.68, 95 % CI 0.94, 2.77).

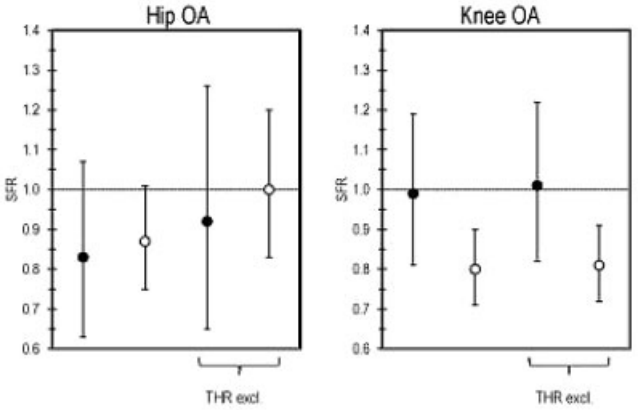

Figure. Standardized hip fracture-rate ratio (SFR) in male (●) and female (○) hip and knee OA patients. The ratio is obtained by dividing the observed fracture rate among OA patients divided by their expected rate based on the hip fracture rate in the background population. In the second set of estimates in each graph subjects with total hip replacement (THR) within the study period are excluded. Error bars are 95% confidence intervals.

Conclusion: In a comprehensive population-based dataset over 4 years, we observed a 20% decreased rate of hip fracture in female knee OA patients compared to the expected, while there was an 70% increased rate in AS patients.

Effect of Oral Ibandronate on Bone Microarchitecture in Women with Osteopenia—A Randomized Placebo-Controlled Trial. Roland Chapurlat[2], Michel Laroche[4], Thierry Thomas[1], Stéphanie Rouanet[5], Pierre D. Delmas[2] and Marie-Christine de Vernejoul[3]. [1]CHU St Etienne, Saint Etienne, France, [2]INSERM U831, Université de Lyon, Hôpital E Herriot, Lyon, France, [3]Lariboisière Hospital, Paris, France, [4]Pôle Institut Locomoteur Hôpital Purpan, Toulouse, France, [5]Roche France, Neuilly, France

Bone microarchitecture is associated with bone fragility, but little is known about the effects of osteoporosis treatments on microarchitecture. The aim of this study was to examine the effect of ibandronate on bone microarchitecture measured non invasively with peripheral high resolution quantitative computed tomography (HR-pQCT).

We have conducted a randomized placebo-controlled trial among 148 women with osteopenia. Patients received either oral 150 mg monthly ibandronate or an identical placebo, over 24 months. Bone microarchitecture was assessed at baseline, 6, 12 and 24 months, using HR-pQCT (XtremeCT, resolution 82 mm, Scanco, Switzerland) at distal radius and tibia; areal bone mineral density (aBMD) was measured with DXA at the spine, hip and radius. The primary endpoint was the trabecular bone volume (BV/TV) at 12 months at distal radius; the secondary endpoints were volumetric BMD (vBMD) at the trabecular and cortical envelopes, trabecular number (Tb.N), trabecular thickness (Tb.Th), trabecular separation (Tb.Sp) and cortical thickness (Ct.Th). The analysis was intent to treat. All the parameters were analyzed using an analysis of covariance model including baseline value as covariate.

The baseline variables did not differ between those women on ibandronate (n = 72) and those on placebo (n = 76). At 12 months, there was no significant difference in BV/TV at the radius between women on ibandronate (0.108 ± 0.025) and placebo (0.105 ± 0.029), p = 0.25. Similarly, there was no significant difference in other radius trabecular and cortical microarchitecture parameters at 12 and 24 months. In contrast, at the tibia, cortical vBMD in the ibandronate group was significantly greater than in the placebo group as soon as 6 months (810.7 ± 50.7 vs 806.9 ± 69.1, p=0.002) and also at 12 (813.1 ± 50.0 vs 807.3 ± 66.9, p<0.001) and 24 months (816.3 ± 50.3 vs 800.5 ± 68.1, p<0.001), in parallel with better Ct.Th at 6 (0,91 ± 0,22 vs 0,89 ± 0,25, p<0.001), 12 (0,91 ± 0,21 vs 0,90 ± 0,25, p=0.004) and 24 months (0,92 ± 0,22 vs 0,87 ± 0,25, p<0.001). Tibial trabecular parameters, however, remained unaltered at 6, 12 and 24 months in treated women compared with placebo. In the ibandronate group, areal BMD was significantly increased at the hip and spine at 12 and 24 months, and significantly superior to placebo only at 24 months at the radius.

We conclude that 12 months of treatment with ibandronate in women with osteopenia did not affect trabecular bone microarchitecture, but improved cortical vBMD at the tibia at 12 and 24 months, as well as Ct.Th at the tibia, possibly corresponding to decreased cortical porosity. This might be relevant regarding protection against non vertebral fracture. The tibia may be a better bone site to evaluate the effects of antiresorptive agents with HR-pQCT.

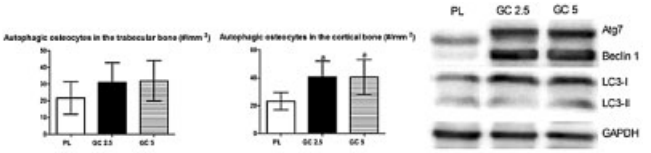
Effects of Glucocorticoid on Osteocyte Autophagy In Vivo. Wei Yao[1], Junjing Jia[1], Weiwei Dai[1], Min Guan[1], Lynda Bonewald[3] and Nancy E. Lane[2]. [1]UC Davis Medical Center, [2]Univ of California at Davis, Hillsborough, CA, [3]Univ. of Missouri at Kansas City, School of Dentistry, Dept. of Oral Biology, Kansas City, MO

Objective: We evaluated dose dependent changes in osteocyte autophagy and apoptosis at both the cancellous and cortical bone sites and serum mineral metabolism in male mice exposed to glucocorticoids (GCs).

Methods: Three month old male Swiss-Webster mice were implanted with prednisolone slow release pellets (2.5mg, 1.5mg/kg/d, or 5 mg/60, 3mg/kg/d, 60-day slow release pellets). The mice were sacrificed at day 28. Minerals and calcitrophic hormones were measured in serum by ELISA or RIA. Autophagy and apoptosis real-time RT-PCR gene pathways were assayed from the tibiae. The percentages of osteocytes undergoing apoptosis or autophagy were measured by immunohistochemistry in both the cancellous and cortical bone regions of the distal femurs.

Results: Twenty-eight days of GC exposure dose-dependently decreased serum phosphorus by about (10% and 25%), 1,25(OH)2 D (65% and 90%) and increased FGF23 (78% and 107%). There was a significant increase in the activation of autophagic RT-PCR gene pathway by an average of 50-fold at 2.5mg dose level and activation of the apoptosis RT-PCR gene pathway by an average of 30-fold at 5mg dose level. Autophagic osteocytes did not differ significantly at the trabecular region of the femurs but were increased by about 50% at the cortical region at both dose levels. Osteocyte apoptosis was not different from placebo-treated group at the trabecular bone region and increased at the cortical bone region by approximately 40% at 5mg dose level.



Conclusions: Mice exposure to GCs for 28 days resulted in significant increase in osteocyte autophagy in the cortical region at 2.5mg dose level. Osteocyte apoptosis was increased in the cortical bone region at 5mg dose level. These data suggest that GC exposure may have created a "stress" that induced osteocyte autophagy that may contribute to the deterioration of the localized matrix around the osteocytes and the death of the osteocytes, which may reduce localized bone material properties and whole bone strength that we previously reported.

Fracture Epidemiology among a Cohort of HIV-Infected Adults in the UK: An Epidemiologic Study. Karen Walker-Bone[1], Reshad Malik[2], Martin Fisher[2], Yvonne Gilleece[2] and Amanda Samarawickrama[2]. [1]Brighton & Sussex Medical School, Brighton, East Sussex, United Kingdom, [2]Brighton & Sussex University Hospitals NHS Trust

Background: HIV is a global pandemic. The devastating mortality associated with HIV infection has been dramatically reduced by highly-active anti-retroviral therapies (HAART). However, this has led to increasing numbers of HIV-infected patients living with comorbidities including metabolic diseases. Low bone mass and osteoporosis were implicated as consequences of HAART approximately 10 years ago but fracture data in HIV-infected populations are rare.

Methods: A well-characterised cohort of HIV-infected adults attending one UK centre for outpatient care was surveyed. Trained nurses administered a questionnaire which enquired about demographic factors, lifestyle factors, diet and exercise, exposure to glucocorticoids and other drugs affecting bone mineral and HIV factors. Exposure to HAART, stage of HIV infection and status of viral load, CD4 counts etc were collated.

Results: In total, 1050 HIV infected adults were surveyed. 859 (82%) responded. Mean age of respondents was 42.7 (range 19–77) years. 87% were Caucasian and 90% were male (predominant mode of transmission of infection: MSM). Mean duration of HIV infection was 6 years and 76% were current users of ARVs. Overall, 125 subjects (119 (15%) men and 6 women (7%)) reported 200 fractures. 65 respondents had fractured their distal forearm, 6 reported hip fractures and 2 vertebral fractures. In total, 57% of the 200 fractures occcurred under age 25 years with the peak age 7–12 years. However, 33 fractures (26%) occurred among respondetns aged >40 years and 8 (24% among those aged >50 years. The second peak of fractures occurred at the distal forearm (n=6, mean age 48.2 years) and there was 1 hip fracture (age 46 years). 15% of those who sustained a fracture at aged >40 years had been exposed to oral glucocorticoids as compared to 9% of those who had not fractured.

Conclusion: Our results suggest a traditional bimodal distribution of fracture in this population. The first peak occurs in childhood/adolescence and is maximal aged 7–12 years. However, our results suggest a second peak of fracture aged >40 years at sites with a high proportion of trabecular bone (distal forearm, hip, vertebrae). This peak is seen much earlier than in non-HIV infected adults but affects similar sites to those of traditional osteoporotic fractures. Although low bone mass has been documented widely in prevalent HIV infection, fracture has not. Our data suggest that fracture may be a consequence of low bone mass in HIV infection. If these data are replicated, HIV may become one of the most important causes of secondary osteoporosis worldwide.

Fracture Incidence, Quality of Life and Back Pain in Women with Osteoporosis and Concomitant Glucocorticoid Use Treated with Teriparatide: 36 Month Results from the European Forsteo Observational Study (EFOS). Willem Lems[9], Bente Langdahl[6], Osten Ljunggren[7], Annabel Barrett[2], Dimitrios Karras[8], James Bernard Walsh[4], Astrid Fahrleitner-Pammer[3], Gerald Rajzbaum[5], Clare Barker[2], Franz Jakob[1] and Fernando Marin[2]. [1]Julius-Maximilians-Univ, Würzburg, Germany, [2]Lilly Research Ctr., Windlesham, UK, [3]Med Univ, Graz, Austria, [4]St James's Hosp Trinity College, Dublin, Ireland, [5]St Joseph Hosp, Paris, France, [6]Univ Hosp, århus, Denmark, [7]Univ Hosp, Uppsala, Sweden, [8]Veterans Admin Hosp, Athens, Greece, [9]VU Univ Hosp, Amsterdam, Netherlands

Aim: To describe clinical fractures (Fx), back pain and health-related quality of life (HRQoL) outcomes in postmenopausal women with osteoporosis and glucocorticoid (GC) use, treated with teriparatide (TPTD) for up to 18 mths and followed-up for a further 18 mths in EFOS.

Methods: Prospective, observational study in 8 EU countries. Data on incident clinical vertebral and non-vertebral Fxs were collected, back pain assessed using a 100mm VAS and questionnaire, HRQoL measured using EQ-5D. Changes in women with incident Fx rates over time analysed using logistic regression with repeated measures (RM). Changes from baseline in back pain VAS & EQ-VAS analysed using an RM model.

Results: Of 1581 EFOS patients with follow-up data, 294 (18.6%) were concomitantly treated with GC. At baseline, GC treated patients had a mean (SD) age of 69.9 (8.2) years and 75.1% had ≥2 Fxs after age 40. Post-TPTD follow-up data were available for 156 patients. Of these patients, 47.4% had rheumatoid arthritis at baseline, and 95.5% received antiresorptive medication after TPTD, including any bisphosphonate (61.5%). During the 36 mths study, 49 (16.7%) women sustained at least one incident Fx, compared with 159 (12.4%) in the non-GC group. There was an 89% decrease in the odds of fracture in the 30–36 mth period compared with 0–6 mths ($p<0.028$). An increase in HRQoL was seen over 18 mths of TPTD treatment ($p<0.001$) and was maintained over the 18 mth post-TPTD follow-up. At all timepoints relative to baseline there was a significant reduction in adjusted mean back pain VAS ($p<0.001$).

Table. Health-related quality of life and back pain in GC treated patients

GC treated patients n = 294	Baseline n = 294	18 mths n = 238	36 mths n = 182
EQ-SD Health State Value (median, IQR)	0.52 [−0.02, 0.69]	0.69 (0.52, 0.80)	0.69 (0.52, 0.81)
EQ-VAS mean (SD)	48.8 (22.19)	63.5 (22.14)	64.8 (24.16)
Back pain*			
	n = 291	n = 232	n = 174
Every day/almost every day	63.9%	26.3%	24.7%
	n = 276	n = 191	n = 137
Moderate/severe	90.9%	68.1%	63.5%
	n = 290	n = 232	n = 178
VAS (mm) mean [SD]	58.4 (27.38)	32.8 (26.06)	31.3 (27.62)

*in the last month

Conclusion: Postmenopausal women with severe osteoporosis receiving GCs who were prescribed TPTD in a routine setting had a significant reduction in back pain and improvement in HRQoL during 18 mths of TPTD treatment. These outcomes were maintained for at least 18 mths after TPTD discontinuation. The results should be interpreted in the context of a non-controlled observational study and the limited number of women taking GCs in this cohort.

Fracture Risk Assessment and Osteoporosis Treatment Disparities in 4027 Japanese Patients with Rheumatoid Arthritis. Takefumi Furuya[2], Takayuki Hosoi[1], Eisuke Inoue[3], Atuo Taniguchi[3], Shigeki Momohara[3] and Hisashi Yamanaka[4]. [1]Department of Clinical Research and Development, National Center for Geriatrics and Gerontology, [2]Institute of Rheumatology, Tokyo Women's Medical University, Tokyo, Japan, [3]Institute of Rheumatology, Tokyo Women's Medical University, [4]Tokyo Women's Medical University, Shinjuku-ku, Tokyo, Japan

Purpose: We previously reported that osteoporosis appeared to be undertreated in Japanese patients with rheumatoid arthritis (RA) (J Rheumatol 2007). Using clinical risk factors from the World Health Organization (WHO) Fracture Risk Assessment (FRAX) tool and recommendations from the National Osteoporosis Foundation (NOF), we evaluated fracture risk and osteoporosis treatment in a cohort of Japanese RA patients.

Methods: Among patients participating in a single-institute, prospective observational cohort study of Japanese RA patents, namely IORRA (Institute of Rheumatology Rheumatoid Arthritis), 4027 (≥40 years of age, 84% female, median age 61 yrs) responded to questions related to fracture risks in October or November 2008. The WHO-FRAX tool without bone mineral density estimated 10-year hip fracture risk and 10-year risk of a major osteoporosis fracture. Multivariable logistic regression evaluated the association between taking any osteoporosis medications and fracture risk, controlling for potential confounders.

Results: Among women (n = 3376), 100% and 82% ≥ 70 years of age (n = 700), 56% and 23% 60–69 years of age (n = 1252), 5% and 2% 50–59 years of age (n = 933), and 0% and 0% 40–49 years of age (n = 491) were identified as having a 10-year hip fracture risk ≥3% and a 10-year risk of a major osteoporosis fracture ≥20%, respectively. Among men (n = 651), 93% and 14% ≥ 70 years of age (n =176), 26% and 0.4 % 60–69 years of age (n = 233), 0% and 0% 50–59 years of age (n = 171), and 0% and 0% 40–49 years of age (n = 71) were identified as having a 10-year hip fracture risk ≥3% and a 10-year risk of a major osteoporosis fracture ≥20%, respectively. Multivariate models identified corticosteroid use (odds ratios (OR) 1.89, 95%

confidence interval (CI) 1.50–2.38), Japanese health assessment questionnaire (HAQ) scores (OR 1.75, 95% CI 1.53–2.01), daily prednisolone dose (mg/day) (OR 1.12, 95% CI 1.08–1.17), age (OR 1.06, 95% CI 1.05–1.07), body mass index (kg/m^2) (OR 0.92, 95% CI 0.89–0.94), and male gender (OR 0.25, 95% CI 0.19–0.33) as significantly associated ($p < 0.01$) with taking any osteoporosis medications. Among the patients with a 10-year hip fracture risk ≥3% or a 10-year risk of a major osteoporosis fracture ≥20% (n = 1685, 41.8%), only 50.1% (n = 844) and 36.0% (n = 607) reported taking any osteoporosis medications and taking bisphosphonates, respectively.

Conclusions: The WHO-FRAX tool identified a substantial proportion of Japanese elderly RA patients who had a high risk of hip and major osteoporosis fractures and for whom the 2008 NOF guidelines recommended treatment. A substantial gap exists between the 2008 NOF treatment guidelines based on fracture risk and osteoporosis treatment in Japanese RA patients. The FRAX tool appears useful for assessing risk and identifying high-risk persons in need of additional evaluation.

Health Care Utilization Following a Fracture: Global Longitudinal Study of Osteoporosis in Women (GLOW). George Ioannidis[3], Jonathan D. Adachi[2], Laura Pickard[3], Roland Chapurlat[4], Kenneth G. Saag[5], Stuart L. Silverman[1], Julie Flahive[6] and Stephen Gehlbach[6]. [1]Cedars-Sinai Medical Center, University of California Los Angeles, Beverly Hills, CA, [2]McMaster University, Hamilton, ON, Canada, [3]McMaster University, [4]Universite de Lyon, [5]University of Alabama-Birmingham, Birmingham, AL, [6]University of Massachusetts

Background: The consequences of fractures are dramatic, including reduced quality of life, and increased mortality and health care costs. Given the high prevalence and negative consequences of fragility fractures resulting from osteoporosis, it is important that health care services are used efficiently to reduce the burden of fracture. However, there is a lack of data regarding the relationship among various fracture types and health care service utilization. The purpose of the study was to determine the health care utilization in women with various fracture types.

Method: The Global Longitudinal Study of Osteoporosis in Women (GLOW) is an observational, prospective study of women 55 years of age and older who were recruited from 723 primary physician practices across 10 countries (17 sites, 60 393 patients). Women were eligible to participate in GLOW if they were non-institutionalized and if they visited their practice within the past 2 years. Self-administered questionnaires were mailed (2:1 over-sampling of women ≥65) at baseline and at 12 months to all eligible patients. The current study was designed to determine the health care utilization among various fracture types using items from both the baseline and year 1 follow-up surveys. New fractures were divided into 4 categories (spine/neck, hip, wrist/hand, and upper arm/shoulder) and occurred during the first year of the study. Health care utilization included where the fracture was treated (doctor's office/clinic, hospital, rehabilitation centre or nursing home), if surgery was performed (yes/no), and the patient's length of stay (days) at the treatment facility.

Results: A total of 120, 115, 358 and 158 new fractures occurred at the spine, hip, wrist and upper arm, respectively. The mean age (SD) and number of prior fractures (%) were 72.7 (9.1 yr) and 64 (54.2%) for spine, 75.7 (9.0 yr) and 56 (50.0%) for hip, 69.6 (8.9 yr) and 138 (38.9%) for wrist, and 72.1 (9.2 yr) and 60 (39.2%) for upper arm fracture participants. The table displays healthcare utilization for participants with fractures at 1 year.

Healthcare utilization	Spine n = 120	Hip n = 115	Wrist n = 358	Upper arm n = 158
Fracture treated: n (%)				
Office/clinic	83 (74.1)	62 (57.9)	245 (71.4)	104 (70.3)
Hospital	61 (55.5)	107 (96.4)	275 (79.7)	127 (84.1)
Rehabilitation center	13 (11.7)	66 (60.0)	55 (16.8)	43 (29.9)
Nursing home	3 (2.8)	17 (16.5)	3 (0.9)	7 (4.9)
Length of stay (days): mean (SD)				
Hospital	12 (13)	11 (12)	6 (12)	9 (13)
Rehabilitation centre	17 (18)	19 (19)	10 (19)	22 (29)
Nursing home	5 (8)	28 (25)	58 (42)	18 (3)
Preformed surgery: n (%)	16 (26.7)	94 (87.9)	97 (36.9)	41 (34.5)

Conclusions: In a large practice-based international cohort study, results reveal a wide range in the use of healthcare resources depending of the fracture type, and included where the fracture was treated, the length of stay at the treatment facility, and whether surgery was performed to treat the fracture. However, treatment strategies across countries may, in part, explain the variation in resource utilization observed among fracture types. These data may aid researchers and decision makers in determining policies that will optimize health care service utilization and improve patient outcomes.

970

High Adherence with Bisphosphonate Therapy in US Veterans with Rheumatoid Arthritis. J. Steuart Richards[10], Grant W. Cannon[9], Candace L. Hayden[8], Richard L. Amdur[11], Ted R. Mikuls[6], Andreas Reimold[2], Liron Caplan[3], Dannette S. Johnson[5], Pascale Schwab[7], Deana Lazaro[1], Bogdan N. Cherascu[4] and Gail S. Kerr[11]. [1]Brooklyn NY VA Medical Center, New York, NY, [2]Dallas TX VA Medical Center, Dallas, TX, [3]Denver CO VA Medical Center, Denver, CO, [4]Iowa City IA VA Medical Center, Iowa City, [5]Jackson MS VA Medical Center, Jackson, MS, [6]Omaha NE VA Medical Center, Omaha, NE, [7]Portland OR VA Medical Center, Portland, OR, [8]Salt Lake City UT VA Medical Center, Salt Lake City, UT, [9]Salt Lake City VA Medical Center, Salt Lake City, UT, [10]Washington DC VA Medical Cener, Washington, DC, [11]Washington DC VA Medical Center, Washington, DC

Background: Patients adherent with prescribed bisphosphonates have a reduction in fractures compared with noncompliant patients. Most reports on compliance with bisphosphonate therapy are for post menopausal osteoporosis with unclear relevance for other groups. We examined predictors of being prescribed a bisphosphonate, as well as predictors of patients who are adherent to therapy and remain on therapy.

Methods: Patient data from the Veterans Affairs Rheumatoid Arthritis (VARA) registry were available for analysis, and included demographics, features of disease severity and activity of rheumatoid arthritis (RA), osteoporosis, prior dual energy X-ray absorptiometry (DXA) testing, use of prednisone and site of enrollment (Dallas, TX; Denver, CO; Jackson, MS; Omaha, NE; Salt Lake City, UT and Washington, DC). Using data from the Veterans Affairs' national Pharmacy Benefits Management (PBM) database for each bisphosphonate prescription, we determined predictors of bisphosphonate adherence and persistence. The time gap between anticipated refill and actual refill of the next prescription was calculated. Treatment course duration was defined as the time from the initial prescription until the expected refill date for the bisphosphonate prescription before a 90 day gap or discontinuation. The medication possession ratio (MPR), a measure of adherence, was calculated as the proportion of treatment time that the patient had drug available. Adherence was defined as an MPR ≥ 0.80.The persistence ratio on bisphosphonate therapy (PRBT), defined as duration of prescribed therapy from the time of the initial prescription until the last expected refill date of the final prescription. Factors associated with receipt of a bisphosphonate, adherence by MPR, and persistence by PRBT were determined by multiple regression analyses.

Results: Bisphosphonates were prescribed to 573 (41.5%) of 1382 VARA subjects. These subjects were mostly males (89.9%), with a mean age of 68.7 years, (± 10.3); 82.4% were Caucasian, 12.7% African American (AA), and 3.5% Hispanic. 258 subjects (45.3%) had a DXA; 66 (11.5%) had osteoporosis and 392 (70.4%) had been prescribed prednisone. Older subjects, females, non-Caucasians, prednisone use, DXA, a higher MDHAQ score and enrollment at Washington, DC site were predictive of receiving a bisphosphonate.

The mean MPR was 0.69 ± 0.28 and only 271 (47.3%) subjects had MPR ≥ 0.80. Subjects from Omaha, NE had the highest rate of adherence (55.3%) while those from Washington, DC had the lowest (30%). MPR ≥ 0.80 was 50%, 35% and 25% for Caucasians, AA and Hispanics, respectively ($p < 0.01$). Gender, age, DXA, and use of prednisone were

not predictive of MPR. In multivariate analysis AA ethnicity was associated with low MPR.

The PRBT for bisphosphonates was 39.2 ± 31.4 months, and longer PRBT was associated with older age and enrollment at Omaha, NE; there was no association with clinical diagnosis of osteoporosis or performance of a prior DXA.

Conclusions: Adherence with bisphosphonates was greater in VARA cohort than most previous reports. Factors associated with higher adherence were Caucasian ethnicity and treatment site.

Background: Published evidence suggests a relationship between osteoporotic fractures and back pain outcomes. Denosumab (DMAb) is a fully human monoclonal antibody that inhibits RANKL, an essential mediator of osteoclast formation, function, and survival. In the FREEDOM trial, DMAb significantly reduced the risk of fractures (Cummings et al., *N Engl J Med*. 2009;361:756). Here we evaluate the impact of incident clinical vertebral fractures on back pain outcomes, regardless of treatment group, in women who participated in the FREEDOM trial.

Methods: The FREEDOM trial randomized 7808 women aged 60–90 years with a total hip and/or lumbar spine DXA T-score < -2.5 and not < -4.0 at either site. Women were randomized to receive subcutaneous DMAb 60 mg every 6 months or placebo for a total of 36 months, in addition to daily calcium and vitamin D. Back pain and limited activity days were assessed with the Back Pain and Limited Activity Days questionnaire (BPLAD) in person at each study visit (baseline and months 6, 12, 18, 24, 30, and 36) and by telephone between study visits (months 3, 9, 15, 21, 27, and 33). The BPLAD recorded subjects' back pain, limited activity, hospitalization, and bed rest experience (yes/no); the severity of back pain (very mild, mild, moderate, severe, very severe); the number of days of back pain; and the number of days of limited activity, hospitalization, and bed rest due to back pain during the past 3 months.

Results: About 24% of women had a prevalent vertebral fracture at study entry (Placebo, N=915; DMAb N=929). Compared to women without incident fractures, a significantly higher percentage of women with incident clinical vertebral fractures reported the occurrence of back pain, limited activity, hospitalization, and bed rest (Table 1). Additionally, women with incident clinical vertebral fractures reported a significant increase in the total days of back pain, limited activity, and bed rest than women without an incident fracture (Table 1). Women with incident clinical vertebral fractures also reported an approximately 2- to 3-fold increase in the rate of all recorded back pain outcomes *after* the fracture occurrence compared with the rate *before* the fracture occurrence (Table 2).

Conclusions: Incident clinical vertebral fractures were associated with a significant increase in the occurrence, severity, and duration of back pain outcomes in the women who participated in the FREEDOM trial. Efforts to reduce the occurrence of clinical vertebral fractures may lead to improved back pain outcomes for postmenopausal women with osteoporosis.

Table 1. Back Pain and Disability Due to Back Pain Through Month 36 by Incident Vertebral Fracture Status

	With Incident Clinical Vertebral Fracture (N = 108)	Without Incident Fracture[a] (N = 6821)	*P* value[b]
Reporting back pain[c]	100% (108)	80% (5424)	<0.0001
Reporting limited activity[c]	75% (81)	37% (2498)	<0.0001
Reporting hospitalization[c]	10% (11)	1% (78)	<0.0001
Reporting bed rest[c]	41% (44)	11% (742)	<0.0001
Total days of back pain	225 (80, 420)	118 (38, 315)	0.0002
Total days of moderate, severe, or very severe back pain	161 (51, 367)	102 (30, 283)	0.0171
Total days of severe or very severe back pain	78 (30, 158)	70 (21, 157)	0.5543
Total days of limited activity due to back pain	62 (23, 111)	29 (10, 90)	0.0015
Total days of hospitalization due to back pain	10 (6, 14)	10 (5, 20)	0.7737
Total days of bed rest due back pain	14 (7, 44)	8 (3, 20)	0.0141

N = Number of subjects.
Includes only post-baseline BPLAD responses.
Data shown are presented as % (n) for binary responses and median (Q1, Q3) for continuous variables
[a]Includes subjects with no incident fractures of any type.
[b]Based on Chi-square test or Fisher's exact test, when expected cell count <5, for binary responses and Wilcoxon rank-sum test for continuous variables.
[c]Includes subjects responding yes and reporting ≥ 1 affected day for the endpoint of interest.

Table 2. Back Pain and Disability Due to Back Pain by Pre and Post Incident Clinical Vertebral Fracture

	With Incident Clinical Vertebral Fracture (N = 108)				Without Incident Fracture (N = 6821)	
	Days of Observation Before Fracture = 72454		Days of Observation After Fracture = 41127		Days of Observation[a] = 6830858	
	Total	Rate	Total	Rate	Total	Rate
Total days of moderate, severe of very severe back pain	10765	14.9	13338	32.4	899811	13.2
Total days of severe or very severe back pain	3368	4.6	4346	10.6	194899	2.9
Total days of limited activity due to back pain	2312	3.2	4247	10.3	171943	2.5
Total days of hospitalization due to back pain	57	0.1	67	0.2	1284	0.0
Total days of bad rest due to back pain	338	0.5	654	1.6	16397	0.2

N = Number of subjects. Total = Sum of days with symptom Rate = 100*(Total)/(Days of Observation)
[a]Observation period includes the entire 36-month study duration for subjects without incident fracture.

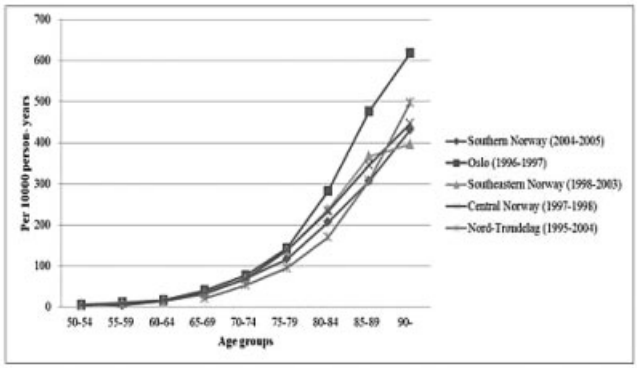
Incidence of Low Energy Hip Fracture in Southern Norway Significantly Lower Than Reported from the Capital of Norway (Oslo). Andreas Diamantopoulos[1], Gudrun Rohde[2], Irene Johnsrud[1], Inger Marie Skoie[1], Villy Johnsen[1], Marc C. Hochberg[3] and Glenn Haugeberg[1]. [1]Department of Rheumatology, Soerlandet Hospital SSHF, Kristiansand, Norway, [2]Faculty of Health and Sport, University of Agder, Kristiansand, Norway, [3]University of Maryland, Baltimore, MD

Background: Hip fractures contribute to increased morbidity and mortality in individuals above 50 years. As the average age of the population is increasing, the burden on the health care system is a growing challenge. The highest incidence of hip fracture worldwide has been reported from Oslo, the capital of Norway. During the last decades the awareness of hip fracture has increased and efforts have been undertaken to reduce fracture risk.

Aim: Our aim was to study the incidence of low energy hip fracture in individuals aged 50 years or older in southern Norway.

Methods: Patients with low energy hip fractures were recruited from the four hospitals in the two most southern counties of Norway in 2004 and 2005. Age adjusted and age specific incidence rates for men and women were calculated. We also searched for differences between seasons and between urban and rural areas. Our age adjusted incidence rates were compared with previous national and international reports.

Results: A total of 920 (261 men, 659 women) individuals aged ≥ 50 years with hip fracture were identified. The age adjusted incidence rate was 33.3 and 74.3 per 10.000 person years for men and women consecutively. Age specific incidence rates were significantly higher in women than in men but only for age groups between 70 and 90 years.Hip fracture were significantly higher in winter ($p<0.05$). No significant difference was seen between rural and urban areas.In the male cohort no major differences in age specific incidence rates was found compared with the Oslo study, however the incidence was lower in women above 80 years in our study.



*Incidence rates from Nord Trøndelag >65 years and only in women.

Fig. 1. Comparing the annual age specific incidence rates of hip fracture among individuals per 10,000 person-years in Southern Norway with previous reports from Oslo, Southeastern, central and northern Norway in women.

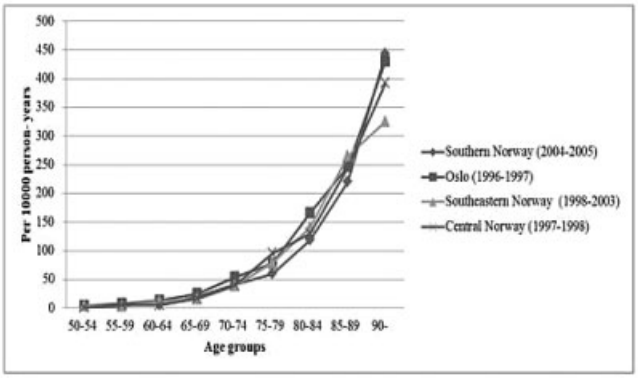


Fig. 2. Comparing the annual age specific incidence rates of hip fracture among individuals per 10,000 person-years in Southern Norway with previous reports from Oslo, Southeastern and Central Norway in men.

Our age adjusted incidence rates are the lowest reported from Norway and among the lowest reported from Scandinavia but is still among the highest in the world.

Conclusion: Age adjusted incidence rates of hip fracture in men and women in Southern Norway are the lowest reported from Norway and among the lowest in Scandinavia. The higher number of hip fractures seen in winter months may indicate that environmental factors increase the risk of hip fractures. Increased awareness and higher preventive and treatment methods are warranted both among men and women to reduce hip fracture risk.

Increases in Macrophage Inhibitory Factor Correlate with Increases in Bone Mineral Density in Glucocorticoid-Treated Patients with RA. Jos Nicolaas Hoes[1], Marlies C. Van der Goes[2], Johannes W. G. Jacobs[2], Johannes W. J. Bijlsma[2] and Joel A. G. Van Roon[2]. [1]University Medical Center Utrecht, Department of Rheumatology & Clinical Immunology, Utrecht, The Netherlands, [2]University Medical Center Utrecht, Department of Rheumatology & Clinical Immunology

Background: Inflammation and bone metabolism are characterized by crosstalk and shared mechanisms. (1) Both glucocorticoids (GCs) and vitamin D can influence each of these mechanisms; by studying these, the process of osteoimmunity in GC-induced osteoporosis could be further unraveled. Of special interest are cytokines, such as macrophage migration inhibitory factor (MIF), IL-13 and IL-7 which could influence bone metabolism by antagonizing the effects of GCs. In addition, vitamin D might add to the anti-inflammatory effects of GCs by acting on the differentiation and/or activity of T cells that are involved in the pathogenesis of rheumatoid arthritis (RA).

Objective: To investigate the correlation of levels of inflammatory mediators and measures of bone turnover in patients with RA who were treated with GCs and to explore whether vitamin D enhances the anti-inflammatory effects of GCs.

Methods: RA patients (n=40) on oral GCs treatment received either active vitamin D (alfacalcidol) or the bisphosphonate alendronate in a double blind double placebo controlled manner for 18 months. Associations of lumbar spine bone mineral density (lBMD) and bone turnover markers procollagen type I C-propeptide (P1CP), osteocalcin, osteoprotegerin (OPG), deoxypyridinoline (dPyr), and cross-linked N-telopeptides (Ntx) with cytokines capable of antagonizing GCs (MIF, IL-13 and IL7), cytokines causing T cell differentiation (IL-6, IL-7, IL12, IL-10 and IL-23), and cytokines produced by effector T cells (Th1, IFNγ; Th2: IL4; Th17: IL17, IL22) were explored with multiple regression analyses.

Results: Treatment active vitamin D treatment did not influence cytokine levels that are associated with T cell differentiation or that are indicative of T cell activity. At baseline, higher levels of IL-6 and IL-23 ($B = -0.001$, $B = -0.00003$, $p = 0.088$, $p = 0.080$) showed a trend of association with low lBMD. Changes in T cell associated cytokines did not predict changes in lBMD or bone markers at 18 months. Alendronate significantly influenced lBMD, (2) but neither vitamin D nor alendronate treatment significantly influenced levels of cytokines antagonizing GCs. However, increases in MIF were significantly associated with increased lBMD ($B=0.055$, $p=0.039$) and decreases of deoxypyridinoline ($B=-0.012$ $p=0.037$). Other cytokines antagonizing GCs were not associated with (changes in) bone parameters, but an increase in GC dose tended to be associated with increase in MIF.

Conclusion: Our data do not provide evidence for an anti-inflammatory effect of vitamin D in RA patients on GCs. Although not influenced by vitamin D or alendronate treatment, increases in MIF, an antagonist of GCs, are associated with increases in lBMD during GC treatment.

Low Bone Mineral Density in Depoprovera Users – An Under Recognised Health Issue. Mani Nallasivan[1] and Tim Gillott[2]. [1]Diana Princess of Wales Hospital, Northern Lincolnshire and Goole Hospitals NHS Trust, Hull, Yorkshire, United Kingdom, [2]Diana Princess of Wales Hospital, Northern Lincolnshire and Goole Hospitals NHS Trust, Grimsby, Northeast Lincolnshire, United Kingdom

Background: Women using Depo-Provera may lose bone mineral density, putting them at increased risk of osteoporosis. In November 2004, the FDA issued a black box warning which stated "Use of Depo-Provera contraceptive injection may cause you to lose calcium stored in bones". As this drug is being used by very young women; it could have serious implications on bone health in future. Oldroyd and colleagues have demonstrated significant decline in BMD in femoral neck but not in the spine, in whom median exposure of Depo-Provera was less than three years.[1] Studies show that discontinuation of Depo-Provera will allow near complete reversal of BMD loss.

Objectives: To examine the bone density in patients, who have been on Depo-Provera (medroxyprogesterone acetate) for contraception, referred for BMD estimation using dual X-ray absorptiometry (DEXA) and analyse whether the bone loss was significant enough to warrant change in the form of contraception.

Materials and Methods: We analysed 50 patients from 2008 and 2009 referrals for Bone mineral density assessment, with history of Depo-Provera use. They were asked to fill in standard questionnaire, about the risk factors, BMI, smoking, family history as well.

Their bone mineral density assessment was recorded using T and Z scores. In addition some had vertebral morphometry performed as well.

Results: Out of fifty patients, 24 were scanned in 2008 and remaining in 2009. Mean age was 28.6 years, mean duration of Depo-Provera use was 4.65 years (range 18 months to 10 years and even long term) and mean BMI-23.5. 42% were found to be osteopenic using T scores and one patient was in the osteporotic range. 56% had normal BMD. Median T score for low the BMD group was −1.14.

Few patients had other risk factors including celiac disease, long term steroid use because of Inflammatory bowel disease or liver transplantation. 3 patients had family history of osteoporosis. The T score was low in only 3 patients in femoral neck, while remaining (18/21) was low in lumbar spine.

Ten patients who have low T scores, were recommended to stop DP and two had already changed to oral pills.

Discussion: With oestrogen deficiency, the lumbar spine has a greater tendency to lose BMD because of its high trabecular bone content. Our findings are in keeping with this. This is in contrast to the finding by Oldroyd and colleagues, which reported significant reduction in femoral neck. We have recommended change in the form of contraception and to stop using DP for those who have T Scores in osteopenic/osteoporotic range. Though this is a small study, this needs further validation with wider cohort and also compare with normal age matched control.

Conclusion: Use of Depo-Provera cause reduced bone mineral density and hence needs risk assessment and appropriate advice given. Perhaps Public awareness also needs attention.

National Registry of Paget Disease of Bone. Estibaliz Loza, Nuria Guañabens, Maria Jesus Garcia de Yebenes, Antonio Morales, Javier Del Pino, Antonio Torrijos, Jesus Garrido, Jesus Tornero, Jorge Malouf, Jordi Carbonell and Manuel Rodriguez. Spanish Society of Rheumatology

Objective: a) To identify and establish a national registry of patients with Paget disease of bone (PDB); b) To describe patient's demographic, clinical, environmental and familiar characteristics.

Methods: A registry-based cross-sectional study was performed. It started with a prevalence study (2006–2007) in which stratified samples throughout Spain of abdominal radiographs, of subjects aged ≥55 years, from stored consecutive digitalized films in selected hospitals were obtained. Radiographs including all lumbar vertebrae, pelvis, sacrum and femoral heads were examined for the diagnosis of PDB, according to standardized criteria. Afterwards, experts on Paget disease were invited to include patients in the registry from their clinics (apart from those identified in the prevalence study). Data were recorded following a standardized electronic form: demographics (age, sex); clinical (diagnosis date, age at the disease onset, symptoms and treatment); quality of life [EuroQol 5D, visual analog scale (VAS) of pain]; environmental factors (infections, place of birth, birth weight, number of brothers/sisters and position, measles virus infection, contacts with domestics animals, non pasteurized milk intake, home characteristics during childhood, ≥ 1 year-places of residence, work status); familiar (positive familiar history and place of birth of positive cases, number of children and their measles exposure/vaccination). A descriptive study was performed.

Results: The crude prevalence of PDB was 1% (95% Confidence Interval (CI): 0.7–1.3) in patients aged ≥55 years, and the estimated prevalence ranged from 1.1% (95%CI: 0.8–1.4) to 1.6% (95%CI: 1.1–2.1) when a reported pelvic involvement in 60–90% of PDB patients was considered. A total of 602 patients with PDB from 24 hospitals were included in the registry. We found more men (55%), with a mean age of 62 years ± 11 years. More than 80% had followed any treatment, 55% risedronate, 32% calcitonin, and almost 50% ≥2 drugs. The mean VAS pain score was 65 ± 21. The dimension which showed the worst score was anxiety/depression (64% reported moderate or severe limitations), followed by mobility (47%), and just 24% reported moderate or severe limitations in usual activities. Most of patients (99%) were born in Spain: Barcelona (11%), Ávila (10%), Toledo (7%) and Salamanca (5%). Measles infection was reported in 65%, and 80% had had contacts with animals: dogs (70%), cats (48%), and birds (38%). Non pasteurized milk intake was observed in 75% of patients and 53% were retired. A positive familiar history was registered in 14%, especially in Ávila and Salamanca, and PBD was identified in 1.5% of patient's children.

Conclusions: The National Registry of PDB includes 602 patients with PDB. Up to 14% have a positive familiar history, 80% contacts with domestic animals, and most of them had been on pharmacological treatment.

976

Prevalence of Osteoporosis and Osteoporotic Fractures: A Population Based Survey Including Vertebral Fracture Assessment by Morphometry (VFA). Liana E. Euller-Ziegler[1], Christian H. Roux[1], Veronique Breuil[1], Virginie Dasilva[1], Christine Albert-Sabonnadiere[1], Christian Grisot[1], Philippe Flory[1], Yacine Allam[1], Hasna Chami[1], Gerard Ziegler[1] and Pascal Staccini[2]. [1]L'Archet Hospital, University of Nice, Nice, France, [2]Labstic Santé, University of Nice, Nice, France

Prevalence studies on osteoporosis (OP) in the general population are scarce; vertebral fractures (VF) are frequently underdiagnosed.

Objectives: To estimate the prevalence of low bone mineral density (BMD), osteoporotic fractures and risk factors in women aged 50 to 85 years.

Methods: After random selection in the national insurance system regional database (French Alpes Maritimes area), a sample of women aged 50 to 85 years, representative of the general population, was evaluated: medical and risk factors questionnaires, bone densitometry (DXA / hip, femoral neck, spine), screening for vertebral fractures (VF) by high density morphometry (VFA, Hologic QDR4500, Genant scoring by 2 independent MD). Statistical analysis was performed using χ^2, ANOVA or Kruskall-Wallis test when appropriated.

Study granted by Ministry of Health and promoted by CHU of Nice (Academic Hospital of Nice, France).

Results: 519 women were evaluated, mean age 63.4± 8.8 years, BMI 25,4± 4,9 kg/m^2, hip fracture in 1st degree relatives (15%), long term steroid treatment (9.4%), alcohol ≥ 3 units (3.7%), current smoking (2.7%), RA (0.8%), early menopause (14.6%), personal history of low energy clinical fracture after 50 years (15%), including non vertebral fractures 13.5%.

DXA demonstrated OP in 13.7% of the women (mean age 68 ± 9.4 years), osteopenia in 59% (63.8± 8.4 years).

The prevalence of VF by *VFA* was 29.7% (presence of ≥1 VF Genant stage ≥1), (18.1% with ≥1 VF Genant stage ≥2). The VF were scored Genant stage 1 (55.1%), stage 2 (39.3 %), stage 3 (5%), with a median number of 2 VF by woman (1 – 8). VF scored Genant stage ≥1 were present in women classified by DXA as having osteoporosis (24%), but also osteopenia (61%), even normal BMD (15%) (and VF scored Genant stage ≥ 2 in respectively 27.7%, 58.5%, 13.8% of the women); conversely, 52% of women classified by DXA as having osteoporosis, 30.7% osteopenia and

16.2% normal BMD had VF Genant stage ≥1 (and 36.6%, 18% & 9.1% had VF Genant stage ≥ 2).

The overall prevalence of osteoporotic fractures was *37.4%* (VF and/or non vertebral fracture), mean age 67.3 ± 8.9 years, classified by DXA as osteoporosis (20.6%), osteopenia (61.3%), normal (18%).

Correlations: T-score decrease (global status and at each site) was linked with age ($p=0.001$) and BMI ($p=0.001$); the presence of fracture was linked with age ($p<0.001$), T-score ($p<0.001$) (globally and for VF), BMI (globally). Fractures were more frequent in subjects with a personal history of prior fracture ($p<0.001$, globally and for VF), without significant link with other risk factors.

Discussion: Methological issues of prevalence studies on OP are well known. The partnership with the national insurance system allowed us to analyse a representative sample of the general population. VFA, delivering a lower dose of radiation than XRays and well accepted by our subjects, allowed easier VF detection (according to Genant stages ≥1 & ≥2) and therefore VF prevalence analysis.

Conclusion: This study brings new data emphasizing the public health dimension of osteoporosis and the high frequency of undiagnosed vertebral fractures in the general population, even in women with osteopenia or normal BMD.

977

Proactively Contacting Men with Prostate Cancer Treated with Anti-Androgen Medications Improves the Evaluation and Treatment of Osteoporosis. Brian P. Oppermann[1], Thomas M. Harrington[2] and William Ayoub[3]. [1]Geisinger Medical Center, Danville, PA, [2]Geisinger Medical Center, Danville PA, [3]Geisinger Medical Group, Scenary Park PA

Purpose: Men treated with androgen deprivation therapy for prostate cancer are at higher risk for osteoporosis and osteoporotic fractures. This relationship is dose and length of therapy dependent. Despite this known association, men treated with anti-androgen therapy do not routinely receive osteoporosis screening with dual energy X-ray absorptiometry (DXA).

Methods: Using an electronic health record (EHR), in a rural tertiary health care system, we identified 64 men followed by our primary care physicians with the diagnosis of prostate cancer who have been treated with anti-androgen therapy (leuprolide acetate) for this pilot study. This EHR search identified any man who met the above criteria from 2007–2009. Of these 64 men, 61 had not undergone osteoporosis screening with DXA scanning. The other 3 men had undergone DXA and one was on bisphosphonate therapy. These three men were excluded. The remaining evaluation naïve 61 men were then contacted via letter. This letter explained reasons that they were being contacted, mainly they may be at high risk for osteoporosis given treatment with anti-androgen therapy. The letter instructed them to call to schedule a DXA scan. If no response was obtained several weeks after the mailing, patients were contacted by telephone to schedule the DXA scan. From initial contact via letter to scheduling the men for evaluation took 4 months.

Results: For the pilot study, 30 of the 61 men contacted agreed to osteoporosis screening with DXA scanning. Of these 30 DXA's, 18 (60%) were low/moderate risk and 12 (40%) were deemed high risk for fracture (osteoporotic) using the 2008 National Osteoporosis Foundation criteria. None of these 12 high risk DXA scan patients had been on bisphosphonate therapy prior to this project, with all 12 being placed on therapy after DXA results.

Conclusion: Using our EHR, we proactively captured a subset of men at high risk for osteoporosis and fracture – those with prostate cancer. As the pilot project demonstrates, a significant proportion (40%) of these patients indeed are at high risk for fracture based on DXA and none of these patients were on approved osteoporosis medications. Unfortunately we only captured 50% of the identified patients, with most refusing to be evaluated given their age or the feeling this did not apply to them. Regardless, this pilot project demonstrates that this specific group of patients is at risk for osteoporosis and there needs to be better awareness to capture these patients and obtain appropriate osteoporosis evaluation and treatment. We plan to develop best practice alerts to identify the patients, risk stratify them with DXA and hopefully prevent future morbidity, mortality and health care expenditures with appropriate medical therapy.

Quality Assurance Study of the Use of Preventative Therapies in Glucocorticord Induced Osteoporosis (GIOP) in Early Inflammatory Arthritis (EIA): Results from the CATCH Cohort. Emily McKeown[10], Vivian P. Bykerk[5], Faye Deleon[4], J. Carter Thorne[6], Carol A. Hitchon[8], Gilles Boire[2], Boulos Haraoui[3], Diane S. Ferland[1], Ed C. Keystone[9] and Janet E. Pope[7]. [1]LaSalle, QC, Canada, [2]CHUS-Sherbrooke University, Sherbrooke, QC, Canada, [3]Institut de Rhumatologie, Montreal, QC, Canada, [4]McMaster University, Hamilton, ON, Canada, [5]Mt Sinai Hospital, Toronto, ON, Canada, [6]Southlake Regional Health Care, Newmarket, ON, Canada, [7]St Joseph Health Care London, London, ON, Canada, [8]University of Manitoba, Winnipeg, MB, Canada, [9]University of Toronto, Toronto, ON, Canada, [10]University of Western Ontario, London, ON, Canada

Background: Exposures to glucocorticoids are common in patients with inflammatory arthritis (IA) despite treatment with DMARDs. The ACR has published guidelines for the prevention and treatment of glucocorticoid induced osteoporosis (GIOP), but adherence to guidelines is variable. This study characterizes steroid use and compliance with GIOP guidelines within a large early IA cohort.

Methods: Using the Canadian Arthritis Cohort Database (CATCH), patients with IA on glucocorticoids (oral or intramuscular) were identified. Steroid exposure was defined as using oral glucocorticoids for two consecutive clinic visits (at least 90 days apart). The primary outcome was the proportion of patients receiving calcium, vitamin D and a bisphosphonate among patients treated with chronic glucocorticoids. Those with postmenopausal osteoporosis were excluded. Secondary analysis was done to determine which factors were associated with use of preventative therapies.

Results: 655 were in the CATCH database, where 311 (47%) were glucocorticoid users of whom 50% were on oral prednisone, 41% received intramuscular or intra-articular (ia) steroids and 9% both. The mean oral daily dose in prednisone users was 6 mg (SD 7.5). Chronic users (CU) compared to non-users (NU) showed that CU were older (56 vs. 50 years, $p=0.002$); similar proportion of females (68% vs. 73%) and rheumatoid factor positivity (55%, RF mean 97 IU/mL in CU vs. 57%, RF mean 171 IU/mL in NU); DAS (CRP) was 4.72, (SD1.48) in CU vs. 4.85 (SD 1.59) in NU, $p=0.50$). Less than half (45%) on chronic steroids were treated with calcium, 41% with Vitamin D, 38% with both and 18% were taking a bisphosphonate. Rates of prophylaxis were only slightly higher for users of chronic oral steroids; 54% were taking Calcium, 48% were taking Vitamin D, 45% were taking both and 23% were on a bisphosphonate. There were no significant differences in use of Calcium, Vitamin D or bisphosphonate among females compared to males (OR 0.49, 95% CI 0.20–1.18, $p = 0.11$), or among post-menopausal females compared to pre-menopausal females (OR 2.34, 95% CI 0.92–5.95, $p = 0.07$). Women with a history of hormone treatment and smokers had no significant increase in being treated (OR 1.50, 95% CI 0.49–4.62, $p = 0.48$ and OR 0.73, 95% CI 0.32–1.66, $p = 0.46$). Treatment rates were similar among patients on steroids for one year compared to those treated for at least 90 days so longer duration of steroids did not increase prophylaxis.

Conclusions: Glucocorticoid therapy is frequently used in early IA. The use of calcium, vitamin D or a bisphosphonate was low among chronic glucocorticoid users and illustrates a care gap.

Relationships between Changes in Bone Mineral Density or Bone Turnover Markers and Vertebral Fractures Incidence in Patients Treated with Bazedoxifene. Olivier Bruyere[2], Johann Detilleux[3], Arkadi Chines[1] and Jean Y. Reginster[2]. [1]Pfizer, [2]University of Liege, Liege, Belgium, [3]University of Liege

Objective: To analyze the relationships between bone mineral density (BMD) or bone turnover markers (BTM) changes and vertebral fractures incidence in women treated with bazedoxifene.

Material and Methods: Post-hoc analysis from a 3-year randomized, placebo-controlled study evaluating the effect of bazedoxifene (20 or 40 mg) on fracture risk reduction. BMD was assessed at baseline and every 6 months during 3 years. Osteocalcin (OC) and C-telopeptide of type I collagen (CTX-I) were assessed at baseline, month 3, 12 and 36. Vertebral fractures were assessed with a semiquantitative visual assessment.

Results: Data was available for 5244 women of which 3476 were treated with bazedoxifene. Using logistic regression analysis and the classical Li approach, the proportion of fracture incidence explained by BMD change after 3 year of bazedoxifene treatment was 29% for the total hip and 44% for the femoral neck. The proportion of treatment explained by lumbar BMD change could not be quantified accurately because of the significant interaction between treatment and change in BMD. With the same model, the 3-month BTM changes explained between 14 and 18% of the fracture risk reduction observed with bazedoxifene. With another new statistical method using structural equation models, the proportion of fracture incidence explained by 3-year BMD change was between 29 and 43%, for total hip and femoral neck, respectively. Using the same methodology, BMD changes after one year of therapy explained between 8 and 15% of the fracture incidence observed during 3 years of treatment.

Conclusion: In women treated with bazedoxifene, changes in femoral neck or hip BMD explained up to 44% of the fracture risk reduction observed during the 3 years of follow-up. Short-term BTM changes poorly explained the fracture risk reduction observed during the 3-year treatment with bazedoxifene.

The Direct Assessment of Nonvertebral Fractures in Community Experience (DANCE) Study: 2-Year Nonvertebral Fragility Fracture Results. Stuart L. Silverman[2], Paul Miller[4], Anthony I. Sebba[1], Michael Weitz[3], Xiaohai Wan[5], Kathleen Taylor[5], Valerie Ruff[5] and Kelly D. Krohn[6]. [1]Arthritis Associates, Palm Harbor, FL, [2]Cedars-Sinai Medical Center, University of California Los Angeles, Beverly Hills, CA, [3]Center Arthritis and Rheumatology, South Miami, FL, [4]Colorado Center for Bone Research, Lakewood, CO, [5]Eli Lilly and Company and/or One of Its Subsidiaries, Indianapolis, IN, [6]Lilly USA, LLC, Indianapolis, IN

Statement of Purpose: To evaluate the occurrence of nonvertebral fragility fractures (NVFX) in subjects treated with teriparatide (TPTD) for osteoporosis (OP) for up to 24 months in a community based setting.

Methods: The DANCE study is a multi-center, prospective, observational trial designed to examine the long-term effectiveness, safety, and tolerability of TPTD. Patients judged by study physicians to be suitable for TPTD therapy received TPTD 20 μg/day for up to 24 months. The percentage of patients experiencing a new NVFX during 4 TPTD treatment duration periods (table) was calculated. The proportion of patients reporting new NVFX during longer TPTD treatment duration categories was compared to the proportion during TPTD treatment duration of 0 to 6 months using a binomial proportion test. The 0–6 months interval was chosen as the reference since Kaplan-Meier analysis of NVFX in the Fracture Prevention Trial showed that the TPTD and placebo groups appeared to begin to separate after approximately 8 months of study drug.

Results: The mean TPTD exposure was 17 (95% CI: [16.8, 17.4]) months, and the median TPTD exposure was 23 months. Overall, 115/3649 (3.15%) experienced a NVFX. The incidence of patients experiencing new NVFX during the four TPTD treatment durations was 1.43%, 0.97%, 0.72%, and 0.78%, respectively (table). The incidence of new NVFX during each TPTD treatment duration longer than 6 months was significantly lower than the incidence during TPTD treatment duration 0 to 6 months ($p<0.0001$). Compared to TPTD treatment of 0 to 6 months, NVFX incidence during treatment durations 6 to 12, 12 to 18, and 18 to 24 months was 32%, 50%, and 45% lower, respectively.

Conclusions: The results of this observational study indicate that the incidence of new NVFX decreased for patients receiving TPTD treatment for greater than 6 months.

Duration (months)	Number of patients with a new NVFX	Number of patients at risk	Incidence (%)
>0 to ≤6	52	3649	1.43 (1.04, 1.81)
>6 to ≤ 12	28	2901	0.97 (0.61, 1.32)*
>12 to ≤ 18	18	2506	0.72 (0.39, 1.05)*
>18 to ≤ 24	17	2172	0.78 (0.41, 1.15)*

*$p<0.0001$ when compared to the 0–6 months study duration period.

The Effects of Biologics on Bone Metabolism of Patients with Rheumatoid Arthritis. Tadashi Okano, Masahiro Tada, Shigeyuki Wakitani, Hiroaki Nakamura and Tatsuya Koike. Osaka City Univ Med School, Osaka, Japan

Background: Rheumatoid arthritis (RA) is associated with systemic bone loss, subchondral bone erosion and cartilage degradation. Biologics therapy has proven efficacious in improving both disease activity and focal bone erosions in patients with RA. We investigated the effects of biologics on bone mineral density (BMD) and biochemical markers in Japanese RA patients.

Objectives: To examine whether treatment with biologics prevents loss of BMD in patients with RA, and to study the changes in markers of bone metabolism during biologics treatment.

Methods: 123 (103 women, 20 men, 55.8±12.9 years old) patients with active RA, who were treated with biologics (Infliximab:93, Etanercept:27, Tocilizumab:3) during 1 year, were included in this study. The disease duration was 13.0±12.8 years. The BMD of the lumbar spine and total hip (DXA:QDR-4500) was measured at baseline and after at least more than one year. As bone metabolic marker, serum bone specific alkaline phosphatase;BAP and urine type I collagen cross-linked N-telopeptide;NTX was measured at baseline and after at least more than one year. 33 patients received bisphosphonates while 84 patients were under oral glucocorticoid, we also assessed these effect.

Results: After biologics treatment, the BMD of the lumbar spine did not reduced from 0.865±0.159 to 0.871±0.149 g/cm2 ($p=0.22$). Similarly, hip BMD did not reduced from 0.726±0.139 to 0.717±0.141 g/cm2 ($p=0.12$). The BMD of the hip in patients who have received glucocorticoid without bisphosphonates (n=55) showed significantly decreases from 0.755±0.136 to 0.738±0.140 g/cm2 ($p=0.03$) compared with patients not receiving glucocorticoid or receiving glucocorticoid with bisphosphonates. Moreover, the BMD of lumbar spine has increased from 0.818±0.151 to 0.838±0.150 g/cm2 ($p=0.04$) in patients who were administered with bisphosphonates (n=32). In whole patients, BAP was not significantly changed from 27.1±12.4 to 26.2±11.8 U/L ($p=0.41$), NTX was significantly decreased from 66.0±67.9 to 51.9±37.7 nmol/mmol CRE ($p<0.01$).

Conclusion: The BMD of the lumbar spine and hip did not reduced after treatment with biologics. However our data provide additional evidence, to maintain BMD, dose reduction of glucocorticoid or the introduction of bisphosphonate should be required, even if biologics are administered.

Table 1. Analysis of the effect of biologics on BMD

The Effects of Denosumab (DMAb) on Bone Mineral Density (BMD), Fracture and Safety Outcomes by Level of Renal Function. Sophie A. Jamal[8], Peter R. Ebeling[7], Osten Ljunggren[9], Catherine Stehman-Breen[1], Steven R. Cummings[5], Michael R. McClung[4], Stefan Goemaere[3], Edward Franek[2], Yu-Ching Yang[1], Ogo I. Egbuna[1] and Paul Miller[6]. [1]Amgen Inc., Thousand Oaks, CA, [2]Central Clinical Hospital, Warsaw, Poland, [3]Ghent University Hospital, Belgium, [4]Oregon Osteoporosis Center, Portland, OR, [5]San Francisco Coordinating Center, CPMC Research Institute and University of California, San Francisco, San Francisco, CA, [6]University of Colorado Health Sciences Center, CO, [7]University of Melbourne, Melbourne, Australia, [8]University of Toronto, Toronto, ON, Canada, [9]Uppsala University Hospital, Sweden

Treatments for osteoporosis in patients with renal impairment, both common conditions in the older population are limited. DMAb is not excreted by the kidney and is a potential treatment option.

The efficacy and safety of DMAb given as a 60 mg s.c injection every 6 months for 3 years among patients in Phase 3 FREEDOM Study was evaluated. Creatinine clearance (CrCl) was estimated using the Cockcroft-Gault equation. A subgroup interaction term was used to assess differences in treatment effect by CrCl. We examined incident fracture rates, changes in BMD, serum calcium, serum creatinine and the incidence of adverse events after 36 months of follow-up in subjects receiving DMAb and placebo, stratified by level of renal function using linear regression models adjusted for multiple baseline characteristics including prevalent vertebral fractures and years since menopause.

Most (97%) women were Caucasian, the mean age was 72.3 ±5.2 years, the mean weight was 63.8 ± 10.4 kg, serum creatinine was 70.8 ± 15.3mmol/L and serum calcium was 2.44 ±0.11mmol/L. Subject disposition by level of renal function was balanced between DMAb and placebo treated subjects. 73 women had a CrCl between 15 to 29ml/min (CKD stage 4); 2817 between 30 to 59 mL//min (CKD stage 3); 4069 between 60 to 89 mL/min (CKD stage 2) and 842 had a CrCl of ≥ 90 mL/min (CKD stage 1/normal). Vertebral and non-vertebral fracture risk reduction and differences in the percent change in BMD at all sites were in favour of DMAb. The test for treatment by subgroup interaction indicated that fracture risk reduction was not statistically different by level of renal function. The difference in the mean % changes in BMD in subjects treated with DMAb compared with placebo did not differ by level of renal function. Changes in serum creatinine, serum calcium and the incidence of adverse, serious adverse and fatal events were similar between the treatment groups and did not differ by level of renal function.

DMAb reduces fracture risk and is not associated with an overall increase in adverse events among patients with impaired kidney function.

983

The Serum Level of Undercarboxylated Osteocalcin (ucOC) in Patients with Rheumatoid Arthritis – A High Dose of Predonisolone Decrease the Serum Level of ucOC. Yoshitada Sakai[2], Akira Hashiramoto[4], Teppei Hashimoto[4], Yoshiko Kawasaki[4], Chihiro Tanaka[4], Shunichi Shiozawa[3] and Masahiro Kurosaka[1]. [1]Department of Orthopaedic Surgery, Kobe University Graduate School of Medicine, [2]The Center of Rheumatic Diseases, Kobe University Hospital, Kobe, Hyogo, Japan, [3]The Center of Rheumatic Diseases, Kobe University Hospital, Kobe, Japan, [4]The Center of Rheumatic Diseases, Kobe University Hospital

Purpose: Rheumatiod arthritis (RA) causes systemic osteoporosis as well as periarticular osteoporosis, and becomes one of the risk factor of osteoporotic fracture. On the other hand, several previous studies have indicated that the higher serum level of undercarboxylated osteocalcin (ucOC) could be a risk factor for osteoporotic fracture. However, the relationship between the serum level of ucOC in patients with RA and the medication of DMARDs or predonisolone (PSL) were still unknown. In this study, we have evaluated the serum level of ucOC in patients with RA, and investigated the related factors, such as medications, biochemical markers and bone mineral density.

Methods: 88 patients with RA were enrolled in this study (83 females, 5 males, average age 63 yrs). We compared the ucOC levels with other biochemical marker (Serum cross-linked N-teropeptide of type1 collagen (NTx), Bone alkaline phosphatase (BAP), Calcium (Ca), phosphorus (P) and C reactive protein (CRP)). The examination of bone mineral density was performed with lumbar spine and femoral neck using dual energy X-ray absorptiometry (DEXA). Oral medications including PSL, methotrexate (MTX) and bisphosphonate (BP) were also examined. The statistical analysis was performed using Mann-Whitney U test.

Results: The average of serum level of ucOC in all patients was 5.25±3.8(ng/ml), and then patients were categorized into high ucOC group (≥4.5ng/ml) and low ucOC group (<4.5ng/ml). The results of biochemical markers and BMD in these two groups were showed in Table1. These data showed that the patients with low serum ucOC level have low biochemical marker of bone metabolism and high dose of PSL (≥5mg/day). When compared the medications with the serum ucOC level in Table2, results indicated that medication of high dose PSL and medication of BP significantly decreased the serum ucOC level.

Conclusion: Our results clearly showed that the serum levels of ucOC were increased in higher state of bone turnover as indicated by biochemical markers, and *vice versa*, decreased when the bone turnover was ameliorated by the high dose of PSL and BP. We should carefully evaluate the risk of osteoporotic fracture of the patient with RA who has a low level of serum ucOC during medication of high PSL and/or BP.

Table 1

"Early Arthritis: Early Act". A Community-Based Knowledge Transfer Program To Improve Ability of General Practitionner to Rapidly Detect and Refer to the Rheumatologist Patients with Early Arthritis. Bruno Fautrel[3], Patrick Froger[1], Cecile Gaujoux-Viala[2] and Eric Leutenegger. [1]Lyon, France, [2]Paris, France, [3]Pitie Salpetriere Hospital, Paris, France

Background: Several guidelines have recommended that early arthritis / early rheumatoid arthritis (EA / ERA) should be detected and rapidly referred

to a rheumatologist, ideally within the 6 weeks after symptom onset according to the French Health Authority guidelines published in 2007. However, guideline implementation and dissemination are always challenging, especially when guidelines concern both specialists and family doctors (GP).

Methods: The collaboration between rheumatologists and a continuous medical education (CME) organization enabled the development of a community-based knowledge-transfer program about the diagnosis of early arthritis, based on a few key messages: early RA diagnosis is a key prognostic factor; detection of EA patients can be based on 3 clinical signs suggestive of early RA[1]; GPs have an pivotal role to detect and refer EA patients to the specialist; remission is an achievable goal in RA.

The program was implemented over the phone among the GP community using the Academic Detailing methodology, which 3 different phases: 1) a first confraternal exchange between the training medical doctor in charge of the program and the practising GP who previously agreed to participate in the program, during which a few key messages were delivered; 2) a 2-month practise phase during which the participating GP had to identify patients for whom the national EA guidelines could applied; 3) a second confraternal exchange with the same medical trainer during which the key messages were recalled and the applicability of EA guidelines into daily practise discussed.

Results: 1,054 GP participated in phase 1 of the "Early Arthritis: Early Act" program between August 2008 and March 2009. 645 of them also participated in the practise phase and collected medical information about 1,116 EA patients. Finally, 852 GP participated to the 3rd phase, i.e., the second phone confraternal exchange. The main impact of the program on GP knowledge is presented in the table below:

Table. Impact of the "Early Arthritis: Early Act" program on GP knowledge about EA and RA

	"Early Arthritis: Act Early" Program	
% respondents	**Before**	**After**
Awareness of the 2007 national EA guidelines	48%	100%
Knowledge of the impact of RA on life expectancy	25%	100%
Awareness of the notion of window of opportunity in EA	13%	100%
Knowledge that remission is an achievable goal in RA	47%	100%
Ability to perform a squeeze test to detect patients with EA	19%	81%

Conclusion: The "Early Arthritis: Early Act" program enabled the exposition of a substantial number of GP to EA guidelines within a rather limited time frame. It was well accepted by the participating GPs: 52% acknowledged they had a definite need for such knowledge update and 85% found acceptable the time investment required by the program.

A Checklist of 10 Measures, 6 from a Patient Questionnaire & 4 Physician Global Scores, Requiring <15 Seconds, To Provide Quantitative Patient History & Physical Examination Data, Analogous to Laboratory Tests, for Usual Clinical Care. Theodore Pincus[4], Yusuf Yazici[2], Martin J. Bergman[1], Tuulikki Sokka[3] and Christopher J. Swearingen[5]. [1]Arthritis and Rheumatology, Ridley Park, PA, [2]Hospital for Joint Diseases, Hastings on Hudson, NY, [3]Jyvaskyla Central Hospital, Jyvaskyla, Finland, [4]New York University Hospital for Joint Disease, Hastings-on-Hudson, NY, [5]University of Arkansas for Medical Sciences, Little Rock, AR

Purpose: To analyze a proposed checklist of 10 quantitative measures, 6 from a patient questionnaire and 4 physician global scores, compiled in less than 20 seconds, to provide quantitative patient history and physical examination (PE) data, which rheumatologists indicate are more important than laboratory tests in clinical decisions in usual care visits.

Methods: The 6 quantitative patient measures are from a self-report multidimensional health assessment questionnaire (MDHAQ) for: physical function (FN) (0–10); 21 circle 0–10 visual analog scales for pain (PN), patient global estimate (PTGL), and fatigue (FT); review of 60-symptom checklist (SX); and RAPID3, a 0–30 total of FN+PN+PTGL whcih requires 5 seconds. The 6 scores are compared on a flow sheet to scores at previous visits prior to the traditional patient encounter. The rheumatologist records 4 global estimates for: overall status (0–10), and 3 0–3 global scales for levels of inflammatory activity, joint or other organ damage, and non-inflammatory/fibromyalgia symptoms, recoded 0–10 to compare to other measures. An updated flow sheet report includes the 10 proposed checklist scores, as well as laboratory tests and medications. Mean 1st visit values for the 10 proposed checklist measures were analyzed in all 874 new patients seen at a weekly academic setting from 1996–2007 in 8 groups: rheumatoid arthritis (RA), osteoarthritis (OA), fibromyalgia (FM), systemic lupus erythematosus (SLE), gout, spondyloarthropathy (Spondy), inflammatory polyarthritis (InflPol), connective tissue disease (CTD), and "other," as well as demographic data, ESR and CRP, compared using Spearman rank order correlations.

Results: The 874 patients appear typical for rheumatic diseases (Table). ESR was >20 mm/Hr in RA, OA, SLE, Spondy, and CTD, while CRP was >10 mg/dL in RA and Spondy. Mean MDHAQ FN was highest in RA and also >3.0 in FM and Spondy. Mean PAIN was highest in FM, and >5 in Spondy, RA and InflPol; PTGL >5 in FM, RA and Spondy; FT >5 in FM, RA, SLE, InflPol, and other. Symptom scores were >20 only in FM. Mean MD global estimates were ≥5.0 in all 8 categories - mean 5.7. Estimates were >5 for inflammation in Spondy, RA, gout, InflPol, and CTD; for damage only in RA and OA; and for noninflam/fibro symptoms in FM, SLE, and other.

Quantitative demographic, laboratory tests, patient MDHAQ scores, and MD global estimates in 874 new rheumatology patients, by diagnosis, Spondy = Spondylarthropathies. InflPol = Inflammatory Polyarthritis.

	RA	OA	FM	SLE	Gout	Spondy	InflPol	CTD	Other	Total
Number of patients	174	32	196	34	12	30	152	50	194	874
Demographic and laboratory measures										
Age (years)	54.5	65.1	47.0	38.8	59.3	43.9	51.9	47.6	51.0	50.7
Disease duration (years)	8.4	6.3	5.9	9.1	9.1	11.3	4.8	6.9	5.4	6.6
Formal education (years)	13.0	15.0	13.7	13.6	13.8	14.9	14.2	13.9	13.9	13.8
% Female	71.3%	65.6%	88.7%	85.3%	16.7%	46.7%	72.9%	82.0%	71.7%	74.9%

CRP (mg/dL) [normal < 10]	17.5	3.9	6.1	6.7	3.6	11.5	6.1	7.9	8.6	9.9
Patient MDHAQ self-report questionnaire measures for proposed checklist										
1. Function (FN) [0–10]	3.2	2.3	3.0	1.9	1.8	3.0	2.2	2.1	2.4	2.7
2. Pain (PN) [0–10]	5.4	4.4	6.5	3.7	5.8	5.9	5.0	3.0	5.2	5.3
3. Global (PTGL) [0–10]	5.4	4.4	6.1	4.3	3.8	5.1	4.5	3.9	4.8	5.1
4. RAPID3 [0–30]	13.7	10.0	15.4	8.5	10.2	13.4	11.4	8.3	11.0	12.4
5. Fatigue (FT) [0–10]	5.7	4.2	7.3	5.4	4.1	4.5	5.3	4.8	5.0	5.7
6. Symptoms (SX) [0–60]	14.1	9.4	20.5	16.1	7.7	11.4	13.8	13.2	12.8	14.9
MD global measures fir proposed checklist										
7. MD Global [0–10]	6.3	6.3	6.3	5.0	5.0	6.3	5.3	5.3	5.6	5.7
8. Inflammation [0–10]	7.0	3.3	2.3	3.6	6.0	7.7	5.7	5.3	3.7	4.7
9. Damage [0–10]	5.0	6.0	1.7	2.3	3.0	4.3	3.0	3.3	3.0	3.3
10. Non-inflam/fibro [0–10]	4.0	3.7	9.0	6.3	2.3	4.0	4.0	3.3	5.0	5.3

Shaded: Lab: ESR>20. CRP>10. Pt measures: FN>3, PN≥5, PTGL≥5, FT≥5, RAPID3>12, SX>20. All MD measures ≥5.

Conclusion: A proposed checklist of 10 measures, 6 from a MDHAQ and 4 global MD scores, provides quantitative data from a history and PE at each encounter in the infrastructure of rheumatology care, in <20 seconds. These data provide quantitative measures to assess patient status over long periods, "treat to target" values, and may lead to improved patient outcomes.

A Model for the Development and Implementation of a National Plan for the Optimal Management of Early Spondyloarthritis: The Esperanza Program. Milena Gobbo[1], Ruxandra Schiotis[9], Santiago Muñoz-Fernández[8], Loreto Carmona[1], Eduardo Collantes[5], Eugenio de Miguel[6], M. Jesús García-Yébenes[1], Juan Mulero[4], Raquel Almodovar[2], Cristina Fernández-Carballido[7] and José Francisco García Llorente[3]. [1]Research Unit, Sociedad Espanola de Reumatología. Madrid, Spain, [2]Rheumatology Department, Fundación Hospital de Alcorcón, Madrid, Spain, [3]Rheumatology Department, Hospital de Basurto, [4]Rheumatology Department, Hospital Puerta de Hierro Majadahonda. Madrid, Spain, [5]Rheumatology Department, Hospital Reina Sofía. Córdoba, Spain, [6]Rheumatology Department, Hospital Universitario La Paz. Madrid, Spain, [7]Rheumatology Unit, Hospital General de Elda. Elda, Spain, [8]Rheumatology Unit, Hospital Infanta Sofía. San Sebastián de los Reyes, Madrid. Spain, [9]University of Medicine and Pharmacy Iuliu Hatieganu, Cluj-Napoca, Romania

The design of a program in early spondyloarthritis (SpA) should have the following objectives: 1) to enable the establishment of early SpA units, 2) to

facilitate early diagnosis; 3) to reduce the variability in SpA; and 4) to improve the knowledge and practical skills on SpA of general practitioners (GPs) and specialists.

Methods: The Esperanza Program includes: 1) a call for the creation of 25 early SpA units with specific requirements; 2) the establishment of a managed care plan with 8 measurable indicators; 3) a web-based platform which may function as an electronic medical record (EMR), and which permits evaluation, and facilitates networking and feed-back; and 4) educational initiatives.

Results: Evaluation of the 25 implemented units covers from April 2008 until October 15th 2009. As of last evaluation, 1812 GPs were participating and 792 patients had been referred by their GPs. Indicators' values: 1) Over 90% of the patients have been attended within 30 days since their visit to PC; 2) the reliability of the referrals was 92%; 3) 53% of first visits had a duration of 30 to 60 minutes; 4) 28% of the patients had a diagnosis of SpA already in the first visit; 5) a report was issued in 25% of the medical visits; 6) 2% of the electronic reports issued were consulted by the GPs; 7) missing data in the EMR was 24%; and 8) an appropriate frequency of revisions was met in 84% of the patients. The patients attended were evenly distributed among sexes, and most of them were active workers. Their disease was active but spinal mobility and structural changes were preserved.

Conclusion: It is possible to implement a large scale program that is measurable and that helps to improve the management of early disease.

A Pilot Study To Quantify Suffering among Patients with Rheumatoid Arthritis—A New Measure for Patient Reported Outcome (PRO). Tom Sensky[2], Rieke Alten[4], Philippe Bertin[1], Boulos Haraoui[3], Ed C. Keystone[5] and Peter C. Taylor[2]. [1]CHU Dupuytren, Limoges, France, [2]Imperial College, London, London, United Kingdom, [3]Institut de Rhumatologie de Montreal, Montreal, QC, Canada, [4]Schlosspark-Klinik UnivMed, Berlin, Germany, [5]University of Toronto, Toronto, ON, Canada

Background: The potential gravity of adverse outcomes in rheumatoid arthritis (RA) is such that there is a need for outcome measures which not only reflect this but are also meaningful to patients, the public and clinicians. Alleviation of suffering is a key goal in medicine. The **P**ictorial **R**epresentation of **I**llness and **S**elf **M**easure (PRISM) is a novel, validated, brief method of measuring suffering consistent with Cassell's seminal conceptualisation of suffering. Pilot data are reported on using PRISM to assessing suffering in RA.

Methods: The survey was conducted on a convenience sample of 245 patients with clinically diagnosed RA from specialist clinics in Berlin, Limoges, London and Montreal during their routine clinic appointments with rheumatologists.

Basic sociodemographic and clinical data were collected, and all patients were asked to complete the PRISM task. Information was collected about patients' perceptions of the causes of their suffering.

Results: PRISM took 1–4 minutes to complete, and was easy to use. Most patients understood the simple instructions. Patients were consistent in their appraisal of their suffering which was related to the perceived controllability of the symptoms of RA, and/or the intrusiveness of the illness on valued aspects of the individual's life. Suffering quantified by PRISM showed significant correlations with global disease VAS (r_s=0.36, p<0.0001) and pain VAS (r_s=0.31, p<0.0001). In logistic regression analysis, with suffering dichotomised into 'high' and 'low', global disease VAS was a significant predictor (Exp(beta)=0.97, 95% CI 0.94 to 0.99, p<0.05), but pain VAS did not contribute significantly.

Conclusions: This pilot survey has confirmed that PRISM is easy to use in different languages without need for specific training, is very acceptable to patients and clinicians, and can be readily incorporated into routine clinical practice. It measures something distinct from pain and global disease burden, but associated with these. These data support further investigation of PRISM as a novel patient-reported outcome which quantifies factors salient to each individual with respect to the impact of the illness and its treatment and is likely to incorporate a wider range of such influences than existing measures. As such, it may have utility in setting agreed therapeutic targets.

Antibodies towards Infliximab Are Associated with Poor Infliximab Maintenance and Low Infliximab Concentrations. Emilie Ducourau[3], David Ternant[2], Denis Mulleman[3], Saloua Mammou[3], Delphine Chu Miow Lin[3], Hervé Watier[1], Gilles Paintaud[2] and Philippe Goupille[3]. [1]Universite François Rabelais de Tours, Laboratoire d'Immunologie, [2]Universite François Rabelais de Tours, Laboratoire de Pharmaco-Toxicologie, [3]Universite François Rabelais de Tours, Service de Rhumatologie

Background: Despite its benefits, infliximab is responsible for the development of antibodies against infliximab (ATI), which is associated with an increased risk of infusion reactions and a reduced response to treatment [1,2]. Herein, we studied the relationship between ATI and infliximab maintenance.

Methods: All patients initiating infliximab from December 2005 to January 2009 were followed until the end of their treatment or until January 2009. Infliximab [3] and ATI serum concentrations were measured by enzyme linked immunosorbent assays before each infusion. The patients were separated into two groups: "ATIpos" if ATI were detected at least once during the follow-up period or "ATIneg" in the other patients. The characteristics (sex, age, disease, mean disease duration, concomitant treatment with methotrexate or prednisone, infliximab dose at initiation, ESR and CRP) of the 2 groups were compared using a student's t-test or a chi-square test. Infliximab treatment maintenance in the 2 groups was studied using a survival analysis and compared with a log rang test. A P value of less than 0.05 was considered statistically significant.

Results: A total of 111 patients were studied: 17 rheumatoid arthritis (RA), 91 ankylosing spondylitis (AS), and 3 others systemic diseases. ATI were detected in 22 patients (7 RA, 14 AS and 1 other disease). Median detection of ATI was 3.5 months (0.4–26.0). Infliximab dose at initiation was lower in ATIpos patients than in ATIneg patients (4.1 mg/kg vs. 4.9 mg/kg; p = 0.005). Proportion of patient with concomitant MTX treatment was lower in ATI+ group than ATI- group but the difference did not reach significant difference (14% vs. 36% p = 0.08). Maintenance of infliximab was poorer in ATIpos group than in ATIneg group, with medians of 10 and 16 months, respectively (p = 0.05). Infliximab trough concentrations during initiation were statistically lower in ATI pos than in ATI neg (see Table).

RA	ATIpos (n=7)	ATIneg (n = 10)	p
C infliximab (mg/L)			
w2	7.7 [2.8–16.9]	27.2 [7.1–41.9]	0.002
w6	0.3 [0–6.2]	15.4 [2.7–35]	0.001
w14	0 [0–0.03]	5.4 [0–21.9]	0.01
SA	**ATIpos (n = 14)**	**ATIneg (n = 77)**	**p**
C infliximab (mg/L)			
w2	25 [4–40.7]	35.8 [14.3–57.2]	0.003
w6	11.9 [0–24.2]	29.5 [3.4–69]	<0.001
w12	1.6 [0–13.5]	15.8 [0.7–47.3]	<0.001

Except where indicated otherwise, values are the median [range]

Conclusion: In our experience, 20% of patients treated with infliximab develop ATI, often within the first 3 months of treatment. High concentrations of infliximab during initiation seem to reduce the incidence of ATI, and absence of ATI is associated with prolonged durations of infliximab treatment. This clearly argues for an early monitoring of infliximab serum concentrations.

Bridging the Gap in Osteoporosis Care, Part I: Results of the SPOOF (Secondary Prevention of Osteoporotic Fracture) Project. Mary A. Langan, John J. Carey, Robert J. Coughlan, Catherine Armstrong, Assumpta O'Brien, Sarah McNamara, Ella Murphy and Mohamed Ballal. Galway University Hospitals, Galway, Ireland

Background: Many agents have been shown to reduce the risk of future fracture in patients presenting with osteoporotic fractures. Despite widespread availability for over a decade, studies show that most patients are not evaluated or treated for osteoporosis following such fractures. Thus effective measures to improve the evaluation and treatment of osteoporosis following fragility fracture are needed.

Purpose: To examine the effectiveness of an outpatient fracture intervention program to improve the rates of osteoporosis evaluation and treatment among fracture patients aged 50 years and older seen in orthopedics fracture clinics.

Methods: Collection and analysis of data was approved by the local Institutional Review Board. We evaluated the rate of osteoporosis evaluation, diagnosis and treatment among a cohort of patients aged 50 years and older presenting to our University Hospital Orthopaedic clinic with a fragility fracture between 2005 and 2007. Groups were either assessed as part of a fracture liaison program or exposed to usual orthopedic care with referral back to their primary care doctor following treatment. A mail and telephone survey was undertaken of 190 patients in both cohorts 2 years following their fracture clinic visit. We compared the rate of osteoporosis diagnosis and treatment between the two cohorts within 2 years of their fracture.

Results: There was a greater response rate among those in active intervention group (74% Vs 63%). The most common fracture site was wrist and forearm in both groups. Age and gender of respondents was similar between the intervention and control groups: 66 years & 92% vs 71 years & 86% respectively. Treatment rates were similar between both groups before fracture (<20%). Significantly more subjects seen by a fracture liaison coordinator received: 1) a bone density measurement (89% Vs 47%, P <0.01); 2) osteoporosis treatment with calcium and vitamin D (81% vs 33%, P<0.01); and 3) pharmacologic therapy for osteoporosis (48% Vs 27%, P<0.01).

Conclusions: A case-finding fracture liaison service improves the rate of osteoporosis diagnosis and therapy following fragility fracture in persons of 50 years and older.

Clues To Differentiate Non-Inflammatory from Inflammatory Symptoms in Patients with Systemic Lupus Erythematosus (SLE), Using a Multi-Dimensional Health Assessment Questionnaire (MDHAQ). Theodore Pincus[2], Isabel Castrejón[5], Jill P. Buyon[6], Chung-E. Tseng[4], Peter M. Izmirly[3], Yusuf Yazici[1] and Anca D. Askanase[3]. [1]Hospital for Joint Diseases, Hastings on Hudson, NY, [2]New York University Hospital for Joint Disease, Hastings-on-Hudson, NY, [3]NYU Hospital for Joint Diseases, New York, NY, [4]NYU Hospital for Joint Diseases, Flushing, NY, [5]NYU Hospital for Joint Diseases, [6]NYU School of Medicine, New York, NY

Purpose: To analyze whether quantitative scores on a multidimensional health assessment questionnaire (MDHAQ) provide clues to the likelihood of inflammatory versus non-inflammatory symptoms and concomitant fibromyalgia, an important challenge in clinical care, according to a global scale for non-inflammatory symptoms completed by a rheumatologist in 50 patients with SLE seen in usual care.

Methods: A cross-sectional study was performed in 50 consecutive SLE patients of one rheumatologist seen in usual care. On arrival at the clinic, patients completed a multidimensional health assessment questionnaire (MDHAQ) which includes scales for physical function (FN), 0–10 visual analog scales for pain (PN), global estimate (PTGL) and fatigue (FT), and a review of systems symptom checklist (SX). SLE patients also completed a self-report Systemic Lupus Assessment Questionnaire (SLAQ). The rheumatologist, unaware of MDHAQ and SLAQ scores, recorded a physician global estimate (MDGL) and an estimate of non-inflammatory symptoms, each scored on a 0–3 scale in 0.1 increments, as well as four SLE indices: SLEDAI-2K (SLE Disease Activity Index), BILAG (British Isles Lupus Assessment Group index), SLAM (SLE Activity Measure) with and without laboratory tests, and ECLAM (European Consensus Lupus Activity Measurement). SLE patients with scores of <0.5 on the non-inflammatory symptom scale were regarded as "low" and those with scores ≥0.5 "high" non-inflammatory symptoms; the two groups were compared using the Mann-Whitney statistic.

Results: The study included 45 women and 5 men, mean age 38.7 years, mean disease duration 7.3 years. Of the 50 patients, 16 had high and 34 low scores for non-inflammatory symptoms. Those with high scores for non-inflammatory symptoms had significantly higher scores for FN, PN, FT, PTGL, SX, SLAQ, and SLAM without laboratory tests, as well as significantly lower CRP. No significant differences were seen patients estimated as "high" and "low" scoring patients for SLEDAI, BILAG, SLAM, ECLAM, C3, C4, antiDsDNA, or ESR. Fewer than 50% of "low" patients had FN, PN, PTGL, or FT ≥2, while 100% of "high" patients had FT >2, and 94% PTGL >2. All patients with high non-inflammatory symptoms (16/16) reported more than 5 SX, compared to 15/34 (44%) "low" patients, and 12/16 (75%) "high" patients reported >10 SX, compared to 6/34 (18%) "low" patients.

Table. Differences in the mean values of the MDHAQ scores, SLAQ, SLE indices and laboratory tests between SLE patients with versus without non-inflammatory symptoms. (Mann-Whitney)

Measure/Index	SLE low *non-inflammatory symptoms* (n=34)		SLE high *non-inflammatory symptoms* (n=16)		*P*
	Mean (± SD)	Median (Range)	Mean (± SD)	Median (Range)	
Physical function	0.74 (±1.25)	0 (0–5.3)	2.7 (±2.4)	2.7 (0–6.3)	<0.01
Pain VAS	2.5 (±2.6)	1.7 (0–9)	4.8 (±2.7)	5.0 (0–9)	<0.02
Patient global	2.2 (±2.5)	1.2 (0–9.5)	5.4 (±2.2)	5.5 (1.5–9)	<0.01
Fatigue VAS	2.8 (±2.5)	2.0 (0–9)	6.3 (±2.1)	6.5 (3–10)	<0.01
# Symptoms	6.9 (±6.8)	5.0 (0–31)	16.9 (±8.2)	17.0 (6–38)	<0.001
RAPID3	5.4 (±5.9)	3.0 (0–22.8)	13.0 (±6.7)	12.4 (4.5–23)	<0.01
SLAQ-total	7.0 (±5.3)	6.5 (0–18)	16.9 (±4.5)	16.0 (10–27)	<0.001
SLEDAI	5.1 (±3.9)	4 (0–16)	4.8 (±3.6)	4.0 (0–12)	0.83
BILAG	4.2 (±4.2)	2.5 (0–15)	5.4 (±4.5)	4.0 (0–15)	0.27
ECLAM	1.9 (±1.3)	1.5 (0–4)	2.2 (±1.6)	2.0 (0–6)	0.65
SLAM	3.7 (±3.2)	3.0 (0–12)	4.2 (±2.3)	4.0 (1–10)	0.32
SLAM-no lab	1.6 (±1.6)	1.0 (0–5)	3.2 (±1.8)	3.0 (0–7)	<0.01
C3	102.1 (±32.5)	103 (43–174)	123.3 (±35.1)	110 (76–197)	0.67
C4	20.1 (±11.3)	17.5 (6–63)	21.1 (±7.7)	22 (9–32)	0.37
ESR	27.1 (±33.1)	12.5 (1–112)	11.2 (±10)	10 (1–38)	0.27
CRP	5.4 (±8.1)	3.1 (0.1–31)	0.7 (±1.3)	0.2 (0.1–5)	0.015

SD= standard deviation

Conclusion: High scores for dysfunction, pain, fatigue, global estimates, and number of symptoms are common in SLE patients with high versus low levels of non-inflammatory symptoms. SLE indices do not distinguish between patients with high versus low levels of non-inflammatory symptoms. A simple global scale to estimate non-inflammatory symptoms may be informative in therapeutic decisions, particularly if consistent with patient questionnaire patterns.

DMARD Use in Rheumatoid Arthritis: An Analysis of HEDIS Data from 2005–2008. Gabriela Schmajuk[4], Amal Trivedi[3], Daniel Hal Solomon[2], Edward H. Yelin[7], Laura Trupin[6], Eliza F. Chakravarty[1] and Jinoos Yazdany[5]. [1]Mountain View, CA, [2]Brigham and Womens Hospital, Boston, MA, [3]Brown University, [4]Stanford University, Stanford, CA, [5]UCSF, San Francisco, CA, [6]UCSF, [7]University of California, San Francisco, CA

Background: Since 1997, all managed-care plans administered by Medicare have reported on quality of care measures from the Health Plan Employer Data and Information Set (HEDIS). In 2005, HEDIS introduced a quality indicator to assess the use of disease modifying anti-rheumatic drugs (DMARDs) among patients with rheumatoid arthritis (RA). We determined sociodemographic, community, and health-plan predictors of performance on the RA measure among Medicare managed care (MMC) enrollees and health plans.

Methods: We analyzed individual-level HEDIS data for 97,587 beneficiaries at least 65 years old with a diagnosis of RA and enrolled in MMC plans between 2005 – 2008. Low personal income was identified by the state buy-in variable in the Medicare denominator file. Zip-code-based

socioeconomic status (SES) was calculated from Census 2000 variables using the Agency for Healthcare Research and Quality SES index score. We constructed logistic regression models with generalized estimating equations to determine individual, community, and health plan predictors of individual adherence to the HEDIS RA measure. We also analyzed rates of DMARD use at the health plan level: Logistic regression was used to adjust health plan rates for case-mix. Health plans in the lowest tertile of case-mix-adjusted performance (DMARD use < 58%) were considered "low-performing," and logistic regression was used to identify predictors of low-performing plans.

Results: The mean age of eligible patients was 74.4 years; 76% were female, and 81% were Caucasian. A DMARD was dispensed to 66% of patients in 2005, rising to 71% of patients in 2008 (p for trend < 0.01). The largest difference in rate of DMARD use was based on age: patients > 85 had a 29% (95% CI (28%, 31%)) lower rate of DMARD use compared to patients 65–69 years old, even after adjusting for all other factors. Males, non-Caucasians, patients with low personal income, and those with lower zip-code-based SES were also less likely to receive a DMARD, as were patients in the Middle and South Atlantic regions (see Table).

Characteristic	N	Unadjusted Difference	Adjusted difference*

* adjusted for all listed variables in addition to calendar year.

DMARD use varied widely by health plan (ranging from 13% to 91%). Health plans that opened their health maintenance organization operation later than 1999 were more likely to be low-performing plans, even after adjusting for case-mix and other health plan characteristics.

Conclusions: One third of Medicare managed care beneficiaries with a diagnosis of RA are not receiving a DMARD. Differences in rates of DMARD use exist based on demographics, socioeconomic status, geographic location, and health plan. Quality improvement initiatives should focus on increasing the performance rates among groups and health plans with lower DMARD use and regions with lagging adherence.

Does Asymptomatic Hyperuricemia Treatment Improve Health? A Decision-Analytic Evaluation. Roopa Akkineni[2], Alexandra Lee[2], Katherine Miller[2], Anna Tosteson[2] and Daniel A. Albert[1]. [1]Dartmouth-Hitchcock Med Ctr, Lebanon, NH, [2]The Dartmouth Institute

Purpose: Recent studies have suggested that elevated uric acid levels are associated with an increase in coronary and cerebrovascular disease. Treatment for asymptomatic hyperuricemia with uric acid lowering drugs, such as Allopurinol, may reduce cardiovascular events. However, some patients have experienced adverse drug reactions while treated with Allopurinol. A decision analysis was designed to identify the optimal treatment strategy for patients with asymptomatic hyperuricemia.

Methods: A Markov state-transition model was constructed to assess the occurrence of cardiovascular events and life expectancy in patients undergoing urate-lowering treatment with Allopurinol, compared with watchful waiting. The model was built for a hypothetical 50-year old asymptomatic hyperuricemic male patient. Probabilities were derived from current literature. Developments of gout or uric acid stones as well as cardiovascular events were modeled. Sensitivity analyses were conducted for drug effectiveness and probability of adverse drug reaction.

Results: In the base–case analysis, the two treatment options had a similar occurrence of vascular events and life expectancy. However, watchful waiting was associated with a slightly greater gain in quality adjusted life years (QALYs) than treatment with Allopurinol (10.61 QALYs versus 10.58 QALYs). A sensitivity analysis was conducted on drug effectiveness, drug protection from cardiovascular events, the probability of adverse drug event, and death from adverse drug reaction. When the probability of having an adverse drug reaction increased, watchful waiting was always favored. The results were similar for probability of death from adverse drug reaction. By contrast, when the effectiveness of drug therapy varied, treatment with Allopurinol was the optimal choice for effectiveness rates over 69.2%. The maximum gain in QALYs assuming 100% effectiveness of Allopurinol therapy was approximately 0.35 QALYs.

Conclusions: Watchful waiting was preferred for patients with asymptomatic hyperuricemia at the base rate of 21% effectiveness of Allopurinol; however, the number of QALYs gained with watchful waiting was small compared to treatment with Allopurinol. At 100% effectiveness, treatment with Allopurinol was the preferred strategy with a gain of 0.35 QALYs, which in magnitude is similar to statin therapy with 0.25 QALYs gained.

Early Experience with the American College of Rheumatology (ACR) Rheumatology Clinical Registry (RCR). Salahuddin Kazi[2], Elizabeth A. Tindall[3], Kristen McNiff[1] and Itara Barnes[1]. [1]American College of Rheumatology, Atlanta, GA, [2]Arthritis Consultation Center, Dallas, TX, [3]Oregon Health and Science University, West Linn, OR

Background: The RCR was launched by the ACR to provide members with an infrastructure for quality reporting related to rheumatoid arthritis, gout, osteoarthritis, osteoporosis, and drug safety. This abstract describes the initial uptake of the RCR, and initial findings related to functional status, DMARD use, TB screening, prognosis, and disease activity assessment for RA patients in rheumatology practice.

Methods: Rheumatology providers and/or designated practice staff conduct retrospective medical records abstraction, for a sample of patients seen by the rheumatologist. Reporters submitted data via a secure, web-based registry system. The analytic specifications for RA measures include adults (≥18 years of age) with a diagnosis with RA receiving treatment by the reporting rheumatology provider. Additional components of each measure are listed in Table 1.

Results: 240 rheumatology providers in 125 practices submitted data on 7,806 patients with RA (mean submission/rheumatologist = 31) from July 1, 2009 to January 31, 2010. Reporting providers practice in sites ranging from solo practitioner offices to large academic medical centers.

Table 1. Concordance with RA Measures Assessed through the RCR (6/09-1/10)

	Total applicable cases	% Concordant
Functional status assessment performed at least once within 12 months, and documented using a standardized descriptive or numeric scale, standardized questionnaire, or notation of assessment of the impact of RA on patient activities of daily living	6131	79%
Patient prescribed, dispensed, or administered at least one ambulatory prescription for a DMARD within 12 months	7260	93%
Documentation of TB screening performed and results interpreted within 6 months prior to receiving first course DMARD	1714	92%
Assessment and classification of disease prognosis at least once within 12 months	Good 4051 Poor 2042 Not assessed 1667	Good 52% Poor 26% Not assessed 22%
Disease activity assessed at least once within 12 months, using a standardized descriptive or numeric scale or composite index, and classified as low, moderate or high	High 929 Moderate 2205 Low 3157	High 15% Moderate 35% Low 50%

Conclusions: Rheumatologists across the country used the RCR in 2009 to report quality data. Establishing RCR as a mechanism for CMS PQRI reporting especially incentivized use and enhanced participation (consistent with the ACR goal that RCR provide maximal benefit from data submission).

Ongoing data collection and analysis will help reveal the clinical significance of the data and monitor improvement over time.

Next steps planned for the RCR include continually enhance the quality of data collected, analytic reports, and EHR-enabled reporting.

RCR provides an opportunity for rheumatology providers to facilitate practice improvement, contribute to collaborative improvement projects, and contribute to national data, led by their professional society.

Evaluating Adherence to Quality Indicators in Prevention of Glucocorticoid Induced Osteoporosis in Patients at the Veterans Affairs in Lexington. Magdalena Winiarska[1], Joseph Conigliaro[2], Heather Bush[2], Lucia Hardi[1], Elnaz N Tabrizi[1] and Leslie J. Crofford[3]. [1]Univ of Kentucky, Lexington, KY, [2]Univ of Kentucky, [3]Univ of KY, Lexington, KY

Background: Osteoporosis is a systemic skeletal disease characterized by low bone mass, microarchitectural deterioration of bone tissue, and a consequent increase in bone fragility and susceptibility to fractures. Glucocorticoids are widely used agents for many inflammatory diseases. Glucocorticoid-induced osteoporosis (GIOP) is the most common type of secondary osteoporosis ultimately leading to fractures in up to 50% of patients. Despite steadily increasing evidence of effective preventive therapies among patients initiating long term glucocorticoid therapy, prevention of GIOP is often neglected, with a low level of awareness among primary and specialist physicians. The specific aim of this study was to evaluate adherence to known recommendations on prevention of GIOP. The long term goal of this study is to improve quality of care among patients treated with glucocorticoids.

Methods: A retrospective computer-generated chart review of electronic health records from the Veterans Affairs Medical Center in Lexington, Kentucky identified 453 patients treated with prednisone 7.5 mg daily or its equivalent for at least six months between October 2004 and October 2009. Using this population we extracted following data: age, race, body mass index, bone density testing, dose of glucocorticoid therapy, bone loss prevention medication use including calcium, vitamin D, bisphosphonate, calcitonin, hormone replacement therapy, testosterone replacement therapy, steroid prescribing practitioner's speciality and diagnosis for which glucocorticoids were prescribed.

Results: The average age of the patients was 68 years (SD = 11.7). Of the 453 patients, 430 were males and 420 were Caucasian. Bone mineral density testing was performed on 128 (28.3%). Of 430 male patients, 69 (15.2%) had testosterone levels checked. Of 22 patients with low testosterone, 8 were on testosterone replacement therapy. Calcium and vitamin D was given to 210 (48.8%) patients and bisphosphonates to 147 (32.5%) of patients; 184 (40.6%) were not on any prescribed pharmacologic therapy to prevent GIOP. Primary care providers wrote 233 (51.5%) of the total prescriptions for glucocorticoids followed by 67 (15%) rheumatologists and 52 (11.5%) pulmonologists. The most common diagnosis for which the patients were prescribed prednisone were chronic obstructive pulmonary disease (n=69) and rheumatoid arthritis (n=49).

Conclusions: GIOP is a common but still relatively neglected problem. Although it is not possible to define an absolute standard of care, the overall adherence to guidelines for prevention of GIOP in our study was low. This study identifies areas amenable to targeted educational efforts that will improve care of patients requiring glucocorticoid treatment.

Formal Joint Counts Are Performed at More Than 50% of Visits of Patients with Rheumatoid Arthritis in Usual Care outside of Clinical Research, by 64% of European Rheumatologists in 2010 Compared to 44% in 2003. Theodore Pincus[2], Ed C. Keystone[4], Marc de Longueville[3] and Sophie Costello[1]. [1]Costello Medical Consulting, [2]New York University Hospital for Joint Disease, Hastings-on-Hudson, NY, [3]UCB Pharma, [4]University of Toronto, Toronto, ON, Canada

Purpose: To analyze responses of European rheumatologists concerning the likelihood of performing of a formal swollen and tender joint count in 2010, and compare results to a similar estimate in 2003.

Methods: About 300 rheumatologists attended a meeting in March 2010 sponsored by a pharmaceutical company. Most had participated in clinical trials of patients with RA. Keypads were available for instant recording of responses. A query was presented: "In patients with RA seen in usual care outside of clinical trials and other clinical research, how often do you perform a formal tender and swollen joint count?" Response options were 0, 1–24, 25–49, 50–74%, 75–99%, and 100% of the time. Results were instantly totaled. Results at this 2010 meeting were compared with results obtained from European rheumatologists in a similar study performed at a similar meeting in 2003 (Pincus T, Segurado OG. *Ann Rheum Dis.* 2006;65:820–2).

Results: Overall, 143 responses were recorded in 2010 for the joint count; only 4% of rheumatologists responded that they "never" performed a formal joint count, 13% at 1–24% of visits, 19% at 25–49%, 16% at 50–74%, 23% at 75–99% of visits, and 25% "always." Each of the 4 countries with more than 5 responding rheumatologists – United Kingdom, Germany, Spain, and Italy – included at least one respondent in 4 of the 6 categories. Results of a similar survey of 500 European rheumatologists in 2003 were 13% "never", 32% at 1–24% of visits, 11% at 25–49%, 14% at 50–74%, 16% at 75–99% of visits, and 14% "always." Overall, 64% of European rheumatologists in 2010 reported that they performed formal joint counts at ≥50% of visits, compared to 44% in 2003.

Question for rheumatologists: For RA patients under your care (when not required for clinical trials or reimbursement), how often do you perform:

Measure	Year	Never	1–24%	25–49%	50–74%	75–99%	Always
Formal joint count	2003	13%	32%	11%	14%	16%	14%
Formal joint count	2010	4%	13%	19%	16%	23%	25%
Formal joint count	2003		56%			44%	
Formal joint count	2010		36%			64%	

Conclusion: An increase in the likelihood of performing a formal joint count among physicians in treatment of patients with RA was reported in 2010 compared to 2003. Nonetheless, one-third of rheumatologists indicated that a formal joint count was performed at fewer than 50% of visits. Further educational efforts for rheumatologists might emphasize greater use of formal joint counts in standard clinical care.

996

Frequency of PAP Smears among Lupus Patients—A Patient Report Survey. Eileen J. Lydon and H. Michael Belmont. NYUHJD, New York, NY

Purpose: In our practice 2 patients (pts) with systemic lupus erythematosus (SLE) who received intravenous (IV) cyclophosphamide (CYC) for lupus nephritis developed anal cancer (ca). Both had a history of human papilloma virus (HPV) & presented with bright red blood per rectum (BRBPR). HPV is responsible for almost all cervical & 90% of anal ca. Studies suggest that women with SLE are at greater risk of developing cervical dysplasia & ca than the general population. It is unknown whether this is attributable to immunosuppressive exposure or baseline defective immunity to HPV. Furthermore, immunocompromised pts & women with a history of cervical ca (or high-grade cervical lesions) are among high risk groups for the development of anal ca. Appropriate screening and knowledge of cervical & anal ca is imperative for SLE pts.

Methodology: We developed a patient report survey (PRS) to assess knowledge & educate our pts regarding cervical & anal ca. From May-June 2010 we surveyed pts at Bellevue & NYUHJD lupus clinics as well as private practice. Both genders were included & questions consisted of HPV awareness, HPV/SLE/ca risk, frequency of cervical & anal pap smears, & HPV vaccine. Education and recommendations were also provided.

Results: 75 pts participated; 69 F, 6 M; Age mean = 48; AA 24, H 32, C 6, A 11; Sexually active 39/75(52%); Unaware of HPV 40/75(53%); Ever told had HPV 11/75(15%); Smoked cigarettes 7/75(9%); Unaware of SLE/HPV/ca risk 67/75(89%); Unaware of utility for cervical PAP 20/69(29%); No GYN 15/69(22%); Greater than 1 year since last cervical PAP 19/69(28%) & 6/19(32%) never had; Abnormal cervical PAP 14/63(22%); Unaware of anal ca risk 64/75 (85%); Had anal pap smear 0/75(0%); Unaware of HPV vaccine 41/75(55%); Had vaccine 3/75(4%). Almost half the cohort were unaware of HPV & a strikingly high number unaware of SLE, HPV & ca risk. The few smokers were encouraged to quit. Many needed to be counseled about the importance of yearly cervical screening & more frequently if abnormal. A few never had cervical PAP smears & were encouraged to make an appointment. The majority of pts lacked knowledge regarding risks of anal ca & screening tools such as anal pap smears. Finally, most were unaware of the HPV vaccine & only a few eligible pts had yet to receive it.

Conclusion: The RPS allowed for assessment of knowledge and the ability to provide education to help decrease the development of cervical and anal ca. Our immunocompromised pts should undergo appropriate screening. Yearly PAP smears with HPV testing can help identify high risk (HR) types of HPV early in the disease. The SLE pts exposed to immunosuppressants also need to receive annual screenings. In addition, eligible pts should be educated about the HPV vaccine which prevents up to 70% of HR HPV. Also, as we experienced, pts exposed to CYC with HPV who develop BRBPR need prompt evaluation. Furthermore, anal ca screening should be considered for our high risk pts even though there are currently no standardized guidelines. Finally, education about these malignancies will help ensure that our pts are screened appropriately & increase awareness to report associated symptoms.

997

Impact of a Screening Protocol with Added Thoracic CT and Quantiferon on Prophylactic Treatment of Latent Tuberculosis in Anti-TNFa Candidate Patients. Nathalie Saidenberg-Kermanac'h[3], Luca Semerano[4], Jean-Marc Naccache[1], Michel Brauner[2], Géraldine Falgarone[4], Dominique Dumont-Fischer[4], Xavier Guillot[4] and Marie-Christophe Boissier[4]. [1]Department of Pneumology, Avicenne Hospital (AP-HP), Bobigny, France, [2]Department of Radiology, Avicenne Hospital (AP-HP), Bobigny, France, [3]Department of Rheumatology, Avicenne Hospital (AP-HP), Bobigny, Bobigny, France, [4]Department of Rheumatology, Avicenne Hospital (AP-HP), Bobigny, France, EA4222, Paris-13 University, France

Background: Screening for latent tuberculosis (LTBI) is current clinical practice before anti-TNFa treatment given the risk of disease reactivation with this class of therapeutics. The current screening protocol for LTBI in France (Sc1) comprises the parallel performance of chest X-ray, TST and anamnesis for LTBI risk factors.

A higher disease prevalence reduces the negative predictive value of a given screening test (i.e. increases the number of false negatives), and, additionally, patients under immunomodulating treatments can be falsely negative to tuberculin skin test (TST). In our hospital, which serves the district with the highest incidence of tuberculosis in France, we had a case of LTBI reactivation under anti-TNFa treatment, in a patient who hadn't been treated for LTBI due to negativity of Sc1.

For these reasons, taking into account the 2006 recommendations of the French Health Authority (HAS), and in accord with local TB experts, it was decided to screen all candidate patients to anti-TNF treatment with a screening protocol (Sc2) where QuantiFERON and chest CT were added to current screening tests for LTBI. The aim of the study was to evaluate the impact of this screening protocol (Sc2) on the prescription of LTBI treatment.

Methods: 96 consecutive patients candidate to anti-TNFa treatment for rheumatoid diseases underwent a screening protocol for LTBI comprising chest x-ray, TST (performed using Mantoux method), anamnesis for LTBI risk factors, a chest CT scan and blood QuantiFERON TB Gold IT (Cellestis) test. All medical records were discussed with a radiologist and a pulmonologist, leading to the final therapeutic decision of treating or not for LTBI before anti-TNF treatment. The ROC curve of sensitivity and specificity of Sc1 and Sc2 were compared, with the final therapeutic decision considered as the gold standard.

Results: among the 96 patients there were 39 positive TST, 12 positive quantiFERON, 10 chest X-rays and 8 CT scans suggestive of LTBI respectively. The sensitivity and specificity and ROC AUC of Sc1 were 88,9%, 93,5% and 0,912 [95% CI 0,843–0,961] respectively. For Sc2 they were 100%, 93,5% and 0.967 [95% CI 0,907–0,993]. The difference between the two ROC curves was not significant (p=0,096) at an a-error of 0,05 and a b-error of 0,2. 48 patients were finally treated with Sc2 vs. 43 that would have been treated with Sc1.

Conclusion: In a population at high prevalence of LTBI a screening protocol before anti-TNFa treatment implying the parallel performance of TST, chest x-ray, quantiFERON and chest CT scan lead to treat more patients than the screening protocol currently adopted in France. This difference was not statistically significant in a study with 80% power.

998

Implementation of an Electronic Interface for Medical Record Documentation in an Academic Pediatric Rheumatology Outpatient Clinic. Jennifer M. P. Woo[2], Miriam F. Parsa[2], Gil Amarilyo[2], Nasim Afsarmanesh[1], Kerry T. Gallagher[2], Ornella J. Rullo[2] and Deborah K. McCurdy[2]. [1]Division of Internal Medicine and Neurosurgery-Medicine; Hospital Medicine and Neurosurgical Clinical Quality Programs, UCLA, Los Angeles, CA, [2]Division of Pediatric Rheumatology, UCLA, Los Angeles, CA

Background: Health information technology (HIT) has gained importance in clinical practice in an effort to improve clinic efficiency and to minimize medical and communication errors resulting from handwritten notes. Our healthcare center utilizes an electronic medical record (EMR) system that requires outpatient clinic physicians to document patient visits on paper clinical notes (PCN) and send them outside the department to be uploaded. This process generates a lag period, ranging from 2 to 14 days when PCN are inaccessible via network computer. In response, we have designed, created, and implemented an EMR interface or electronic note (EMRI) that mimics the paper template, allowing the physician use a portable tablet computer in the exam room to directly upload their findings to an established clinical document system (CDS) and the EMR. We are assessing patient perception of the use of an EMRI in clinic and evaluating its effects on the workflow of the pediatric rheumatology outpatient clinics.

Methods: Our EMRI is a Microsoft Excel form and includes measures to verify medication dosing based on body surface area and weight, to maximize billing criteria, and to facilitate retrieval of clinical data for future research. Patients or their parents were asked, via paper survey, to anonymously assess the quality of care and their perception of EMRI use in clinic; we will continue these observations until our EMRI is fully integrated into clinical practice. Clinic efficiency was evaluated by monitoring the length of time physicians spent with each patient, the additional time dedicated to charting following the patient visit, and the time required for the clinical notes to be uploaded to the EMR.

Results: With the implementation of our EMRI, we have reduced the average time required to upload clinical documents by 6 days and increased the average percentage of notes uploaded within 48 hours of the patient visit by 75% ($p < 0.0001$). Currently, 93% of patients/parents

surveyed (n = 25) were receptive to the use of a clinical EMRI and 75% believed that an EMRI would benefit the patient's quality of care. There was no significant difference in perceived satisfaction in visit length or quality of care between visits documented with EMRI compared with those documented using PCN. On average, rheumatologists spent 38 minutes with each patient when using PCN, comprising about 40% of the clinic visit. Patients generally spent the majority of the remaining 60% of their visit waiting to be roomed or to be seen by the rheumatologists. These PCN times will be compared with EMRI times to assess improvement in clinic workflow.

Conclusions: Patients and their parents have indicated receptiveness to EMRI use in clinic and believe that it would benefit patient care. The implementation of an EMRI can improve clinic efficiency and minimize errors resulting from handwritten notes in an academic outpatient rheumatology practice without compromising patient perception of quality of care.

999

Inpatient HiROC (High Risk Osteoporosis Clinic): Improving Osteoporosis Care Post Fracture. Gwynne L. Maloney-Saxon[2], Thomas P. Olenginski[3], Cynthia K. Matzko[2], Haiyan Sun[1], Karen Mackiewicz[4] and Eric D. Newman[2]. [1]Center for Health Research, Danville, PA, [2]Geisinger Medical Center, Danville, PA, [3]Geisinger Medical Center, Danville, PA, [4]Geisinger Medical Center, Davnille, PA

Purpose: Ineffective care pathways and process flows hinder post fracture care. To enhance the care of high risk osteoporosis patients across our health system, the rheumatology department created HiROC (High Risk Osteoporosis Clinic). Success was achieved by partnering with fellow stakeholders (orthopedists, hospitalists) to provide comprehensive post fracture care to this high risk group.

Method: HiROC utilizes rheumatology physician experts, clinical nurse specialists, electronic tools, and redesigned care processes in an efficient manner to provide comprehensive osteoporotic care to patients after fracture. HiROC has both inpatient and outpatient components. Inpatient HiROC involves an auto-consult to the Inpatient HiROC Team on all patients admitted with a low-impact fracture. Patients are logged into a task management database. Vitamin D testing and supplementation is initiated. At 6 weeks post-fracture, all Inpatient HiROC patients are contacted to re-assess their status. They are then seen in Outpatient HiROC, or their treating physician is contacted and given a consultative osteoporosis management plan, if they decline outpatient HiROC followup. We report on the first 200 Inpatient HiROC patients, including baseline demographics, risk assessment, treatment, and financial performance. High risk for future fracture was assessed by fracture type (vertebral or hip) and/or DXA results.

Results: Inpatient HiROC admission fracture types included hip (50.5%), vertebral (13.0%), other (38.0%). Mean Vitamin D level at time of consultation was 23.9 ± 11.7 ng/mL and increased to 46.3 ± 21.9 ng/mL at HiROC return. All 200 patients reached their 6 week assessment point with 48 % of patients transitioning to Outpatient HiROC, 26 % returning to a non-system primary physician, 13% to an in-system primary care physician (PCP), 1.5% were lost to follow up, and 11.5 % were deceased. Significantly more high risk patients received treatment in the Outpatient HiROC group (83%) than the in-system PCP group (25%), ($p<.0001$). Financial evaluation demonstrated the program to be self supporting, sustainable, and scalable.

Conclusion: By combining inpatient and outpatient components, organized task management, and electronic tools, the HiROC program demonstrates significant treatment success. Quality of care was greatest when an Inpatient HiROC visit was paired with an Outpatient HiROC visit. We are exploring ways to increase this connectivity by expanding Outpatient HiROC site availability and increasing patient motivation. HiROC is effective, self-sustainable, scalable, and may serve as a model for other groups to improve osteoporosis care for the patients they serve.

Lipid and C-Reactive Protein Screening Thresholds and CVD Risk in a Community Lupus Cohort. Christie M. Bartels[4], Kevin Buhr[5], Jerry Goldberg[2], Carolyn Bell[3] and Robert Greenlee[1]. [1]Marshfield Clinic Research Foundation, [2]Marshfield Clinic Rheumatology, [3]Univ of Wisconsin School of Medicine and Public Health, Dept of Medicine, Rheumatology, [4]Univ of Wisconsin School of Medicine and Public Health, Dept of Medicine, Rheumatology, Madison, WI, [5]University of Wisconsin Department of Biostatistics

Background/Purpose: Systemic Lupus Erythematosus (SLE) is an independent cardiovascular (CVD) risk factor without clear guidelines informing cholesterol screening intervals or treatment thresholds. In non-lupus populations, the JUPITER trial demonstrated that highly sensitive CRP (hsCRP) elevation, as an indication for statin treatment, reduced CVD risk. We sought to examine current thresholds for lipid screening, CRP testing, and statin treatment in a community-based lupus cohort, as well as hazards for CVD events relative to these thresholds.

Methods: This retrospective cohort study examined all patients with incident SLE diagnosed between 1991–2008 in a regional medical care system capturing >90% of all regional health care encounters. "Definite lupus" cases were verified by the 1997 revised 1982 ACR SLE criteria. CVD events including myocardial infarction, stroke, or heart failure hospitalization were MD verified by record review. Screening and risk thresholds examined include (a) ever receiving US Preventive Task Force (USPTF) recommended standard adult lipid screening (b) identification of LDL> 130 mg/dl or >100mg/dl or (c) CRP>1 mg/dl (normal <1, analogous to hsCRP<10). Medical history of documented hyperlipidemia diagnosis or ever receiving statins was also examined. Comparison between SLE cases without and with CVD new events (n= 22 events) used Wilcoxon and Chi-Square tests and hazard ratios.

Results: Among 71 incident lupus cases followed for a mean of 9 years (mean age 52, 82% female) only 60% of females and 85% of males ever received lipid screening (Table). Among those tested, 43–72% had LDL elevation at >130 mg/dl and >100 respectively. Only 20% of all SLE patients ever received a hyperlipidemia diagnosis, and only 15% (n=11) ever received statin treatment. CRP was more commonly tested and showed less of a gender gap than cholesterol testing. CRP elevations were seen in 49% of patients. Ever or current CRP elevations reflected higher hazards of CVD events than formal hyperlipidemia diagnosis or LDL elevation.

Lipid and CRP Screening and Predicted Hazards of CVD Events Among 71 Patients with SLE

	Total SLE n = 71	%	Female n = 58	%	HR* CV Event	95% CI	p
Lipid Screen Ever	46/71	65%	35/58	60%			
LDL>130	20/46	43%	15/35	43%	0.99	[0.35, 2.74]	0.98
LDL>100	33/46	72%	24/35	69%	0.52	[0.19, 1.47]	0.22
Diagnosed Hyperlipidemia	9/71	20%	6/58	17%	2.96	[1.08, 8.15]	0.04
CRP Ever	53/71	75%	42/58	72%			
CRP>1 Ever	26/53	49%	19/42	45%	3.31	[1.17, 9.33]	0.02
CRP>1 Current	16/53	30%	11/42	26%	4.33	[1.68, 11.2]	<0.01

* Hazard ratios calculated at each level of risk among screened patients relative to event status.

Conclusions: While possible thresholds for lipid screening and treatment vary widely in the lupus literature, these findings demonstrate a clear gap in adherence to USPTF recommended lipid screening in this community based cohort of lupus patients. Women were more likely to lack lipid screening. Regardless of gender, more patients ever had CRP screening, and associated hazards of CRP elevation in this population exceeded those with hyperlipidemia. In this observational study CRP monitoring was not controlled and may reflect indication bias, however, a prior report showed low rates of serious SLE disease in this cohort. Sample size limited meaningful adjustment. Future work is needed to close gaps in standard USPTF recommended lipid screening in community lupus patients, and to determine the role of CRP and hsCRP for informing CVD risk management.

Measuring the Impact of Patient Educational Materials about Medications in Meeting Patient Needs: Development and Validation of the Medication Education Impact Questionnaire (MeiQ). Sabina Ciciriello[3], Rachelle Buchbinder[1], Ian Wicks[4] and Richard H. Osborne[2]. [1]Cabrini Medical Center, Malvern, Australia, [2]Deakin University, Melbourne, Australia, [3]Royal Melbourne Hospital, Melbourne, Victoria, Australia, [4]Royal Melbourne Hospital, Melbourne, Australia

Background: Patient education is essential for patients to participate in decision-making and self-management. Evaluation of new educational interventions should incorporate outcomes that are relevant to patients as well as healthcare professionals. At present there are no measures that adequately evaluate the impact of education in meeting patient needs. The objectives of this study were to: (i) To determine the perceived needs of patients when starting a new medication; (ii) to develop a questionnaire assessing the impact of education about medications in meeting patient needs, facilitating shared decision-making and self-management and (iii) to validate this questionnaire within the target population.

Methods: Patients perceived needs when starting a new medication were explored in concept mapping workshops with patients (N=24). Quantitative and qualitative analyses were used to identify and define distinct areas of need (constructs). 130 questions were drafted to capture these needs and administered to 653 patients taking various medications for their rheumatic conditions. Exploratory and confirmatory factor analyses (CFA) were undertaken to create a robust questionnaire. A refined set of 29 questions divided into 6 scales, each measuring a patient need, were administered to 876 patients and a further CFA validation step was undertaken. To assess test-retest reliability, 200 respondents were sent a second copy of the MeiQ two weeks later (response rate of 90%).

Results: Four key independent areas of need were identified for patients starting a new medication: The need for quality information; the ability to participate in decision-making; coming to terms with their diagnosis and treatment; and the ability to self-manage. Statistical analyses revealed that some of the subheadings within the constructs worked best as separate scales: self-management as 3 scales measuring role & responsibility, capacity and support to self-manage. Decision-making as 2 scales: active communication and informed decision-making. All questions within the scales were strongly congruent with their underlying construct. No items had substantial associations with other constructs (cross-loadings), and CFA fit indices supported the hypothesized factor model. The refined MeiQ consisted of 29 questions across 6 scales; Perception of information quality, Ability to communicate with health professionals, Coming to terms with diagnosis and treatment, Self-management role and responsibility, Self-management capacity, and Self-management support. The final scales were found to be valid, reliable (Cronbach alpha $\geq$ 0.7) and stable over time (ICC 0.68 to 0.87).

Conclusions: The MeiQ was developed using advanced psychometric processes and found to be a robust, multidimensional questionnaire which incorporates the patient's perspective. The MeiQ is generic and can therefore be used to evaluate education about any medication. It is likely to fill an important gap in the evaluation of educational interventions about medications.

Multispecialty Unit for Infusion Therapy: Patient, Nursing and Provider Satisfaction. Barbara E. Ostrov, Kristine Reynolds and Lisabeth V. Scalzi. Penn State Hershey, Hershey, PA

Background: Current treatment of many complex diseases includes infusion therapy. In recent years, individuals with autoimmune diseases have been increasingly treated in infusion centers (Pat Pref Adherence 2009:3 335), second only to the long term tradition of infusion therapy for hematology-oncology (HO) patients. Patients with rheumatologic diseases may have reservations about being treated in a unit for "cancer" patients. Additionally, due to long term experience, infusion nurses may be more at ease caring for HO patients than individuals with RA, for example. Education about the different needs of non-HO patients is lacking for infusion nurses (J Infusion Nurs 2008;31:350). Therefore, in 2009, when building a new Cancer Institute, we considered moving non-hematology-oncology (non-HO) patients into a separate infusion unit. We assessed patient versus provider and staff satisfaction with the multispecialty combined unit to determine whether a separate infusion unit should be recommended.

Methods: A 7-question Likert scale survey about satisfaction with the infusion unit was collected over 2 weeks from 3 groups: infusion nurses, non-HO physicians and non-HO patients. The tool was designed to assess differences in patient satisfaction and perceived patient satisfaction by staff with our multispecialty infusion unit. Reliability of the tool was measured using Cronbach's alpha. Mean sums for all questions were calculated for individuals within their groups and analyzed using a one-way ANOVA. A post-hoc analysis was examined to determine which groups were similar.

Results: Surveys were completed by 13 nurses, 52 non-HO patients and 18 non-HO physicians. Missing responses resulted in a total of 49 patients, 12 nurses, and 14 physicians. The tool was reliable, with good internal consistency (Cronbach's alpha=0.92). The overall mean of the 7 items in the instrument was 28.1 $\pm$ 6.8. Patients had higher satisfaction than perceived by providers and nurses across all of the items, as evidenced by higher total mean score: patients 31.3 $\pm$ 4.8, nurses 22.1 $\pm$ 6.8, physicians 21.9 $\pm$ 4.8. These results demonstrated significant intergroup differences ($p<0.001$) shown in the figure.

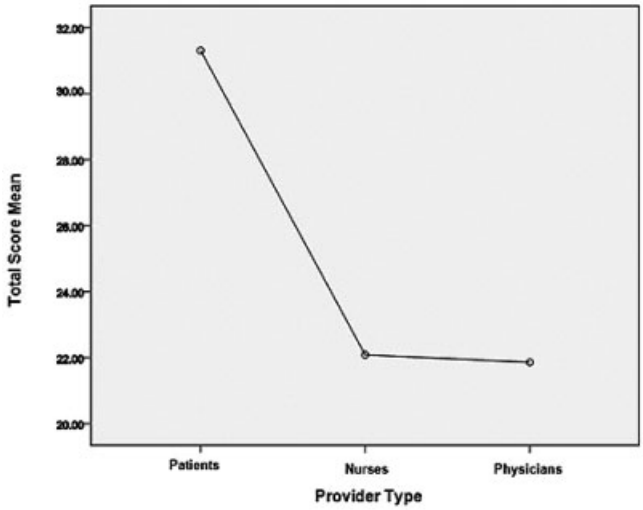

Figure 1. Mean infusion satisfaction scores by provider type.

The post-hoc analysis demonstrated that patients were significantly different from nurses and doctors ($p<0.001$), but nurses and doctors were not different from one another ($p=0.9$).

Conclusions: Physicians and nurses were more concerned than were patients about non-HO infusion therapy in a multispecialty but primarily cancer infusion center. Based on this survey, a combined multispecialty infusion center is acceptable to patients. Improved understanding of patient preferences were demonstrated to providers and nurses by this assessment. A follow-up survey is planned.

Disclosure: B. E. Ostrov: None; **K. Reynolds:** None; **L. V. Scalzi:** None.

Rheumatoid Arthritis (RA) Disease Activity Assessment and Treatment Decisions in Rheumatology Practice. J. Timothy Harrington[6], Leslie R. Harrold[4], George Reed[5], Hong Chang[3], Joel M. Kremer[2] and Jeffrey D. Greenberg[1]. [1]Millburn, NJ, [2]The Center for Rheumatology, Albany, NY, [3]Tufts Medical School, [4]UMass Medical Schl, Worcester, MA, [5]UMass Medical Schl, [6]University of Wisconsin, Madison, WI

Background: Disease Activity Scores (DASs) for RA include a variety of patient, physician, and laboratory derived data. DASs have been used in clinical trials, but seldom in rheumatology practice in the United States. Treatment is guided instead by a variably determined Physician Global Assessment (PhGA). We have studied the PhGA and other DASs using the CORRONA registry (the Consortium of Rheumatology Researchers of North America, Inc).

Objectives: 1. To compare the correlations between the PhGA and the Clinical Disease Activity Index (CDAI), Disease Activity Score 28 joint (DAS28), Global Assessment Score (GAS), and the Patient Global Assessment (PtGA). 2. To evaluate treatment changes in relation to the PhGA and PtGA.

Methods: RA patients enrolled from 6/2001 to 11/2008 were included in this study if they had 2 visit reports within 3–6 months indicating no treatment changes during that interval, and if all data required to calculate each DAS

were reported, including the 0 – 100 visual analogue PhGA, PtGA, and patient global pain scores, swollen and tender 28 joint counts, ESR, and mHAQ. Correlation coefficients were computed for the PhGA versus the PtGA and the 3 composite measures. Both the PhGA and PtGA were stratified by disease activity as controlled [0–10], mild [11–40], moderate [41–80], and high [81–100]. Agreement or disagreement between the PhGA and PtGA in terms of controlled to mild disease activity (≤40) or moderate to high disease activity (>40) were determined, as were the proportions of patients in each group whose non-biologic or biologic DMARDs were changed at their second visit or during the following 6 months.

Results: The 2456 CORRONA-enrolled RA patients who met the study inclusion criteria had a mean age was 62 (SD = 13), and most were female (76%) with established disease (mean disease duration of 12.0 years). The majority had low to moderate disease activity (mean PhGA=15.1, PtGA = 25.7, CDAI=9.3, DAS28=3.1 and GAS=10.5). After adjusting for clustering of physicians, the correlation coefficients versus the PhGA were, CDAI=0.774, DAS28=0.629, GAS=0.644, and PtGA=0.445. There was slight correlation between the PhGA and PtGA (kappa=0.20). Table 1 shows agreement between the PhGA and PtGA in 1859 patients (76%) of whom 125 (7%) had moderate to high disease activity. DMARD initiation or dose escalation occurred in only 32% of the latter patients.

Conclusions: 1. The variable correlations between the PhGA and other disease activity measures and the level of discordance between the PhGA and PtGA reflect the complexities of using DASs in clinical practice. 2. Their adoption will also require better understanding of the weak relationships observed between treatment changes and both the PhGA and PtGA, especially for those patients with moderate or high disease activity.

Table 1. Agreement/Disagreement Between the Physician and Patient Global Assessments and Treatment Changes Related to These Assessments

	Agreement		Disagreement	
	Controlled to mild disease N=1734	Moderate to high disease N=125	MD > pt* N=54	Pt > MD** N=543
DMARD initiation (N, %)	128 (7%)	28 (22%)	11 (20%)	78 (14%)
DMARD dose increases (N, %)	206 (12%)	13 (10%)	7 (13%)	72 (13%)

*Physician states moderate to high disease activity but patient reports controlled or mild disease ** Patient reports moderate to high disease activity but physician states controlled or mild disease

Scleroderma QuERI: Reduced Utility of Echocardiography in Pulmonary Hypertension Screening in the Community. James R. Seibold[6], Amparo Casanova[1], Mary Tan[1], Daniel E. Furst[5], Nicholas Hill[4], Vallerie V. McLaughlin[7], Richard M. Silver[3], Virginia D. Steen[2] and Anatoly Langer[1]. [1]Canadian Heart Research Centre, [2]Georgetown University Medical Center, Washington, DC, [3]Medical University of South Carolina, Charleston, SC, [4]Tufts Medical Center, [5]University of California Los Angeles Medical School, Los Angeles, CA, [6]University of Connecticut Health Center, Farmington, CT, [7]University of Michigan

Objective: Strategies are needed for early recognition of pulmonary arterial hypertension (PAH) in patients with systemic sclerosis (SSc, scleroderma). Current modalities include history and physical exam information, pulmonary function testing, biomarkers of myocardial stress (NTproBNP) and echocardiography with Doppler for estimate of right ventricular systolic pressure. None are fully validated and few measures have been made of a potential "care gap" between specialty centers and primary care settings.

Methods: Physicians (27 US rheumatologists including 22 community practice settings) enrolled 207 scleroderma patients (known or newly diagnosed) and provided data on a recommended panel of diagnostic tests. The QuERI methodology prompts by computerized feedback for completeness of testing and use of appropriate follow up testing, e.g. right heart catheterization (RHC). We report results on the use of echocardiography (echo).

Results: Data are reported as median, 25th and 75th percentile. Patients enrolled were 57 years old (49, 66), 90% female. There were a total of 193 patients (93%) that had at least one echo done during the study, however, only 86 (45%) of these had an RVSP value recorded and only 108 (56%) had the presence of TR jet mentioned. Estimated RVSP value was greater than the a priori threshold of 40 mmHg in 24 patients (12%) and of these 6 had RHC, 9 had only echo repeated and 9 had neither. During the follow up period, mortality/hospitalization rate was 29% among those with RVSP >40 vs 5% in those with RVSP reported <40 vs 19% in those in whom RVSP was not reported (p =0.008).

Conclusions: Echocardiography with Doppler is a robust tool for screening for pulmonary hypertension in a research setting and in specialized programs. However, these data derived from community practices suggest that RVSP and or tricuspid jet velocity measures are inconsistently reported. This is in spite of these tests being utilized as part of a funded research project focused on PAH. Interdisciplinary teamwork and education between rheumatologists and cardiologists continues to require attention Better understanding and stricter adherence to published guidelines could advance quality of care of these high-risk patients.

1005

Secondary Fracture Prevention in Home Health Care: Initial Results from a Group Randomized Trial. Meredith L. Kilgore[2], Jeffrey R. Curtis[4], Ryan C. Outman[5], Julie Locher[1], Jeroan Allison[3] and Kenneth G. Saag[5]. [1]Univ of Alabama at Birmingham, Birmingham, AL, [2]Univ of Alabama at Birmingham, [3]Univ of Massachusetts, Worcester, MA, [4]University of Alabama-Birmingham, Birmingham, AL, [5]University of Alabama-Birmingham, Birmingham, AL

Statement of Purpose: To develop and evaluate a multimodal intervention to increase rates of osteoporosis treatment in high risk patients receiving home health services.

Methods: We developed and tested an intervention to improve the rates of treatment, particularly use of prescription osteoporosis drugs, among patient with a history of fracture receiving home health services. The intervention included an educational component for nurses, a computerized care plan that prompted the nurse to initiate specific actions related to osteoporosis management, easy reference materials for physicians, prepared order sheets to facilitate osteoporosis drug prescription, and patient education materials focused on osteoporosis, fracture risks, fracture prevention, and medication adherence. Field offices (n=24) of a home health agency operating throughout Alabama were randomized to receive the intervention or serve as controls. The primary outcome measure was the rate of osteoporosis medications prescribed among patients with a fracture history. A t-Test of proportions was used to assess difference between groups

Summary of Results: We found an absolute difference of 3.9% (NS) between the treatment and control group in post-intervention osteoporosis care. The figure shows the monthly distribution of treatment rates by office before and after the intervention.

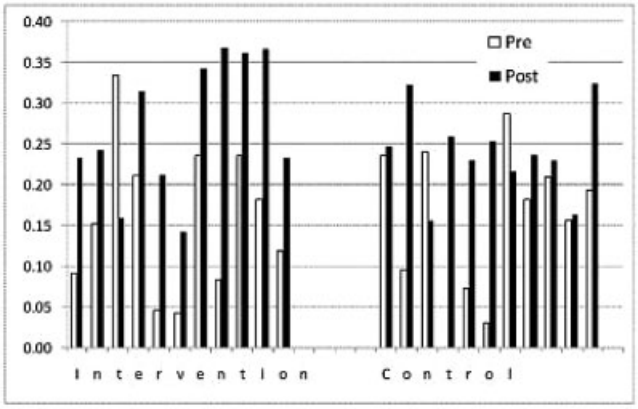

Figure 1. Pre- & post-intervention osteoporosis medication prescription rates in intervention and control groups.

While all but one of the treatment offices showed an improvement, overall rates were low, and the corresponding rates in the control arm improved as well.

A secondary analysis tested whether treatment rates increased when the nursing care plan was activated. In this case the difference was 15.3% (p < 0.0001).

Conclusions: Preliminary results do not demonstrate significant efficacy of the intervention overall, but suggest that improvements in processes of care could have significant effects on appropriate osteoporosis care delivery. Future studies should examine the impact of reinforcement of the nursing in-service training with audit and feedback to field offices on their relative performance rates, particularly with respect to activating the nursing care plan.

1006

Self-Scheduling of DXA Scans To Improve Osteoporosis Screening in Women. Amy H. Warriner[2], Ryan C. Outman[5], Kenneth G. Saag[5], Sarah L. Morgan[1], Elizabeth Kitchin[3] and Jeffrey R. Curtis[4]. [1]U of Alabama in Birm, Birmingham, AL, [2]Univ of Alabama at Birmingham, [3]Univ of Alabama at Birmingham, Birmingham, AL, [4]University of Alabama-Birmingham, Birmingham, AL, [5]University of Alabama-Birmingham, Birmingham, AL

Purpose: U.S. guidelines recommend bone density screening with central dual energy x-ray absorptiometry (DXA) in all women 65 years or older. However, less than one-third of eligible U.S. women undergo DXA testing. The main barrier in achieving greater rates of osteoporosis screening is identifying a systematic, effective and generalizable way for healthcare providers and patients to schedule and receive DXA results.

Methods: We conducted a group randomized, controlled trial involving 39 primary care physicians at the University of Alabama at Birmingham. Women 65 years or older with no identifiable DXA scan in the past 4 years cared for by these physicians were identified using administrative billing data (n=5122). Randomization was performed in two waves, each forming a cohort. In each of the two cohorts, 30 patients per physician were randomized to the intervention (sent mailed materials twice), the remainder of each physician's patients comprised the control group (received no mailing). The intervention included a patient brochure regarding osteoporosis and fracture risk and a letter providing patients the opportunity to self-schedule a DXA. Results from the two cohorts were similar and pooled for analysis. Stratified results compared receipt of DXA among women receiving primary care proximate to the site where the DXA scanner was located (62% of study population) vs. a more distant location which required additional travel to the DXA scanner.

Results: Of 5122 identified women meeting inclusion criteria, 978 women were randomized to the intervention group and 4,144 to the control group. A total of 19.5% of women in the intervention group scheduled and received a DXA, compared to 6.3% women receiving DXA in the control group (Risk Difference for DXA receipt 13.2%, 95% CI 10.8 16.0).

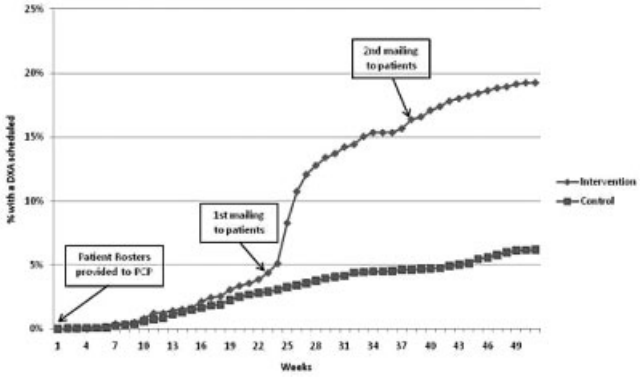

Figure. Scheduling of DXA scans in control and intervention.

Receipt of DXA in main clinic patients compared to patients from satellite clinics was greater in the main clinic patients for both the intervention group (22.7% vs. 13.4%, respectively; RR 0.59, 95% CI 0.43 0.80) and the control group (7.6% vs. 4.3%, RR 0.57, 95% CI 0.43 0.74).

Conclusions: DXA scan scheduling and receipt was improved significantly through the use of a simple mailed osteoporosis brochure and the availability for patients to self-schedule their own scans. This modality may be an effective component of a multi-faceted quality improvement program to increase rates of osteoporosis screening.

1007

Spanning Generations: Appointment Reminder Preferences among Outpatient Rheumatology Patients. Carl Gauthier[3], William E. Davis[2] and Robert J. Quinet[1]. [1]Ochsner Med Ctr-New Orleans, New Orleans, LA, [2]Ochsner Med-Ctr-New Orleans, New Orleans, LA, [3]Ochsner Med-Ctr-New Orleans, Hammond, LA

Background: Up to 21% of patients miss their outpatient clinic appointments. Forgetfulness is a major reason for non-attendance, and studies have shown that appointment reminders increase attendance rates. Text/Short Message Service (SMS) technology has been a promising modality in the deliverance of appointment reminders in primary care and subspecialty clinics. Sociologic studies have reported differences in technology usage among generational ages. While studies focusing of the appointment reminder preferences of patients in outpatient rheumatology clinics are limited, they have suggested that age may be a determinant of preferred reminder modality. No studies performed in the United States have been published. The goal of the present study is to determine appointment reminder preferences among outpatients in a United States rheumatology clinic and ascertain whether these preferences vary by generational age.

Methods: Between December 2009 and April 2010 an anonymous, self-directed questionnaire was intermittently administered to all rheumatology outpatients attending our clinic. Included in this survey were questions concerning age, current opinions regarding the usefulness of appointment reminders, access to technology, and preferences regarding method and timing of appointment reminders. Patients were divided into generational age groups as follows: Generation Y (18–28 years), Generation X (29–49 years), Baby Boomers (50–67 years), Silent Generation (68–85 years), and GI Generation (≥ 86 years). Overall group preferences, as well as preferences by generational age, were analyzed.

Results: A total of 637 surveys were included in the final analysis. The patients surveyed ranged in age from 18 to 94 years, with a mean age of 58 years. Baby Boomers comprised the largest percentage of the patient population (46%), followed by Generation X (25%), and the Silent Generation (24%). Over 99% of patients viewed appointment reminders as a good idea. Overall, the preferred method of reminder was a phone call (52%), followed by standard mail (24%). SMS was the least preferred modality (4%). There was a significant difference in the mean ages between reminder groups ($P < 0.0001$). Generation Y was more likely to prefer SMS reminders ($P < 0.0001$) and this was the preferred method of reminder in that age group. The mean age of those preferring SMS reminders was 39 years, which was significantly younger than any other reminder group. Overall, the preferred time frame in which to receive reminders was 1–2 days (46%), followed closely by 3–4 days (26%). Only 12% of patients surveyed wished to be reminded about their outpatient appointments ≥ 8 days in advance. Preferred time frame did not vary between age groups. Patient who preferred letter reminders were more likely to desire advanced notice ($P < 0.0001$).

Conclusions: Improved attendance rates in rheumatology clinics would be beneficial given the requirement for disease and medication monitoring. Patients value appointment reminders. Phone call reminders are preferred in all generational age groups except Generation Y. The preference of new modalities such as SMS varies with age and is limited to the younger patients of Generation Y.

1008

Survey of Teen Transition Needs among Pediatric Rheumatologists in the United States and Canada: Barriers, Services and Opportunities. Tova Ronis[3], Stacy P. Ardoin[2], Patience H. White[1] and Peter Chira[3]. [1]Arthritis Foundation, Bethesda, MD, [2]Ohio State University, Columbus, OH, [3]Stanford University, Palo Alto, CA

Purpose: To assess teen transition needs, barriers and opportunities among pediatric rheumatology providers

Methods: Using surveymonkey, we queried all Childhood Arthritis and Rheumatology Research Alliance (CARRA) members about teen transition care including needs, barriers and opportunities for transition program development. We compared our results to the American Academy of Pediatrics (AAP) 2008 survey on transitional care.

Results: 158/291 (54%) providers responded. Top two major stated barriers to transition are fragmented adult medical care and lack of sufficient time to provide services (Table 1).

Table 1. Barriers Affecting the Provision of Transition Support Services in Pediatric Rheumatology Practices

Barriers	Major Barrier	Somewhat a barrier
Pediatric staff lack sufficient time to provide transition services	40.3%	42.4%
Fragmentation of primary and specialty care in adult care	39.2%	44.8%
Adolescents/parents/physicians have developed an effective bond that is hard to break	32.6%	59.7%
Adolescents' lack of knowledge about their own condition and/or skills to self-advocate at physician visits	31.3%	61.8%
Pediatric staff lack skills in transition planning	28.7%	51.7%
Lack of knowledge about or linkages to community resources that support older adolescents/young adults	27.0%	61.0%
Lack of available adult specialists to care for older adolescents/young adults with special needs	26.4%	47.9%
Lack of insurance reimbursement for transition services	25.4%	38.7%
Lack of available family physicians and internal medicine physicians to care for older adolescents/young adults with special needs	24.5%	44.8%

As a part of routine transition care services, respondents help with finding an adult rheumatologist (70%), discuss confidentiality and consent before 18 (49%), assist with medical summary (51%), provide educational packets (42%), create an individualized transition plan (21%), utilize an assessment of transition readiness (30%), and 2/3 discuss patient's educational and vocational plans. Compared with AAP survey participants, pediatric rheumatologists are similar or more proficient in many transition practices, except for creating a medical summary and referring to a primary care provider.

Useful resources for the transition process include brochures and pamphlets (91%); open ended discussions during visits (91%); and having a portable personal health/medical record (82%). 78% use open ended discussions already, but use of phone calls (56%) and emails (43%) directly with teens is less frequent. Providers do not want to communicate via texting (58%) or social networking (49%).

Outcomes ranked as very important in defining a successful transition are survival (76%), seeing an adult rheumatologist within 6 months of the final pediatric rheumatology visit (66%), and maintaining insurance coverage (57%).

Discussion: Pediatric rheumatologists report many barriers to transition care, revealing unmet needs in improving teen self-efficacy, and assuring adequate provider time, education and reimbursement for transition planning. Technology offers some potential solutions including portable personal health records and health information access via hospital/health insurance portals. From the provider perspective, assessment of long term transition outcome is focused on quantitative measures rather than qualitative items as provider/patient satisfaction or patient quality of life.

Conclusion: Pediatric rheumatologists report the same concerns about providing transition care as general pediatricians. Opportunities include creating a standardized transition protocol to be followed by CARRA members, incorporating technology to facilitate the process such as developing personal health records, educational programs, and tracking long term outcomes after transfer of care.

Testing Patient Knowledge about Methotrexate: Development and Validation of the Methotrexate in Rheumatoid Arthritis Knowledge Test (MiRAK). Sabina Ciciriello[3], Ian Wicks[4], Richard H. Osborne[2] and Rachelle Buchbinder[1]. [1]Cabrini Medical Center, Malvern, Australia, [2]Deakin University, Melbourne, Australia, [3]Royal Melbourne Hospital, Melbourne, Victoria, Australia, [4]Royal Melbourne Hospital, Melbourne, Australia

Background: The study describes the development and validation of the MiRAK, a new tool designed to specifically measure patient knowledge about methotrexate (MTX) treatment for RA. MTX is an effective treatment for RA and is the cornerstone of modern RA treatment. However it is not without risks and patients need to understand complex information in order to make an informed decision about starting MTX and to take it safely. In planning a randomized controlled trial to assess the effectiveness of a new multimedia patient education program about MTX and RA we found no suitable outcome tool designed to measure patient knowledge about MTX.

Methods: The knowledge tested by the MiRAK was guided by a literature review and consultation with rheumatologists (N=15) as well as concept mapping workshops with RA patients (N=24) exploring their information needs when starting MTX. To ensure face validity, draft items of the MiRAK were tested with both patients and rheumatologists. The draft questionnaire was administered to 317 RA patients treated with MTX (response rate 53%). The data was analyzed using item response theory with a Rasch model. To assess test-retest reliability, 146 respondents were sent a second copy of the MiRAK two weeks later (response rate 90%).

Results: 60 candidate questions were generated, with True/False/Don't Know response options, to test a wide range of knowledge about MTX. Rasch analyses revealed that the MiRAK was unidimensional allowing the questions to be summated into a single knowledge score. Scores ranged from 8–57 correct responses out of 60 (mean (SD) 35.78 (7.7)). Scale fit indices revealed that the observed responses fit well with the Rasch model indicating sound measurement properties. The MiRAK questions covered all levels of underlying knowledge in the sample population. The MiRAK had excellent internal consistency (Cronbach's alpha 0.84) and test-retest reliability (ICC 0.89).

Conclusions: Advanced psychometric analyses were used to generate the MiRAK and provide strong evidence for its validity and reliability. Further work is underway to evaluate its sensitivity to change. The MiRAK may be useful as an outcome measure in both clinical trials of interventions designed to educate patients about MTX, and in routine care to assess patient knowledge of MTX prior to commencement of treatment.

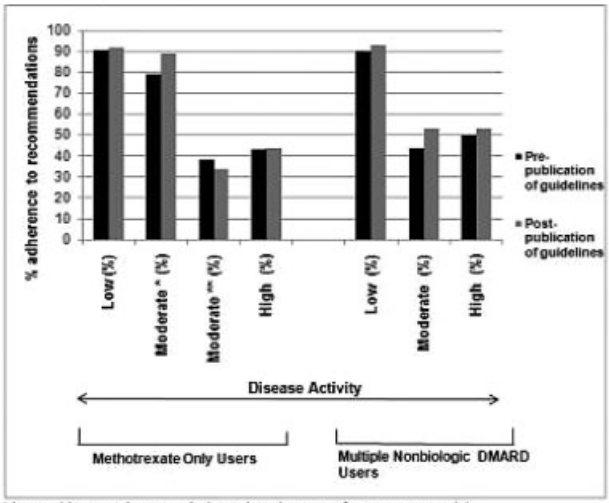
The Impact of the ACR Treatment Recommendations on Physician Prescribing in a U.S. Cohort of Rheumatoid Arthritis Patients. Leslie R. Harrold[3], Jeffrey D. Greenberg[1], Jeffrey R. Curtis[5], Daniel E. Furst[6], Mary Jane Bentley[4], Ying Shan[4], George Reed[2] and J. Timothy Harrington[7]. [1]Millburn, NJ, [2]george.reed@umassmed.edu, [3]UMass Medical Schl, Worcester, MA, [4]Umass Medical School, [5]University of Alabama - Brimingham, Birmingham, AL, [6]University of California Los Angeles Medical School, Los Angeles, CA, [7]University of Wisconsin, Madison, WI

Purpose: To examine changes in prescribing patterns in relation to publication of the American College of Rheumatology (ACR) Recommendations for the Use of Nonbiologic and Biologic Disease-Modifying Anti-Rheumatic Drugs (DMARDs) in Rheumatoid Arthritis (RA). Specifically we examined nonbiologic and biologic DMARD use based on disease activity in order to evaluate the impact of the ACR recommendations on medication patterns.

Methods: We identified biologic naïve RA patients cared for by US rheumatologists participating in the CORRONA registry with visits prior to and/or at least 6 months after publication of the ACR recommendations on 6/15/08 (time period: 2/02–6/08 vs. 12/08–12/09). Initiation or dose escalation of biologic and nonbiologic DMARDs in response to active disease (using the CDAI) was assessed in comparison to the ACR recommendations. The population was divided into two mutually exclusive cohorts: 1) methotrexate (MTX) only users; and 2) multiple nonbiologic DMARD users. The proportion of patients with treatment regimens compliant with the ACR recommendations before and after publication was compared in the two cohorts stratified by disease activity using regression models adjusting for clustering of physician and geographic region.

Results: In MTX only users, 91–95% of those with low disease activity and 79–89% of those with moderate disease activity and good prognosis were receiving nonbiologic DMARDs, consistent with the recommendations. Among those with moderate disease activity and poor prognosis, 20–23% had their MTX dose increased and/or initiated another nonbiologic DMARD and 14–15% initiated a biologic, resulting in 34–38% of patients receiving care consistent with the recommendations. Similarly, among those with high disease activity, 24–26% had their MTX dose increased and/or were initiated on a non-biologic DMARD and 18–19% initiated a biologic (43–44% receiving care consistent with the guidelines). In the multiple nonbiologic DMARD users with moderate activity, 44–53% received care consistent with the recommendations (30% had initiation and/or dose escalation of their nonbiologic DMARD therapy and 14–21% initiated a biologic). Among those with high disease activity 50–53% received care consistent with the recommendations (30% with initiation and/or dose escalation of their nonbiologic DMARD therapy and 9–22% initiated on a biologic). In adjusted analyses there were no significant differences in prescribing pratices after publication of the treatment recommendations.



*those with a good prognosis (meaning absence of a poor prognosis)
**those with a poor prognosis (mHAQ >0.5, presence of rheumatoid nodules, erosive changes on x-ray, rheumatoid factor positive and secondary Sjogren's

Figure 1. Proportion of patients adherent to the ACR Recommendations stratified by disease activity and drug use.

Conclusions: Only approximately 40 to 50% of RA patients in the CORRONA US registry with high disease activity or moderate disease activity with a poor prognosis received care consistent with the current ACR treatment recommendations within 6 to 18 months after their release. In addition, publication of the recommendations did not appear to change prescribing patterns.

The Preliminary Testing of a Core Set To Monitor SLE Patients in Routine Clinical Practice. Marta Mosca[6], Chiara Tani[6], Federico Quaglierini[6], Katia Goehner[5], Joao Matos Costa[2], Oskar Psenak[3], Magdalena Szmyrka-Kaczmarek[7], Jan Sznajd[4], Nuntana Kasitanon[1] and Stefano Bombardieri[6]. [1]Chiang Mai, University, Thailand, [2]Hospital de Santarem, Portugal, [3]Saltzbugr University, Austria, [4]University Hospital, Krakow, Poland, [5]University Hospital, Zurich, Switzerland, [6]University of Pisa, Italy, [7]Wroclaw University, Poland

Introduction: Systemic lupus erythematosus (SLE) is a complex disease; patient assessment in clinical practice mainly relies upon the experience of the treating physician and thus is subject to great variability. Unexplained variability may affect health care and lead to poor outcomes and complicates comparisons among practices. Recently "EULAR Recommendations for monitoring SLE patients in clinical practice and in observational studies" have been published. In addition a core set of minimal assessments to evaluate SLE patients in clinical practice was developed. The strength of this core set is represented by the fact that it was developed by combining available evidence and expert opinion, it includes only feasible variables and can be easily done in routine clinical practice.

Aim of the Study: Aim of the present study was to preliminary test the feasibility of this core set in routine clinical practice and to develop a computerized data base to collect patient's data.

Methods: Seven centres (Austria, Italy, 2 Poland, Portugal, Switzerland, Thailand) participated to the study and were asked to collect data of at least 5 consecutive SLE patients during routine assessment.

Results: Sixty-five patients were enrolled (55 Caucasians and 10 Asians; F: 64; M: 1; mean age 41 years), on average 10 minutes were required to fill the chart of the core set, although the time required appeared related with the type of organ involvement.

Disease activity using validated indices was calculated in all patients in routine clinical practice (ECLAM (15 patients): mean 2, SLEDAI (50 patients): mean 5), while the SLICC/ACR damage index (mean value 1) and the quality of life were evaluated only in 49% of patients. With respect to the adherence to recommendations, interestingly, this preliminary analysis showed that 86% of patients treated with immunosuppressive drugs had been assessed for the presence of chronic HBV and HCV infections and only 38% for tuberculosis. In addition, 15% of patients had never been assessed for osteoporosis or for lipid profile.

Following this preliminary testing, and based on the participants comments and suggestions, a Web based data base has been developed to collect data on SLE patients using the core set chart and including the ECLAM and SELENA- SLEDAI and the SLICC/ACR damage index. Recorded data can be downloaded and used for additional statistical analysis.

Conclusions: These preliminary data show that the use of a standardized core set in routine clinical practice is feasible and could represent a tool to reduce variability in data collection and to increase adherence to recommendations in clinical practice and therefore could lead to improvement of quality of care and of data travelling.

1012

The Use of Electronic Health Record To Improve Tuberculosis Screening in Pediatric Rheumatology Patients Receiving Biologic Response Modifiers. David W. Moser[4], Elaine Haddix[5], Mary Beth Burns[5], James Brown[3], Anna Carmela P. Sagcal-Gironella[4], Thomas A. Griffin[1], Hermine Brunner[2] and Esi M. Morgan DeWitt[6]. [1]Childrens Hospital Med Ctr, Cincinnati, OH, [2]Cincinnati Child Hosp Med Ctr, Cincinnati, OH, [3]Cincinnati Children's Hospital, [4]Cincinnati Children's Hospital Medical Center, Cincinnati, OH, [5]Cincinnati Children's Hospital Medical Center, [6]Cincinnati Children's Hospital, Cincinnati, OH

Purpose: Activation of latent tuberculosis (TB) has been associated with tumor necrosis factor inhibitor (TNFi) use. As a result, screening with tuberculin skin testing (TST) is recommended prior to initiating treatment with biologic response modifiers (BRMs). However, compliance with this recommendation is imperfect. The electronic health record (EHR) can be leveraged to measure and improve compliance. We conducted a quality improvement (QI) project using the EHR and other interventions to increase the proportion of patients with Juvenile Idiopathic Arthritis (JIA) screened for TB prior to the start of BRMs.

Method: During January 2010 to May 2010 we conducted a QI initiative employing "Plan, Do, Study, Act" (PDSA) cycle improvement ramps. Baseline data from March 2008 to December 2009 was obtained by querying the EHR for all patients who initiated a BRM, the date of TST placement, and whether a result was reported. During the project's first three months, we developed non-EHR based interventions which included: Introduction of a log to track patients who had a TST placed, development of a patient instruction sheet and TST results card, and initiation of reminder phone calls 40–48 hours after TST placement. Rheumatology providers completed a weekly survey of new BRM starts to ensure that no eligible patients were missed. At the end of the third project month, the intervention was modified to include an EHR based best practice alert (BPA) instructing physicians to confirm the placement of a TST each time a BRM is ordered. An EHR BPA is a pop-up box programmed into the EHR with a reminder and an order that

satisfies the alert. The outcome measure was the proportion of patients who received a TST with documentation of results within 180 days of BRM start.

Results: Our baseline data spanned a period of 21 months. There were 247 eligible patients identified; of these, 65 (26.3%) had both a TST placed and resulted. During the 3 month period of non-EHR based interventions, 30 eligible patients were identified, 60.0% of which had both a TST placed and resulted. After the EHR BPA was activated 9 patients were identified in six weeks, 8 (88.9%) of which had TSTs ordered and resulted. A t-test comparing non-EHR based interventions to baseline was significant at $p<.001$. A t-test comparing the EHR BPA phase to the non-EHR phase generated a $p=0.225$.

Conclusion: We observed a statistically significant improvement in the proportion of patients with JIA screened for TB prior to the start of BRMs compared to baseline during the non-EHR portion of our QI project. Further improvements were seen once the EHR BPA was activated. Additional time and patients will be required to determine if the improvement with the EHR BPA intervention reaches conventional levels of statistical significance. We conclude that the use of EHR in conjunction with non-EHR based interventions may be an effective tool to improve the proportion of JIA patients screened for TB prior to the start of BRMs.

Purpose: An international survey was conducted to measure the level of agreement and application of the 10 recommendations developed by the Treat to Target initiative (Smolen JS, et al. *Ann Rheum Dis*. 2010), aimed at defining therapeutic goals and achieving optimal outcomes for rheumatoid arthritis (RA).

Methods: A10-point Likert items scale (1 = fully disagree, 10 = fully agree) measured the level of agreement with each of 10 recommendations. A 4-point Likert items scale (1 = never, 2 = not very often, 3 = very often, 4 = always) assessed the degree to which each recommendation was being applied in current daily practice. If responders answered "never" or "not very often", they were asked whether they would change their practice according to the particular recommendation.

Results: 1568 physicians, representing 33 countries, participated. Practices in University hospitals, general hospitals, and private clinics were well represented, with 37%, 31%, and 21% of respondents, respectively. Years in practice ranged from 0 to 52 years (mean 18+/−10.72. Both agreement with and application of the recommendations were high. Recommendations #1 ("The primary target for treatment of RA should be a state of clinical remission") and #10 ("The patient has to be appropriately informed about the treatment target and the strategy planned to reach this target under the supervision of the rheumatologist") received the highest agreement scores of 9.156 and 9.272, respectively. Recommendations #5 ("Measures of disease activity must be obtained and documented regularly, as frequently as monthly for patients with high/moderate disease activity or less frequently [such as every 3 to 6 months] for patients in sustained low disease activity or remission") and #3 ("While remission should be a clear target, based on available evidence low disease activity may be an acceptable alternative therapeutic goal, particularly in established long-standing disease") received the lowest agreement scores, 8.445 and 8.515, respectively, although these are still very high. In regard to application of recommendations in daily practice, the majority of responses were "always" and "very often". However, recommendation #5 also received the highest number of "never" or "not very often" responses (12.43%). Of the participants who were currently not applying these recommendations in clinical practice, many (36.27% to 68.18% depending on the recommendation) were willing to change practice according to the recommendations. However, 38.92% of participants not applying recommendation #5 indicated they would not change their practice.

Conclusion: The results of this survey demonstrated great support of "Treating RA to Target" recommendations amongst the international rheumatology community. Since these recommendations are based on evidence and consensus, additional efforts may be needed to encourage their application also amongst clinicians who are hesitant to change their practice.

Funding for this initiative was provided through Abbott Laboratories.

Using an Electronic Data Capture System To Measure Outcomes in Patients on Biologic DMARD Therapy: The Rheumatology Health Tracker (RHT). Sita A. Narayanan[1], Jeffrey R. Lisse[2], Alexis A. Alvarez[4], Catherine Lo, Rafael G. Grau[3], Eric P. Gall[2] and Oscar Furet[4]. [1]Univ of Arizona, Tucson, AZ, [2]Univ of AZ Arthritis Ctr, Tucson, AZ, [3]Univ of AZ Arthritis Ctr, Indianapolis, IN, [4]Univ of AZ Arthritis Ctr

Background: Patient outcomes are increasingly important to track the response to disease modifying drugs (DMARD) over time. The Rheumatology Health Tracker (RHT) is an electronic capture system that tracks the outcomes in patients with rheumatoid arthritis on different biologic DMARDS over time in a real world setting, and can be important in detecting outcomes. This report evaluated outcome measures for a patient population undergoing biologic DMARD therapy after a second year of analyzing RHT use in an academic rheumatology clinic.

Methods: Patients with rheumatoid arthritis were already participating in an observational study using a web based electronic capture system. After informed consent, at each visit they were asked to record the following outcome parameters: Involved Joint Count (IJC), Short Form 12 (SF-12), Health Assessment Questionnaire (HAQ), and Visual Analog Scale of their overall disease activity (VAS), demographic information, and information on health care utilization. Practitioners then filled out a Tender Joint Count (TJC), Swollen Joint Count (SJC), and a visual analog scale. These outcomes were analyzed after a year and found to be statistically and clinically stable. A second annual analysis was performed on the same biologics with inclusion of newly consented patients resulting in a larger sample size.

Results: There were 155 patients enrolled in the study who were on biologic DMARDs. Overall HAQ was 0.824, SJC was 5.062, TJC was 6.662, SF-12 was 35.302, and VAS was 24.175. Initial baseline HAQ scores for the different biologics was 0.5547 for etanercept (n=41), 0.9184 for infliximab (n=39), 0.642 for adalimumab (n=41), 0.99 for rituximab (n=20), and 1.18 for abatacept (n=14). The change in HAQ score between the initial visit and the first follow up visit was +0.175 for etanercept, −0.088 for rituximab, −0.218 for infliximab, +0.121 for adalimumab, and −0.151 for abatacept. SF12 scores all increased however infliximab, rituximab, and abatacept showed the most improvement in patient-perceived health status.

Conclusions: Electronic medical records offer a means to record outcome parameters in patients on biologic DMARDs in a clinic outpatient setting over time. This reflects the use of different biologics in our practice. This second

annual analysis showed the utility of using this system over time to record patient and physician reported outcomes.This allows long-term monitoring of patients on biologic DMARDs with the RHT, and gives physicians the opportunity to adjust treatment accordingly. It is an accessible, reproducible electronic information source that can be accessed by multiple practitioners to assess and treat their patients over time.

Anti-Cyclic Citrullinated Peptide Antibodies in Rheumatoid Arthritis Patients with Lymphoma. Eva Baecklund[10], Karin Ekström Smedby[3], Carin Backlin[5], Johan Rönnelid[2], Erik Åhlin[2], Rene Toes[6], Johan Askling[4], Ephraim Hochberg[1], Mandakolathur Murali[7], Lars Klareskog[8], Tom Huizinga[9], Fred Hochberg[1] and Jonathan Kay[11]. [1]Cancer Center, Massachusetts General Hospital, Boston, [2]Clinical Immunology, Uppsala University, [3]Epidemiology Unit, Karolinska Institutet at Karolinska University Hospital, Stockholm, [4]Epidemiology, Rheumatology, Karolinska Institutet at Karolinska University Hospital, Stockholm, [5]Genetics and Pathology, Uppsala University, [6]Immunology, Leiden University Medical Center, [7]Immunology, Massachusetts General Hospital, Boston, [8]Karolinska University Hospital, Stockholm, Sweden, [9]Rheumatology, Leiden University Medical Center, [10]Rheumatology, Medical Sciences, Uppsala University, Uppsala, Sweden, [11]UMass Memorial Medical Center, Worcester, MA

Background: The risk for lymphoma and, in particular, diffuse large B-cell lymphoma (DLBCL), is increased in patients with rheumatoid arthritis (RA). No biomarkers for the development of lymphoma in patients with RA have been identified.

Objective: To investigate if anti-CCP antibody levels and subclasses are associated with occurrence of lymphoma in patients with RA.

Methods: We identified 37 index patients with RA and subsequent lymphoma from two population-based Swedish case-control studies, one of lymphoma (the SCALE study, 1999–2002) and the other of RA (the EIRA study, 1996–2006). To each index RA-lymphoma case, three pairs of control subjects were matched based upon age at diagnosis of RA or lymphoma (± 5 years) and lymphoma subtype. Controls consisted of 73 patients with RA (EIRA), 73 patients with lymphoma only (SCALE), and 74 individuals with neither disorder (EIRA). Blood samples were collected from all subjects at either diagnosis of lymphoma (SCALE) or of RA (EIRA). The self-reported RA diagnosis (SCALE) was validated in medical records. Blood samples from all 257 study subjects were analyzed for anti-CCP IgG (ELISA, Eurodiagnostica) and ACPA-isotypes: anti-CCP IgG1–4, IgA, and IgM (Leiden). Anti-CCP IgG levels ≥25 U/ml were defined as positive. The chi^2 and Wilcoxon rank sum tests were used for statistical analysis.

Results: Similar proportions of patients with RA only (65%) and of patients with RA-lymphoma (65%) had positive anti-CCP IgG levels, as did lymphoma cases (1.4%) and population controls (3%). Similar results were obtained for all anti-CCP subclasses. The median level of anti-CCP IgG in index patients with RA- lymphoma (306 U/ml; min 1- max 5033) was higher than in non-lymphoma RA patients (140 U/ml; min 0-max 5706), but the difference was not statistically significant ($p=0.25$).

The most common lymphoma subtype among the index cases was DLBCL (37%). The median anti-CCP IgG was numerically higher in RA patients with DLBCL (495 U/ml; min 1-max 5033) compared to patients with RA and other non-Hodgkin lymphoma subtypes (175 U/ml; min 1-max 3626), ($p=0.87$).

Conclusion: This population-based study with carefully matched controls does not support an association between IgG anti-CCP antibody positivity or levels or ACPA subclasses (IgG, IgG1–4, M or A) and lymphoma occurrence in RA. Further studies are needed to identify other potential biomarkers of lymphoma occurrence in RA.

1016

Assessment of Cardiovascular Risk in Rheumatoid Arthritis. Impact of the New EULAR Recommendations. Montserrat Robustillo, Carmen Gomez-Vaquero, Javier Narváez, Jesus Rodriguez-Moreno, Paula Estrada, Laura López-Vives and Joan M. Nolla. Rheumatology Service. Hospital Universitari de Bellvitge

Introduction: Rheumatoid arthritis (RA) is a systemic inflammatory disease that is associated with an increased cardiovascular risk and a greater number of ischemic events than the general population.

Objectives: To evaluate the cardiovascular risk and frequency of ischemic events in a group of patients diagnosed with RA.

Material and Methods: We have included, consecutively, two hundred patients with rheumatoid arthritis diagnosed according to 1987 criteria of American College of Rheumatology (ACR), which are monitored regularly in the outpatient clinic of a tertiary care university hospital. We have reviewed retrospectively both the physical and the informatised medical record in the hospital and primary care and have gathered the following variables: a) age, sex, weight and height, b) duration of RA, c) parameters of activity of the disease, d) rheumatoid factor and anti-CCP, e) cardiovascular risk factors (smoking history, hypertension, hyperlipidemia, diabetes mellitus) and f) vascular ischemic events registered to date. From the age, sex, smoking history, arterial blood pressure levels and serum total cholesterol, we calculated the SCORE cardiovascular risk index (low-risk model). We calculated the SCORE cardiovascular risk index and we multiplied the result by 1.5 in patients who fulfilled the last EULAR recommendations (modified SCORE). The data were collected in an Access 2003 database and analyzed with the statistical software SPSS. Statistical significance was set at $p < 0.05$.

Results: The mean age of patients was 60 ± 12 years. 76% were women. The mean duration of RA was 12 ± 10 years. 82% were rheumatoid factor positive and 77%, positive anti-CCP. According to the DAS28, 51% of patients had a low activity, 39% moderate and 10% high. With regard to cardiovascular risk factors: 30% of patients were smokers or former smokers, 41% were diagnosed with hypertension, 52% were dyslipidemic and 12% had diabetes (2%, treated with insulin). The medium SCORE index (modified according to EULAR criteria) was 2.7 ± 2.9%, the change was indicated in 59% of patients. The cardiovascular risk calculated by SCORE correlated with classical vascular risk factors (age, male gender, smoking, hypertension and diabetes) and C-reactive protein. The modified SCORE is correlated also with positive RF and positive anti-CCP.

With regard to ischemic events, nine patients had had one or more: coronary (2 angina pectoris and 5 acute myocardial infarctions) or neurologic (two transient ischemic attacks and three strokes). Patients who had presented an ischemic event had higher age and higher modified SCORE than the other patients and they were more frequently male and smokers in a statistically significant way.

Conclusions: In patients with RA in our series, the incidence of cardiovascular risk factors and ischemic events is significant and is related to classical cardiovascular risk factors and C-reactive protein.

1017

Association between Serum Osteoprotegerin Levels and Carotid Atherosclerotic Plaque in Patients with Rheumatoid Arthritis. Yu Asanuma, Yuki Shimada and Toshihide Mimura. Department of Rheumatology and Applied Immunology, Faculty of Medicine, Saitama Medical University

Background: Osteoprotegerin (OPG), a regulator in bone resorption, is implicated in pathogenesis of rheumatoid arthritis (RA) and atherosclerosis. The expression of OPG is detected in human atherosclerotic

plaque. OPG concentrations are elevated in patients with coronary artery disease and associated with severity of disease and increased cardiovascular mortality in general population. The purpose of this study is to determine the relationship of serum OPG levels, traditional coronary risk factors and RA-related factors to carotid atherosclerotic plaque in patients with RA.

Methods: Ninety-six patients with RA were studied (84.4% female, age 60±10(SD) years). Serum OPG levels were measured by ELISA. All patients underwent carotid ultrasonography. The relationship between the patients' clinical characteristics and the presence or absence of carotid atherosclerotic plaque was examined. Spearman correlation analyses and Mann-Whitney tests were used to define the association between OPG levels and other variables. Logistic regression was used to assess association among OPG, cardiovascular risk factors, markers of inflammation and carotid plaque.

Results: OPG concentrations were significantly higher in patients with plaque than those without plaque (median: 1374 vs. 868 pg/ml, $P<0.001$). The prevalence of carotid plaque increased across OPG quartiles (p trend=0.005). Older age and higher levels of CRP or MMP-3 were more common in RA patients with plaque. Significant difference was not found in sex, disease duration, blood pressure, BMI, smoking, LDL cholesterol, DAS28, modified Sharp score and daily dose of prednisolone between RA patients with and without plaque. Serum OPG levels were correlated with CRP after adjusting for age and sex ($P=0.009$). After adjusting for age, sex and CRP, increased levels of OPG were associated with carotid plaque in patients with RA ($P=0.024$), however the association was not found between other risk factors for atherosclerosis, markers of inflammation or disease activity and presence of carotid plaque.

Conclusions: Patients with RA, a group that is known to have accelerated coronary atherosclerosis, also have increased concentrations of OPG, a mediator linked to coronary artery disease in other populations. OPG concentrations are independently associated with carotid plaque. Increased OPG levels would be a useful biomarker for atherosclerosis in patients with RA.

Body Composition Trends in Patients with Rheumatoid Arthritis: Associations with Disease Characteristics and Inflammatory Markers. Henry R. Kramer[1], Joan M. Bathon[1] and Jon T. Giles[2]. [1]Division of Rheumatology, Johns Hopkins University, Baltimore, MD, [2]Johns Hopkins Univ, Baltimore, MD

Background: Recent evidence suggests that patients with rheumatoid arthritis (RA) have altered body composition (BC) relative to non-RA patients. However, while it is hypothesized that systemic inflammation and the RA disease process play a major role in the development of these alterations, these associations have not been thoroughly evaluated.

Methods: Using a longitudinal study design, BC was evaluated by total body dual-energy x-ray absorptiometry (DXA) in 152 patients enrolled in the Evaluation of Subclinical Cardiovascular Disease and Predictors of Events in Rheumatoid Arthritis (ESCAPE-RA) study. DXA was performed at visits 1 and 3. DXA-derived measures included total body fat mass (TFM), fat mass index (FMI; kg/m^2 of height), total body lean mass (TLM), and fat-free mass index (FFMI; kg/m^2). Associations of RA characteristics with yearly rates of change in BC measures were explored using multivariate linear regression, adjusting for baseline BC and pertinent sociodemographic and lifestyle characteristics identified from univariate models.

Results: Of the 152 patients, mean age was 63 years, 64% were women, and 88% were Caucasian. Median RA disease duration at baseline was 12 years, 75% of patients were seropositive by RF or CCP, and median DAS28-CRP was 3.1. Median follow-up time was 3.2 years. As expected, significant gender differences in BC were detected, with men having significantly greater TLM than women and women having greater TFM than men. However, the rates of change were similar by gender, with a median gain of 0.31kg/year for TFM and a median loss 0.27kg/year for TLM. FMI increased at a median rate of 0.16kg/m^2·year, and FFMI decreased at a median rate of 0.43kg/m^2·year. Yearly change in FMI was negatively correlated with depression score ($p=0.044$) and cumulative CRP ($p=0.038$). Compared to seronegative patients, those with RF or CCP had a significantly lower adjusted yearly change in FMI (Figure 1A). Patients with higher baseline Sharp scores demonstrated a higher adjusted yearly change in FFMI compared to those with lower scores (Figure 1B).

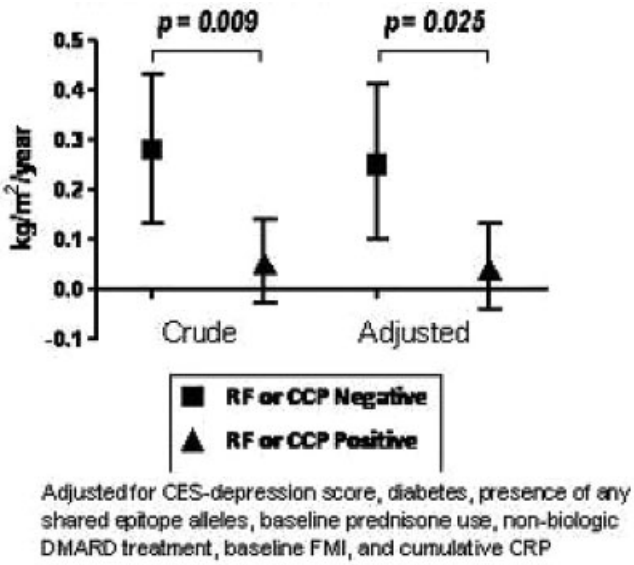

Figure 1A. Crude and adjusted average yearly change in FMI according to RF or anti-CCP status.

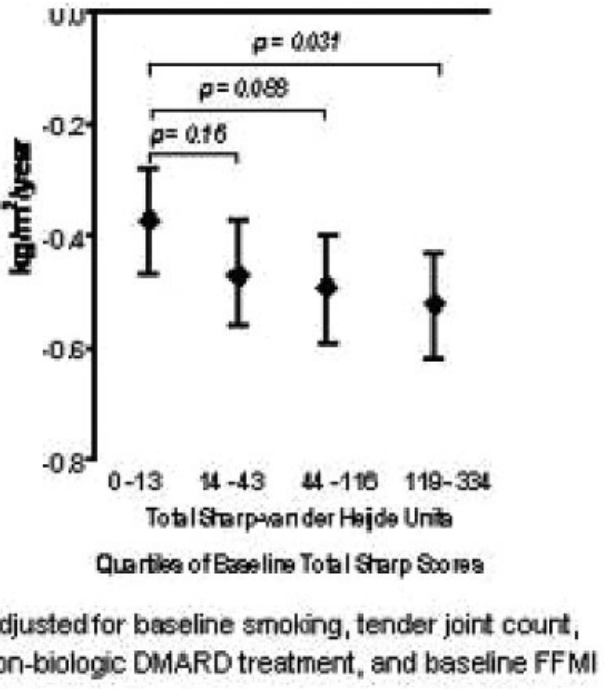

Figure 1B. Adjusted average yearly change in FFMI stratified by quartiles of baseline total Sharp scores.

Conclusions: In RA patients, yearly changes in BC were similar in both men and women, and patients with greater disease burden by radiograph experienced a higher rate of loss of lean mass. Interestingly, in our study population with a median of 12 years of disease, patients with RF or CCP did not experience the same yearly increases in fat mass compared to seronegative patients. These data suggest that factors associated with RA severity may promote low body mass, a state associated with all-cause and cardiovascular mortality, by both accelerating loss of lean mass and limiting the gain of fat associated with normal aging.

Cardiovascular Risk Estimates in Rheumatoid Arthritis in the Netherlands. Inger L. Meek[3], Harald E. Vonkeman[2] and Mart A. F. J. van de Laar[1]. [1]Enschede, The The Netherlands, [2]Enschede, The Netherlands, [3]Rheumatology Centre Twente, University Twente & Medisch Spectrum Twente, Enschede, The Netherlands

Background: Over the past decades many reports have shown a relationship between rheumatic disease and cardiovascular morbidity and mortality. This relationship may be due to clustering of risk factors or a feature of the chronic inflammatory processes. In recent years both these factors have received special attention as part of general healthcare and development of potent anti-inflammatory agents and goal directed antirheumatic therapy respectively. Therefore new data concerning cardiovascular risks in modern rheumatologic practice are needed.

Objective: To assess the prevalence of traditional cardiovascular risk factors in current daily clinical rheumatoid arthritis (RA) outpatient care compared to the general population.

Methods: A cohort containing all consecutive patients attending a large rheumatology outpatient department in The Netherlands was cross-sectionally examined for prevalent cardiovascular risk factors. Data were collected between May and December 2009, and included demographics, lifestyle, body mass index (BMI), blood pressure, laboratory tests, rheumatologic diagnosis and disease activity, use of medication and medical history. Parameters of cardiovascular risk in RA patients were compared with data from the general population from the same region. Also, the SCORE 10-year risk estimate for the development of fatal cardiovascular events (developed for the use in daily clinical practice as described previously, a risk estimation above 10% or above 5% with one additional risk factor being regarded an indication for primary cardiovascular risk intervention[1]) was calculated for each RA patient.

Results: Cardiovascular risk profiles were measured in 334 RA patients (mean age 60 years, 72% women, mean disease duration 88 months, 70% being in remission according to DAS28 or expert opinion, 8,7% having previously documented atherosclerotic cardiovascular disease). In RA patients we found significantly more hypertension (67 vs. 43% in men and 59 vs. 41% in women), higher mean BMI in women (27,7 vs. 26,4) and lower mean values of total cholesterol (5,0 vs. 5,79 mmol/L in men and 5,3 vs. 6,09 mmol/L in women) and total/HDL cholesterol ratio (4,2 vs. 5,1 mmol/L in men and 3,5 vs. 4,6 mmol/L in women) compared to the general population. In RA patients the calculated mean SCORE 10-year risk for fatal cardiovascular events was 8,3% in men and 4,5% in women; 73% and 52% having a SCORE risk calculation above 5% and one additional risk factor, respectively.

Conclusions: When compared to the general population this cohort of RA patients, treated according to the current standard of goal directed therapy aiming at remission or low disease activity, shows reassuring results regarding traditional cardiovascular risk factors, with even surprisingly favourable serum cholesterol profiles. Possible advantageous effects of effective antirheumatic therapy on serum lipid profiles and the consequences of our findings on cardiovascular event rates need further investigation.

Circulating Immune Complexes in Patients with Severe Extra-Articular Rheumatoid Arthritis Induce Tumour Necrosis Factor Production by Peripheral Blood Mononuclear Cells. Carl Turesson[1], Linda Mathsson[3], Lennart Jacobsson[1], Gunnar Sturfelt[2] and Johan Rönnelid[3]. [1]Skåne University Hospital, Malmö, Sweden, [2]Skåne University Hospital, Lund, Sweden, [3]Uppsala University Hospital, Uppsala, Sweden

Objective: A subset of patients with rheumatoid arthritis (RA) develop severe extra-articular disease manifestations. Autoantibodies and immune complexes (IC) have been implicated in the pathogenesis, but their role in systemic inflammation in RA remains to be defined. Our aim was to study circulating IC and their influence on cytokine production by peripheral blood mononuclear cells (PBMC) in patients with active, severe extra-articular RA (ExRA) compared to RA controls with no extra-articular manifestations.

Methods: Thirty-five consecutive patients with RA and severe ExRA manifestations according to predefined criteria (pericarditis, pleuritis, major cutaneous vasculitis, Felty's syndrome, glomerulonephritis, vasculitis related neuropathy, scleritis, episcleritis, retinal vasculitis or major organ vasculitis involving other organs) were studied. Seventy controls with RA but no ExRA manifestations, individually matched for age, sex and disease duration, served as the comparison group. Blood was drawn directly after ExRA was diagnosed and before any new treatment was started, and samples were stored at –70°C until investigated. IC prepared as serum polyethylene glycol (PEG) precipitates were added to serum-free PBMC cultures and tumour necrosis factor (TNF) levels were measured after 20 hours using ELISA. Circulating C1q-binding IC and anti-CCP antibodies were determined using ELISA. RF was detected using nephelometry.

Results: Circulating IC levels were higher among patients with ExRA compared to RA controls [median 8.52 μgEq/mL; interquartile range (IQR) 3.63–24.27 vs median 4.51 μgEq/mL; IQR 1.81–10.45 ($p=0.005$)]. TNF induction from PBMC was greater after adding serum PEG precipitates from ExRA patients [mean 17.7 pg/mL; standard deviation (SD) 12.1 vs mean 12.9; SD 7.6; for RA controls ($p=0.02$)], and levels of C1q-binding IC correlated with IC-induced levels of TNF among ExRA patients ($r=0.40$; $p=0.02$) as well as among RA controls ($r=0.35$; $p=0.004$). There was a strong association between circulating IC levels and RF among patients with ExRA ($r=0.62$; $p<0.001$), in particular in the subset with major cutaneous vasculitis ($n=9$; $r=0.76$; $p=0.03$). Anti-CCP antibodies did not correlate with circulating IC levels in patients with ExRA.

Conclusion: Patients with severe ExRA manifestations were characterized by high levels of circulating IC, and IC from ExRA patients were stronger inducers of TNF production from PBMC compared to IC from RA controls. These results suggest that circulating IC enhance RF production and systemic inflammation in severe ExRA.

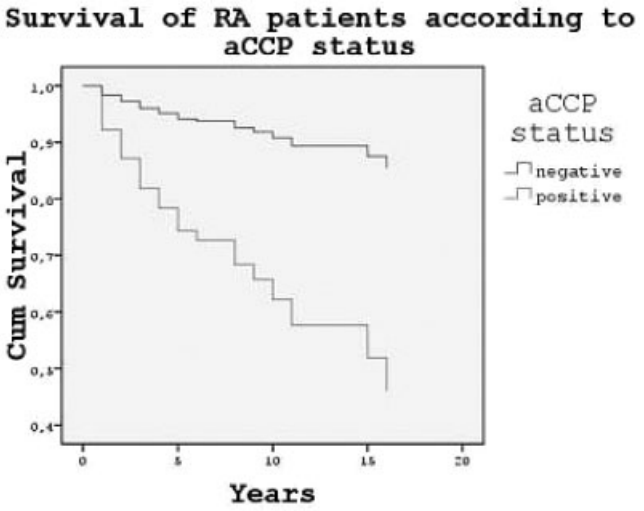
Clinical and Laboratory Risk Factors of Cardiovascular Disease (CVD) in a Cohort of Greek Patients with Early Rheumatoid Arthritis (RA). Nikolaos Papadopoulos[3], Georgios Tsiaousis[2], Marios Katsounaros[1], Dimitrios Baltzis[3] and Vasiliki Galanopoulou[3]. [1]B' Internal Medicine Clinic, Papanikolaou General Hospital, Thessaloniki, Greece, [2]Cardiologist, Kastoria, Greece, [3]Rheumatology Unit, Papageorgiou General Hospital, Thessaloniki, Thessaloniki, Greece

Background: Previous studies have shown that RA patients are at increased risk of developing cardiovascular disease.

Aim of the Study: To investigate the contribution of various clinical and laboratory risk factors to the development of CVD in a cohort of Greek patients with early RA.

Patients and Methods: From January 2000 until June 2009, one hundred and ninty seven patients with early RA and without a prior history of CVD, were first diagnosed and subsequently followed-up, every three months at the rheumatology unit of our hospital.Demographic, clinical, laboratory and therapeutic parameters were evaluated during every follow-up. At the end of the study, patients were divided, according to the development or not of CVD, which included accute myocardial infarction, diagnosis of a stable coronary artery disease, ischaemic cerebral vascular disease and thrombosis of a large vessel.

Results: At the end of the study 37 patients (18.27%) had suffert a CVD event. Univariate analysis revealed that late onset of RA ($p<0.0005$), male sex ($p<0.008$), high mean CRP and ESR ($p<0.008$ and 0.017 respectively), presence of extra-articular manifestations ($p<0.05$) and positivity of anti-CCP autoantibodies and RF($p<0.0005$ and 0.05 respectively), were in a statistically significant manner associated with the development of CVD. Concerning co-morbidities, the presence of hypertension ($p<0.0005$) and dyslipidaemia ($p<0.0005$) were also associated with CVD. A logistic regression model showed that anti-CCP positivity, age at RA onset, presence of extra-articular manifestations and history of hypertension and dyslipidaemia were independent risk factors of CVD. Cox regression analysis demonstrated that anti-CCP positivity significantly influenced the time of first CVD occurence (Figure 1).



Conclusion: Patients with early RA, positive to anti-CCP autoantibodies, who display extra-articular manifestations and a history of hypertension and dyslipidaemia are at higher risk of developing CVD.

Computed Tomographic Densitometry (CTD) for the Evaluation of Interstitial Lung Fibrosis in Rheumatoid Arthritis (RA). Dimitrios A. Pappas[3], Jon T. Giles[4], Geoffrey Connors[2], Noah Lechtzin[2], Joan M. Bathon[3] and Sonye Danoff[1]. [1]Division of Pulmonary and Critical Care, Johns Hopkins University, Baltimore, MD, [2]Division of Pulmonary and Critical Care, Johns Hopkins University, [3]Division of Rheumatology, Johns Hopkins University, Baltimore, MD, [4]Johns Hopkins Univ, Baltimore, MD

Background: Pulmonary disease is a major source of morbidity and mortality in RA patients. Current diagnostic modalities lack sensitivity and are highly dependent on observer experience. We compared the reliability of expert visual CT scan evaluation ("Visual evaluation") of interstitial lung fibrosis, with CT densitometry (CTD), an automated modality for determining the density of pulmonary parenchymal tissue, and the association of both methods with the presence of respiratory symptoms, pulmonary function test (PFT) abnormalities, impaired quality of life (QOL) and fatigue.

Methods: RA patients were evaluated with chest CT, PFT, respiratory questionnaires, fatigue (FACIT-F) and QOL (SF-36) instruments. Fibrosis by CTD was measured as the percentage of voxels with attenuation between −640 and – 250 Hounsfield units (HU). A single expert radiologist evaluated the same CT scans for the presence of fibrosis. A subset of scans was blindly read twice by the same reader who was not aware of any patient characteristics.

Intra-operator/observer reproducibility was evaluated by means of percent agreement. Univariate analyses were applied to evaluate the relationship of visual and CTD measurements with the presence of respiratory symptoms and PFT abnormalities.

For multivariable analysis, the SF36 physical function scale and the FACIT –F subscale were used as outcomes and were handled as binary variables (lower quartile vs. upper quartiles). Independent variables were selected based on biologic plausibility. Final logistic regression models were built using forward and backward stepwise selection of variables.

Results: Among the 192 patients who underwent CTD, fibrosis affecting ≥10% of lung parenchyma was observed in 39 (20%). Fibrosis of ≥7.5% of parenchyma was observed in 79 (41%). Among the 176 scans with visual evaluation, 57 (32%) were read as having fibrosis. The intraoperator percent agreement for CTD fibrosis was 100% while the intraobserver agreement for visual evaluation was only 65%.

In univariate analysis, the presence of ≥10% fibrosis by CTD was associated with impaired diffusion capacity with or without coexistent restriction (Odds Ratio (OR): 2.6, 95% CI:1.1–6.1), breathlessness while walking on level ground (OR: 3.1, 95% CI: 1.2–8.1) or breathlessness while walking 100 yards (OR: 3.9, 95% CI: 1.3 –11.5). Visual evaluation was associated with the presence of impaired diffusion capacity with or without coexistent restriction (OR: 3.4, 95% CI: 1.5–8.0), but not with the presence of respiratory symptoms.

Multivariate logistic regression analysis revealed that the presence of ≥ 10% fibrosis by CTD was associated with a worse SF36 physical function scale (OR: 5.2, 95% CI: 1.9–14.1). The presence of ≥ 7.5% CTD fibrosis was associated with a worse FACIT-F score (OR: 2.5, 95% CI: 1.1– 5.3). No similar association was detected between visual evaluation and outcomes of interest.

Conclusions: In RA, visual evaluation of lung CT for evaluation of fibrosis has inferior reliability than evaluation with CT densitometry. The later is associated with the presence of respiratory symptoms, worse quality of life and fatigue.

1023

Cystatin C, Renal Function and Atherosclerosis in Rheumatoid Arthritis. Ratchaya Lertnawapan[2], Aihua Bian[2], Yong Hee Rho[2], Vivian Kawai[2], Paolo Raggi[1], Annette Oeser[2], Joseph Solus[2], Tebeb Gebretsadik[2], Ayumi Shintani[2] and Charles Michael Stein[2]. [1]Emory University, Atlanta, GA, [2]Vanderbilt University, Nashville, Nashville, TN

Purpose: Cystatin C, a novel marker of renal function, is a more accurate measure of glomerular filtration rate (GFR) than serum creatinine. Cystatin C is a cysteine protease inhibitor and its serum concentrations are associated with inflammation, insulin resistance, and cardiovascular risk. Patients with rheumatoid arthritis (RA) frequently have inflammation, insulin resistance, subclinical renal dysfunction and premature atherosclerosis. We examined the hypothesis that cystatin C is increased in RA, and associated with inflammation, insulin resistance and coronary artery atherosclerosis.

Methods: We measured serum cystatin C, creatinine, C-reactive protein (CRP), tumor necrosis factor-α (TNF-α), and interleukin-6 (IL-6) concentrations in serum samples from 167 patients with RA and 91 control subjects without inflammatory rheumatic disease. Coronary calcium score, homeostasis model assessment (HOMA) index, Modified Diet in Renal Disease formula-estimated GFR (MDRD-eGFR) and clinical parameters including RA disease activity (DAS28) were also measured. We compared cystatin C concentrations in patients with RA and controls using a multivariable regression analysis that adjusted for demographic variables and renal function (MDRD-eGFR). In patients with RA we assessed the relationship between cystatin C and measures of inflammation, Framingham risk score (FRS) and coronary-artery calcium score (CACS) using Spearman correlation and multivariable regression.

Results: Concentrations of cystatin C were significantly higher in patients with RA (median (IQR): 1.16 (0.99–1.35) mg/L) than controls (1.01 (0.90–1.19) mg/L), (adjusted $P<0.001$). Serum creatinine concentrations ($P=0.62$) and MDRD-eGFR ($P=0.53$) did not differ significantly among RA and control groups. In patients with RA, cystatin C concentrations were significantly positively correlated with creatinine ($rho=0.43$, $P<0.001$) and significantly inversely correlated with MDRD-eGFR ($rho=-0.43$, $P<0.001$). In RA cystatin C was positively correlated with ESR ($rho=0.26$, $P<0.001$), CRP ($rho=0.20$, $P=0.01$), DAS28 ($rho=0.19$, $P=0.006$), FRS ($rho=0.44$, $P<0.001$) and TNF-α ($rho=0.20$, $P=0.01$), but not with IL-6, or HOMA (both $P>0.05$) (Table). After adjustment for age, race and sex, only associations with ESR, CRP, DAS28 and FRS retained statistical significance. Cystatin C also correlated with CACS ($P<0.001$) in RA but this was not significant after adjustment for age, race, sex and FRS ($P=0.67$).

Conclusions: Cystatin C concentrations are higher in patients with RA than compared to subjects without RA; this may reflect undetected subclinical renal dysfunction and inflammation. Cystatin C provides information regarding the risk of atherosclerosis in RA, but this is not independent of the information provided by conventional cardiovascular risk factors.

Table. Relationship between Cystatin C and Cardiovascular Risk Factors, Inflammation and Coronary Calcium Score in RA

Factor	Rho** (ρ)	Cystatin C Unadjusted p-value	Adjusted p-value*
Age	0.44	<0.001	–
Homocysteine	0.49	<0.001	<0.001
HOMA index	0.09	0.261	0.15
Framingham score	0.44	<0.001	0.05
DAS28	0.19	0.013	0.006
ESR	0.26	0.001	<0.001
CRP	0.20	0.01	0.009
TNF-α	0.20	0.011	0.11
IL-6	0.10	0.185	0.322
Coronary calcium score	0.32	<0.001	0.674

*Adjusted p-values are all adjusted for age, race and sex, except for coronary calcium score that is additionally adjusted for Framingham risk score. Multivariable linear regression was used in Adjusted p-value.
**Univariate Spearman correlation coefficient (n=167)
HOMA Index=Homeostasis Model Assessment Index; DAS28=Disease Activity Score 28-joint assessment; ESR=Erythrocyte Sediment Rate; CRP=C-Reactive Protein; TNF-α=Tumor Necrosis Factor-α; IL-6=Interleukin-6

Depressive Symptoms and Perceived Communication around Shared Decision Making among Patients with Rheumatoid Arthritis. Jennifer L. Barton[1], Laura Trupin[2], Mary E. Margaretten[1], Laura J. Julian[5], Jonathan D. Graf[1], John Imboden[2], Edward H. Yelin[4] and Dean Schillinger[3]. [1]UCSF, San Francisco, CA, [2]UCSF, [3]UCSF, Center for Vulnerable Populations at San Francisco General Hospital, [4]University of California, San Francisco, CA, [5]University of California San Francisco, San Francisco, CA

Background: Due to the high cost and potential toxicity of therapies for rheumatoid arthritis (RA), shared decision making is central to patient safety and quality of care. While depressive symptoms have been associated with poor clinician-patient communication in diabetes and coronary heart disease, this has not been studied in RA. We sought to examine whether depressive symptoms influence clinician-patient communication around shared decision making among RA patients.

Methods: Data were derived from a cohort of adults with diagnostically confirmed RA seen at two university-affiliated clinics. Subjects completed a structured telephone survey in English, Spanish, or Chinese, that included the Interpersonal Processes of Care Survey (IPC), a validated patient-reported measure. The IPC decision-making subscale is based on the mean score for two items, "How often did you and your doctors work out a treatment together?" and "If there were treatment choices, how often did doctors ask if you would like to help decide your treatment?" (range: 1 "never" to 5 "always"). Mean scores <4 (corresponding to never/rarely/sometimes) were categorized as poor communication. The Patient-Health Questionnaire-9 (PHQ-9) was administered in-person in the patient's preferred language to determine depression symptom severity. PHQ-9 was categorized using three severity classifications: none-minimal (0–4), mild (5–9), and moderate to severe ($\geq$ 10). Multivariate logistic regression was used to evaluate the independent association of depressive symptoms with poor communication, adjusted for demographic and disease characteristics, and trust in physician.

Results: The 227 subjects were 84% female with a mean age of 55 $\pm$ 14 years and mean disease duration of 11 $\pm$ 11 years; 143 (63%) spoke English, 52 (23%) Spanish, and 32 (14%) Cantonese. Fifty-five (24%) had moderate to severe depressive symptoms on the PHQ-9 and 70 (31%) reported poor communication on the decision-making subscale. Results from the multivariate model suggest that moderate to severe depressive symptoms were independently associated with poor communication (AOR = 3.8, 95% CI 1.4–10.7) (Table).

Table. Predictors of Poor Doctor-Patient Communication Around Shared Decision Making Among 227 Patients with RA

	Age-adjusted OR (95% CI)	p-value	MV adjusted* OR (95% CI)	p-value
Depressive symptoms (ref. PHQ-9† <5)				
Mild (PHQ-9 5–9)	1.5 (0.7–2.9)	0.27	2.3 (0.9–6.1)	0.082
Moderate to severe (PHQ-9 ≥10)	2.2 (1.1–4.4)	0.03	3.8 (1.4–10.7)	0.011
Age, per 10 years	1.2 (1.0–1.5)	0.103	1.6 (1.2–2.2)	0.003
Language (ref. English)				
Spanish	5.7 (2.7–11.9)	<0.001	5.6 (1.7–18.3)	0.004
Cantonese	5.9 (2.6–13.6)	<0.001	7.4 (2.0–26.9)	0.002
Less than high school education	2.8 (1.5–5.3)	0.001	0.6 (0.2–1.7)	0.34
Disease severity				
Disease duration	1.0 (0.9–1.0)	0.09	1.0 (0.9–1.0)	0.45
Health Assessment Questionnaire (HAQ)	1.3 (0.9–2.0)	0.15	0.8 (0.5–1.4)	0.5
Suboptimal Trust in Physician	1.3 (0.7–2.6)	0.46	2.7 (1.1–6.4)	0.03

† PHQ-9=Patient Health Questionnaire-9 *Multivariate model adjusts for age, gender, language, education, along with variables shown in the table.

Conclusions: Among patients with RA, we found that moderate to severe depressive symptoms were independently associated with poor doctor-patient communication around shared decision making. While older age and suboptimal trust in physician have been associated with poorer communication in prior studies, depression status has not been observed as a correlate of shared decision making in RA. This study highlights the need for interventions to improve shared decision making in rheumatology practices, especially for those RA patients at greatest risk of poor communication.

Differences in the Autonomic Reactivity Pattern upon Various Stressors in Patients with Rheumatoid Arthritis. Olga Malysheva[2], Petra Baum[2], Anke Voitzsch[1] and Christoph G. O. Baerwald[2]. [1]University Hopital, Leipzig, Germany, [2]University Hospital, Leipzig, Germany

Background: Stress is recognized as an important risk factor in the pathogenesis of rheumatoid arthritis (RA). However, it is still incompletely understood how the autonomic nervous system and the immune system interact in patients with RA.

Methods: To characterize the stress pattern in 90 RA patients the autonomic response upon various stressors the heart rate variability (HRV) test (ProSciCard III, Version 2.2a, Medi-Syst GmbH, Germany) was performed and compared to 30 osteoarthritis (OA) patients exhibiting equal distribution of age and gender. Standardized stress tests included mental arithmetic tasks to induce mental stress (MST), Ewing test, deep breathing test (DBT) and Valsalva maneuver (VM). HRV measures including frequency domain analysis (employing rapid processing of a 5 minute ECG rhythm strip) yielding measures of parasympathetic and sympathetic activity as well as the total power (TP) of autonomic nervous system influence on various parameters: high frequency (HF), low frequency (LF), and very low frequency (VLF) index of heart rate variability, variation coefficient (VC), and square root of the mean of the squares of successive R-R interval differences (RMSSD).

Results: At base line patients with RA were characterized by a combination of reduced TP as well as decreased parasympathetic activity compared to OA patients (TP: 4.79 $\pm$ 0.5 Hz vs. 10.5 $\pm$ 3.6 Hz; HF 1.47 $\pm$ 0.18 Hz vs. 4.6 $\pm$ 1.5 Hz, respectively, $p < 0.01$). Stress tests revealed a disturbed sympathetic activity in RA patients compared to OA patients in the MST (LF HRV: 1.69 $\pm$ 0.21 Hz vs. 3.05 $\pm$ 1.0 Hz, and LF/HF HRV: 1.1 $\pm$ 0.09 vs. 1.34 $\pm$ 0.06, $p < 0.05$, respectively) as well as in the DBT (RMSSD: 34.7 $\pm$ 2.16 ms vs. 46.5 $\pm$ 4.2 ms, and VC: 7.02 $\pm$ 0.4 vs. 9.46 $\pm$ 0.43, $p<0.05$, respectively). Comparing low disease activity RA patients (DAS $\leq$ 2.3, LDA) to RA patients with high disease activity (DAS $>$ 3.2, HDA) demonstrated a significant improvement in the sympathetic activity of LDA patients at base line (LF/HF HRV: 1.36 $\pm$ 0.1 Hz vs 0,87 $\pm$ 0.02 Hz, $p<0.01$) as well as in various stress tests (MST, Ewing test, VM). Furthermore, in RA patients with HDA the DBT showed a disturbed sympathetic activity compared to LDA RA patients (VC: 6.2 $\pm$ 0.2 vs 8.1 $\pm$ 0.3, $p<0.01$). Stratifying the patients for therapy revealed an increase of the parasympathetic tone at base line, as well in various stress tests (DBT, Ewing test), for RA patients under anti-TNF medication compared to methotrexate mono-

therapy (at base line RMSSD: 30.7 ± 1.8 ms vs. 26.1 ± 0.6 ms, LF/HF 0.88 ± 0.02 vs. 1.1 ± 0.02, respectively, $p<0.05$).

Conclusions: To study autonomic nervous system reactivity in RA patients a panel of standardized stress tests is mandatory. Our findings demonstrate that in RA patients the autonomic response to minor stress is characterized by a reduced sympathetic activity which is associated with disease activity. Therapeutic interventions leading to low disease activity in RA patients, e.g. anti-TNF therapy may modify the stress reactivity. Further studies are warranted to determine the role of the autonomic nervous system in the disease process of RA and the modulation of neuro-immune interactions by various medications.

Disease Specific Cardiovascular Risk Factors in Patients with Rheumatic Diseases. Stefan Kleinert[2], Margret Breunig[1], Hans Peter T. Tony[3], Martin Feuchtenberger[4], Stefanie Bouma[1], Angermann E. Christiane[1], Georg Ertl[1] and Stefan Stoerk[1]. [1]Department of Cardiology, Med. Klinik 1, University of Wuerzburg, [2]Rheumatology / Clinical Immunology, Med. Klinik 2, University of Wuerzburg, Wuerzburg, Germany, [3]Rheumatology / Clinical Immunology, Med. Klinik 2, University of Wuerzburg, Wuerzburg, Germany, [4]Rheumatology/Clinical Immunology, Med. Klinik 2, University of Wuerzburg

Introduction: The increased cardiovascular risk in patients with rheumatic diseases (RD) may be attributed to traditional cardiovascular (CV) as well as to RD-specific risk factors. We aimed to identify RD-specific correlates of CV risk in patients with RD.

Methods: 628 consecutive patients attending the rheumatology outpatient department of the University Hospital were assessed regarding CV risk factors by structured history taking, questionnaires, ECG and laboratory measurements including natriuretic peptides (NT-proBNP). Screening for increased risk of CV disease was regarded positive (RISK+) if any of the following was present: European CV Risk Score (EURO-Score) ≥3% or NTproBNP >200 pg/ml or any pathological ECG pattern.

Results: Patients had rheumatoid arthritis (RA, n=333), spondylarthropathies (SpA, n=124), connective tissue diseases (CTD, n=145) and no RD (Control, n=73). For details of patients' characteristics see table 1 and 2.

	% female	Mean Age (years)	Disease Duration (years)	NSAR+	Steroids+	DMARD+	Biologic+
RA (1)	79	55	8.7	42%	66%	83%	20%
SpA (2)	37	44	9.3	55%	14%	49%	29%
CTD (3)	86	49	9.2	15%	49%	47%	1%
Control (4)	73	48	–	27%	13%	3%	0%

"+" indicates use of substance class

	DM	pAVK	Stroke	FamHx	Hypert	HLP	Smoker	ESC ≥ 3	ECG	BNP >200	RISK +
RA	15%	12%	2%	42%	38%	47	19%	32%	14%	18%	43%
SpA	10%	12%	1%	465%	24%	39%	33%	17%	16%	5%	32%
CTD	6%	16%	3%	49%	35%	40%	19%	18%	14%	17%	34%
Con	4%	12%	3%	61%	18%	32%	23%	22%	18%	14%	34%

DM=Diabetes mellitus, pAVK=peripheral artery disease, stroke=history of stroke, FamHx = family history of myocardial infarction, Hypert=Arterial Hypertension, HLP=Hyperlipoproteinemia, Smoker (ex)=current smoker, ESC=EURO-Score, ECG=Electrocardiogram, BNP=NTproBNP > 200 pg/ml, RISK+=at least one risk factor positive i.e. EURO-Score ≥3% or NTproBNP > 200 pg/ml or pathological ECG.

Logistic regression (dependent variable RISK+) was performed within the 4 groups using rheumatoid factor, disease duration, sex, haemoglobin, GFR, CRP, LDL-cholesterol, BSG, usage of NSAR, Steroids, DMARDs, or Biologicals, as well as DAS28 in RA. Odds ratio and 95% CI are reported. Positive correlates of RISK+ were **in the RA group:** use of DMARD 4.1 (1.49–11.30; p=0.006), disease duration 1.05 per year (1.01–1.09, p=0.011), LDL-cholesterol 1.01 per g/dl (1.00–1.03, p=0.017), and CRP 1.27 per mg/dl (1.00–1.61; p=0.048); negative correlates were: male sex 0.16 (0.07–0.39; p<0.001) and renal function (GFR per ml/min/kg 0.98 (0.96–0.99; p=0.007)).

In the SpA group a high CRP 2.25 per mg/dl (1.23–4.10, p=0.008) and haemoglobin 2.20 per g/dl (1.16–4.17, p=0.015) were associated with a worse risk profile.

Screening results in *patients with connective tissue diseases* were more likely to be positive in patients using DMARDs (3.73, 1.25–11.19, p=0.019) and less likely if patients were male (0.18, 0.04–0.85, p=0.031) and if renal function was good (GFR per ml/min/kg (0.96, 0.94–0.99, p=0.002)). In the *control group* male sex (0.17, 0.001–0.25; p=0.003) was associated with a reduced and ESR per mm (1.19, 1.003–1.42; p=0.003) with an increased risk profile.

Conclusion: In different rheumatic conditions disease-specific risk factors indicating an increased cardiovascular risk could be identified, justifying further cardiologic diagnostics and closer long-term follow-up.

Do Men and Women Cope Differently with Disease Impact of Rheumatoid Arthritis, and If So, Why? Matthias Englbrecht[2], Laure Gossec[1], Anita DeLongis[3], Tore K. Kvien[4], Marieke Scholte-Voshaar[6], Tuulikki Sokka[5] and Schett Georg[2]. [1]APHP, Rheumatology B Department, Paris Descartes University, Medicine Faculty, Paris, France, [2]Department of Internal Medicine 3, University of Erlangen-Nuremberg, Erlangen, Germany, [3]Department of Psychology, University of British Columbia, Vancouver, Canada, [4]Department of Rheumatology, Diakonhjemmet Hospital, Oslo, Norway, [5]Jyvaskyla Central Hospital, Jyvaskyla, Finland, [6]Rheumatology, VU University Medical Center and Jan van Breemen Institute, Amsterdam, Netherlands.

Background: Coping with impact of disease is recognized as essential by RA patients(1). However, the knowledge of promising strategies to handle RA is still very limited and gender differences in coping have only been scarcely investigated. We therefore checked the use of a previously introduced 18-item questionnaire(2) during the validation process of the RAID-questionnaire(1).

Objectives: First, to investigate the usage of coping strategies among men and women. Secondly, to find reasons for eventually occurring differences.

Methods: We analyzed the data of 433 RA patients from 12 countries stemming from the RAID study database(1) and providing complete information on all coping items. Before the start of the validation process, two numeric rating scales asking for the extent of coping effectiveness and helplessness were added to the original coping questionnaire(2). First, we evaluated to which extent men and women are using cognitive reframing, pushing through the pain, emotional expression and active problem solving – the coping scales previously derived(2) from the questionnaire. We then addressed the question whether there are gender differences with respect to coping effectiveness and perceived helplessness. Finally, we set these results into relation to other common outcome variables measuring disease activity and health status.

Results & Conclusion: Men (N=99) and women (N=334) had longstanding (mean disease duration, men: 10.27±9.77yrs; women: 13.47±10.24yrs) and active (mean DAS28, men: 3.45±1.72; women 4.3±1.54) RA. Women made significantly more use of coping strategies when compared to men and showed a strong trend towards higher levels of perceived helplessness whereas coping effectiveness was not different.

Table 1. Descriptive data of coping scales and comparison of gender differences

	Mean ± SD (sample)	Mean ± SD (stratified for gender)		p Value	Significance test
Pushing Through The Pain*	1.90 ± 0.78	Male	1.79 ± 0.80	0.11	t-test
		Female	1.93 ± 0.77		
Active Problem Solving*	1.66 ± 0.87	Male	1.51 ± 0.86	0.04	t-test
		Female	1.72 ± 0.87		
Cognitive Reframing*	1.73 ± 0.79	Male	1.57 ± 0.79	0.03	t-test
		Female	1.78 ± 0.78		
Emotional Expression†	1.43 ± 0.74	Male	1.30 ± 0.74	0.04	t-test
		Female	1.47 ± 0.73		
Helplessness†	4.00 ± 2.75	Male	3.54 ± 2.60	0.06	t-test
		Female	4.13 ± 2.78		
Coping Effectiveness†	5.65 ± 2.22	Male	5.64 ± 2.19	0.94	t-test
		Female	5.66 ± 2.23		

*Scale ranging from 0–3 †Scale ranging from 0–10

We set these results into relation to measures of disease activity and found significantly elevated levels of the patient's and physicians evaluation of general health (VAS), the tender joint count 28, the HAQ-DI and accordingly

the DAS28 in female patients (all $p < 0.01$). Hence, female RA patients seem to have both, a higher disease activity and worse physical functioning. Therefore, they might be urged to cope more frequently with impact of disease, while tending to feel more helpless at the same time.

Effects of HMG-CoA Reductase Inhibitor on Progression of Carotid Intima-Media Thickness and Arterial Stiffness in Rheumatoid Arthritis – A Randomized Controlled Trial. Lai-Shan Tam[3], Edmund K. Li[2], Qing Shang[3], Brian Tomlinson[3], Vivian W. Lee[3], Kenneth K. Lee[3], Martin Li[3], Woon-Pang Kuan[1], Tena K. Li[3], Lorraine Tseung[3], Gabriel Yip[3], Ben Freedman[4] and Cheuk-Man Yu[3]. [1]Hospital Selayang, Malaysia, [2]The Chinese University of Hong Kong, Hong Kong, China, [3]The Chinese University of Hong Kong, [4]University of Sydney

Objectives: To ascertain the efficacy and safety of rosuvastatin in the prevention of subclinical atherosclerosis and arterial stiffness markers in patients with rheumatoid arthritis (RA)

Methods: Fifty RA patients with stable disease activity (DAS<5.1 for at least 3 months) were randomized in a double-blind placebo-controlled trial to receive 10mg rosuvastatin (n=24) or placebo (n=26). Patients were prospectively followed every 3 monthly for 12 months. Intima-media thickness (IMT), augmentation index (AIx) and subendocardial variabilty ratio (SEVR) were measured at baseline, 6 and 12 months.

Results: Three out of 24 (12.5%) subjects in the rosuvastatin arm did not complete the study because of adverse event (n=1) and major flare (DAS> 5.1) requiring escalation of DMARDs (n=2), while 5/26 (19.2%) subjects had major flare requiring escalation of DMARDs in the placebo arm (p=0.704). Rosuvastatin resulted in statistically significant reductions of total cholesterol (TC), low density lipoprotein-cholesterol (LDL-C), apolipoprotien B (Apo B) and urate levels vs placebo. After 1 year, rosuvastatin treatment resulted in a mean (±SE) percent change of LDL-C: −35.8 ± 5.0 compared to placebo: 16.8 ± 10.5 ($p<0.001$). Comparing the changes within each group, significant reduction in the TC, HDL-C, LDL-C, Apo B, fibrinogen and urate levels were observed at 6 and 12 months compared with baseline in the rosuvastatin group.

Data are expressed as mean ± SD or median (interquartile range) unless specified otherwise. EMS=duration of early morning stiffness, VAS=visual analog scale, HAQ=health assessment questionnaire, ESR=erythrocyte sedimentation rate, CRP=C-reactive protein, DAS28-CRP=28 joint disease activity score, WCC=white cell count. † General linear model with repeated measures. *p<0.05, #p<0.005 compared with baseline using paired-t tests. ^p<0.005, ∞p<0.05 using Friedman test.

The treatment group had a significant increase in the changes of the SEVR, but no significant effect was observed in the changes of IMT and AIx.

Table 3. Changes in intima-media thickness, augmentation index and subendocardial variability ratio.

		Baseline	6 months	12 months	p-value†
Mean IMT, mm	Rosuvastatin	0.90 ± 0.14	0.94 ± 0.14*	0.91 ± 0.14	0.877
	Placebo	0.92 ± 0.18	0.96 ± 0.18*	0.93 ± 0.16	
Maximum IMT, mm	Rosuvastatin	1.08 ± 0.20	1.08 ± 0.21	1.06 ± 0.20	0.386
	Placebo	1.11 ± 0.30	1.17 ± 0.30*	1.13 ± 0.25	
AIx @ 75, %	Rosuvastatin	32.5 ± 9.5	28.9 ± 10.0	31.3 ± 8.5	0.269
	Placebo	29.4 ± 8.8	30.6 ± 10.5	30.9 ± 10.4	
SEVR, %	Rosuvastatin	157 ± 28	148 ± 26*	163 ± 33	0.023
	Placebo	143 ± 18	144 ± 24	143 ± 26	

Data are expressed as mean ± SD. IMT=intima-media thickness, AIx @ 75 = augmentation index standardized to a heart rate of 75 b.p.m., SEVR=subendocardial variability ratio. † General linear model with repeated measures. *p<0.05 compared with baseline using paired-t tests.

Conclusions: Our data suggest that rosuvastatin has modest anti-inflammatory effect in RA patients with low disease activity in terms of reduction in DAS score and fibrinogen level. Rosuvastastin may also improve subendocardial perfusion and lower urate level. Future large scale randomized controlled trial will be required to ascertain whether statins can prevent progression of atherosclerosis in RA.

Elevated Prevalence of Hypothyroidism in Female Inflammatory Arthritis Patients in Primary Care Amplifies the Prevalence of Cardiovascular Disease. Hennie G. Raterman[2], Mark M. J. Nielen[1], Mike J. L. Peters[2], Robert A. Verheij[1], Francois G. Schellevis[1] and Michael T. Nurmohamed[2]. [1]Netherlands Institute for Health Services Research (NIVEL), Utrecht, The Netherlands, [2]VU University Medical Center, Amsterdam, The Netherlands

Objectives: Inflammatory arthritis is an emerging risk factor for cardiovascular disease (CVD). Hypothyroidism is another CVD risk factor and appears related to inflammatory arthritis, best exemplified in secondary care arthritis patients. The aim of this study was, first, to compare the prevalence of hypothyroidism in inflammatory arthritis patients and a background population and, second, to study the association of hypothyroidism and cardiovascular disease (CVD) in subjects with and without inflammatory arthritis registered in primary care.

Methods: Data was used from the Netherlands Information Network of General Practice (LINH), which was retrieved from electronical medical records kept by a representative Dutch sample of 96 general practices with 360000 registered patients in 2006. Prevalences of hypothyroidism were calculated for subjects with and without inflammatory arthritis. Logistic multilevel multivariate regression analyses were used to study associations of hypothyroidism and CVD in inflammatory arthritis.

Results: Overall, the prevalence of hypothyroidism was 5.0 per 100 patients in inflammatory arthritis and 2.4 per 100 patients in control subjects ($p < 0.0005$). The prevalence of hypothyroidism in female arthritis patients was 6.5% compared to 3.9% in female control subjects ($p < 0.0005$). In female subjects the prevalence of CVD (14.3%) was significantly higher in hypothyroid inflammatory arthritis patients when compared to inflammatory arthritis patients (5.9%), hypothyroids (4.3%) and control subjects (2.1%) (see table 1, model 1). These results attenuated, but remained significant after adjustment for age, hypertension, dyslipidemia and diabetes (see table 1, model 2).

	Model 1* OR (95% C.I.)	Model 2† OR (95% C.I.)
Controls (n=84655)	1.0	1.0
Hypothyroidism (n=3471)	1.94 (1.63–2.31)	1.19 (0.99–1.43)
Inflammatory arthritis (n=910)	2.44 (1.83–3.24)	1.48 (1.10–2.00)
Hypothyroidism & inflammatory arthritis (n=63)	6.38 (3.10–13.12)	3.72 (1.74–7.95)

*Logistic multilevel multivariance regression analysis with CVD as outcome variable; crude analysis. †Adjustment for age, hypertension, hypercholesterolemia and diabetes only slightly changed associations

Conclusion: In primary care the prevalence of hypothyroidism is elevated in female inflammatory arthritis patients and is associated with an amplified CVD prevalence independent of traditional cardiovascular risk factors. Therefore, clinicians must be more aware of coexistence of other autoimmune disease like hypothyroidism, as our results indicate a synergistic effect of hypothyroidism and inflammatory arthritis patients for cardiovascular disease.

Elevations in ApoC-III Containing Apolipoprotein Complexes Predict Coronary Atherosclerosis Progression in Rheumatoid Arthritis Patients. Joan M. Bathon[3], Michael Centola[4], Jon T. Giles[2], Nicholas Knowlton[5], Joshua Wages[5], Adam J. Payne[5], Guy Cavet[1] and Petar Alaupovic[5]. [1]Crescendo Biosciences, Inc., South San Francisco, CA, [2]Johns Hopkins Univ, Baltimore, MD, [3]Johns Hopkins Univ Ste, Baltimore, MD, [4]Oklahoma Med Research Foundation, Oklahoma City, OK, [5]Oklahoma Medical Research Foundation, Oklahoma City, OK

Purpose: Higher rates of cardiovascular (CV) associated events and mortality in rheumatoid arthritis (RA) cannot be accounted for with conventional lipid measures. However, alterations in the equilibrium among apolipoprotein complexes that traffic plasma lipids may have atherogenic consequences in RA.

Method: Apolipoprotein complexes were measured at baseline in RA patients participating in the Evaluation of Subclinical Cardiovascular Disease and Predictors of Events in Rheumatoid Arthritis (ESCAPE RA) study by precipitation and immunoturbidimetric analysis. Coronary artery calcium (CAC), a measure of coronary atherosclerosis, was assessed by cardiac computed tomography (CT) at two timepoints spanning approximately 3.5 years. Patients with a change in CAC ≥1 were designated as progressors, and patients with no change or improvement in CAC were designated as nonprogressors. Univariate comparisons were made using t-tests. To model all the ApoC-III containing complexes together, we combined them using a Principal Component Analysis (PCA). Multivariate analyses were performed using logistic regression.

Results: Baseline DAS 28 and ethnicity did not differ significantly between the groups ($p=0.53$ & $p=0.419$ respectively). However, gender and age distributions were significantly different between the groups, ($p=0.011$ & $p=0.009$, respectively). Of the 152 participants who had CAC measurements at two time points, 89 (59%) were progressors and 63 (41%) nonprogressors. Of the 12 apolipoprotein complexes measured, baseline mean values of 7 were statistically significantly higher in the progressors, compared to nonprogressors (see fig. 1). Interestingly, in contrast to the complexes not associated with progression, these 7 complexes all contain ApoC-III, which is predominantly a triglyceride carrier. All 7 complexes, when combined via PCA, were statistically associated with progression, both in crude analyses (OR 1.86; $p=0.003$) and after adjusting for Framingham Risk Score, age, and gender (OR 1.83; $p=0.016$).

Conclusion: Associations between ApoC-III plasma levels and CVD progression were more pronounced in RA patients than outcome associations of conventionally assessed lipoproteins (i.e. LDL-, HDL-cholesterol). Elevated plasma levels of apolipoprotein complexes containing ApoC-III particles were strongly predictive of progression of coronary atherosclerosis in RA. Elevation of these triglyceride rich particles is caused by defects in plasma triglyceride transport and metabolism, which may contribute to accelerated atherosclerosis in RA. These findings provide a means of developing a standardized assay to identify high risk CVD in RA patients and a potential therapeutic target for intervention.

Marker	Mean (SD) Nonprogressors	Mean (SD) Progression	P-Value

Factors Associated with Upper and Lower Gastrointestinal Perforation in a Cohort of Patients with Rheumatoid Arthritis. Jeffrey R. Curtis[5], Angel Lanas[4], Winifred Werther[2], Ani John[2], David A. Johnson[1] and Kathy L. Schulman[3]. [1]Eastern Virginia Medical School, Norfolk, VA, [2]Genentech, a Member of the Roche Group, South San Francisco, CA, [3]Outcomes Research Solutions, Inc. Bolton, MA, [4]Universidad de Zaragoza, Zaragoza, Spain, [5]University of Alabama at Birmingham, Birmingham, AL

Purpose: To evaluate the incidence of upper and lower gastrointestinal (GI) perforation and to identify associated risk factors in a cohort of patients (pts) with rheumatoid arthritis (RA).

Methods: In this retrospective, claims-based study (January 2001-June 2009), pts aged >18 were selected from the MarketScan® databases if they had at least 2 diagnoses of RA (ICD 9 CM 714.0, 714.3), between 30 and 365 days apart, and at least 1 year of continuous enrollment (defining "baseline period") prior to the beginning of follow-up time. Pts were excluded if they had a baseline history of hospitalized GI perforation or any GI malignancy. A validated algorithm for identifying hospitalized GI perforation in claims data was used to identify the first upper GI (UGI) and first lower GI (LGI) perforation. Pts were followed up until the date of GI perforation, database disenrollment, or study end. The GI perforation rate was reported in years of observed person time (PY). A Cox proportional hazards model was used to estimate the relative risk of GI perforation in the first 12 months of follow-up as a function of baseline demographics (age, gender, region, population density), comorbidities (Charlson Comorbidity Index), and use of RA and GI medications during the baseline period. These medications included NSAIDs, corticosteroids, biologic agents, methotrexate (MTX), and other DMARDs.

Results: The study population included 143,433 RA patients (mean age [SD], 57.7 [14.1]; 74.8% female) with mean (SD) follow-up of 2.9 (1.9) years. Hospitalization with GI perforation occurred in 0.5% of pts (n=696), with 6.6% of patients dying during admission. At baseline, pts with GI perforation were older (57.6 vs. 62.0 years; $p<.0001$) than pts without perforation and had lower RA severity scores ($p=.01$) and higher Charlson Comorbidity scores ($p<.01$). Overall, the GI perforation rate per 1000 PY was 1.73 (95% CI, 1.61–1.86), with the majority of events concentrated in the LGI: 1.44 (1.32–1.55) vs. UGI 0.30 (0.24–0.35). The unadjusted GI perforation rate per 1000 PY was higher in pts aged ≥65 years (2.3), with exposure

to corticosteroids without accompanying NSAID (2.2), among pts with a pre-period history GI disturbance (3.4), specifically, diverticulitis (19.3), diverticulosis without diverticulitis (6.7), unspecified noninfectious gastroenteritis/colitis (4.9), esophageal or GI hemorrhage (4.2), ulcer (3.8), Crohn's disease (3.7), and ulcerative colitis (2.1). The adjusted relative risk of GI perforation associated with demographic and RA-related medications during the first year of follow-up is presented in the Table.

Conclusions: GI perforation is a rare but serious condition impacting patients with RA, most frequently in the LGI tract. The short-term risk of GI perforation increases with age and is highest among patients with a history of diverticulitis, diverticulosis, and exposure to corticosteroids and NSAIDs.

Table. Adjusted Relative Risk of GI Perforation by Significant (p<.05) Risk Factor

Baseline Parameter	Hazard Ratio	95% Confidence Limits	
		Lower	Upper
Age			
Age <40		Referent	
Age 40 to 64	2.60	1.21	5.58
Age 65 and older	3.55	1.63	7.76
Exposure to NSAIDS & corticosteroids			
No exposure to either NSAIDS or corticosteroids		Referent	
Exposure to NSAID, no corticosteroid	1.77	1.13	2.79
Exposure to corticosteroid, no NSAID	2.23	1.45	3.45
Exposure to both NSAID & corticosteroid	1.71	1.11	2.63
Exposure to MTX vs. no exposure to MTX	0.75	0.57	0.99
Diverticulosis without diverticulitis	4.26	1.73	10.45
Diverticulitis	15.47	8.57	27.93

Fatigue in Inflammatory Arthritis: Clinical Characteristics, and Contributory Factors Following 6-Months of Anti-TNF Therapy. Patricia Minnock[1], Barry Bresnihan[3], Gabrielle McKee[2], Oliver FitzGerald[3] and Douglas Veale[3]. [1]Rheumatology Rehabilitation, Our Lady's Hospice and Care Services, Dublin, Ireland, [2]School of Nursing & Midwifery, Trinity College, Dublin, Ireland, [3]St Vincent's University Hospital, Dublin, Ireland

Background: The unique contribution of fatigue to the assessment of patients with inflammatory arthritis has been demonstrated. The aim of this study was to elucidate the clinical characteristics of, and contributory factors to, fatigue in patients with inflammatory arthritis prescribed anti-TNF therapy.

Methods: Patients with rheumatoid arthritis (RA) and psoriatic arthritis (PsA) commencing anti-TNF therapy underwent standard clinical assessment of disease activity and fatigue at baseline, 3-months and 6-months. Fatigue was measured using the multidimensional assessment of fatigue scales (MAF), validated for use in RA. The MAF comprises 16 questions concerning the quality, degree, distress, impact and timing of fatigue, compiled to give a final score of 1–50; a low score corresponds to a low level of fatigue. The clinical characteristics of, and the relationship between fatigue and 6 core outcome measures was evaluated.

Results: One-hundred thirty seven patients were evaluated (RA, 93; PsA, 44). Mean age (SD) years, and disease duration at inclusion were 52 (13), 12 (11), respectively. Both fatigue and the core outcome measures demonstrated a significant improvement over the 3-timepoints. Mean (SD) MAF levels were 27.5 (11.1) at baseline, 18.07 (12.1) at 3-months and 19.04 (11.8) at 6-months ($p<0.001$). Mean (SD) SJC were 7.6 (6.2) at baseline, 2.2 (3.1) at 3-months, and 1.6 (2.6) at 6-months ($p<0.001$). Mean (SD) TJC were 9.4 (7.8) at baseline, 2.9 (4.5) at 3-months and 2.6 (5.1) at 6-months ($p<0.000$). Mean (SD) Pain were 5.4 (2.1) at baseline, 3.5 (2.3) at 3-months and 3.5 (2.0) at 6-months ($p<0.000$). Mean (SD) GH were 5.9 (2.2) at baseline, 3.7 (2.4) at 3-months and 3.8 (2.1) at 6-months ($p<0.000$). Mean (SD) HAQ were 2.5 (1.0) at baseline, 0.78 (0.80) at 3-months and 0.75 (0.66) at 6-months ($p<0.003$). Mean (SD) CRP were 20.6 (25.4) at baseline, 71.0 (7.8) at 3-months and 8.8 (15.3) at 6-months ($p<0.000$). Tests were significant at the 0.01 level (2-tailed). Fatigue was moderately correlated with Pain 0.423 (0.578), (0.482); GH 0.425 (0.578), (0.500) and HAQ 0.470, (0.345), (0.344) ($p<0.001$) at baseline, at 3-months, and at 6-months, respectively. The strongest correlation found between fatigue and SJC (0.358) and TJC (0.409) were at 3-months only. All correlations were significant at the 0.01 level. The only variable that made a significant contribution to explanation of fatigue at 6-months was GH ($R^2=35\%$), $F=0.65$; $p=0.000$; Beta=0.345). At 6-months the relative independent variance in fatigue was 17%, greater than most of all the core clinical measures: HAQ 17%, SJC 16%, TJC 15%, CRP 14%, Pain 10%, GH, 10%.

Conclusion: Fatigue provides unique information in the assessment of outcome for patients with inflammatory arthritis which warrants further in-depth examination.

Favorable Changes in the Lipid Profile in the First Year of Early Arthritis. Karin Britsemmer[1], Dirkjan van Schaardenburg[1], Willem F. Lems[2] and Michael T. Nurmohamed[1]. [1]Jan van Breemen Institute Amsterdam, [2]VU University Medical Center Amsterdam

Background: Several studies provided evidence for excess cardiovascular (CV) morbidity and mortality in rheumatoid arthritis (RA). The inflammatory process and traditional CV risk factors, e.g. dyslipidemia, are considered as the two major contributors to this excess CV disease. Recent studies suggested that abnormal levels of apolipoprotein A (ApoA-I) and apolipoprotein B (ApoB), and particularly the ApoB/ApoA ratio, is at least comparable with the total cholesterol:HDL-cholesterol ratio as predictor of CV morbidity. In this study we investigated the conventional lipid profile and levels of ApoA-I and ApoB in untreated patients with early arthritis and the effect of anti-rheumatic treatment on these levels after six and 12 months.

Methods: Patients from the Amsterdam Early Arthritis Cohort (EAC) with a disease duration of <2 years, at least 2 swollen joint and no prior DMARD treatment were studied. Patients with osteoarthritis, crystal arthropathy, connective tissue diseases and infectious arthritis were excluded. Lipid levels, inflammation markers and disease activity score (DAS28) were evaluated at baseline and after six and 12 months.

Summary of Results: The study population comprised 155 patients (mean age 53 [14], 72% female, median symptom duration 1.8 [IQR 1.1–3.7] months, median swollen and tender joint count 5 [3–10] and 7 [5–10], respectively, mean DAS-28 4.9 [1.4]). DMARDs were prescribed in 100% and 96% at 6 and 12 months, respectively. Biologic treatment was given in 2% and 32% at 6 and 12 months, respectively. Table 1 summarizes the mean lipid levels, disease activity markers and acute phase reactants at baseline and after 6 and 12 months. Total cholesterol, ApoA-I levels, LDL- and HDL-cholesterol increased significantly after 6 and 12 months of treatment. Since the changes were larger in HDL cholesterol and ApoA-I, this resulted in a decreased and more favorable total cholesterol:HDL ratio and ApoB:ApoA-I ratio. During the 12 months follow-up decreasing levels of CRP and DAS-28 were significantly associated with increasing levels of total cholesterol, ApoA-I and HDL-cholesterol and decreasing total cholesterol:HDL ratio and ApoB:ApoA-I ratio's.

Table 1. Lipid profile of 155 patients at baseline and after 6 and 12 months

	Baseline	*6 months (n=89)**	*12 months (n=45)***
Disease activity markers			
CRP, mg/L	8 (IQR 2–20)	2 (IQR 1–5)	2 (IQR 1–4.5)
DAS-28	4.9 ± 1.4	2.7 ± 1.2	2.9 ± 1.2
Lipid levels			
Total cholesterol, mmoles/L	5.07 ± 1.06	5.56 ± 1.07	5.59 ± 1.09
Apo A-I, gm/L	1.53 ± 0.31	1.70 ± 0.31	1.65 ± 0.32
Apo B, gm/L	0.84 ± 0.22	0.84 ± 0.21	0.82 ± 0.20
LDL, mmoles/L	3.06 ± 0.91	3.30 ± 0.93	3.35 ± 0.94
HDL, mmoles/L	1.27 (IQR 1.05–1.63)	1.49 (IQR 1.29–1.85)	1.57 ± 0.39
Total Cholesterol: HDL ratio	4.02 ± 1.32	3.66 ± 1.03	3.72 ± 0.97
Apo B:Apo A-I ratio	0.55 ± 0.17	0.50 ± 0.15	0.51 ± 0.16

* $p<0.007$ except for Apo B ** $p<0.03$

Conclusion: This is one of the first studies demonstrating that patients with early arthritis have favorable changes in the lipid profile after six and 12 months of treatment that ultimately may lower their CV risk. These changes in lipid profile, including the total cholesterol:HDL and ApoB:ApoA-I ratio, are significantly associated with decreasing levels of CRP and DAS-28.

Free Fatty Acids Are Associated with Insulin Resistance but Not Coronary Artery Atherosclerosis in Rheumatoid Arthritis. Michelle J. Ormseth[2], Larry Swift[4], Sergio Fazio[4], MacRae F. Linton[4], Cecilia P. Chung[3], Paolo Raggi[1], Young-Hee Rho[2], Joseph Solus[4], Annette M. Oeser[5], Aihua Bian[4], Tebeb Gebretsadik[4], Ayumi Shintani[4] and C. Michael Stein[4]. [1]Emory University, [2]Vanderbilt University, Nashville, TN, [3]Vanderbilt University, Baltimore, MD, [4]Vanderbilt University, [5]VUMC 23rd Ave South Pierce, Nashville, TN

Background: Free fatty acids (FFA) affect insulin signaling and are implicated in the pathogenesis of insulin resistance and atherosclerosis. Inflammatory cytokines such as interleukin-6 (IL-6) increase lipolysis and thus FFA concentrations. Patients with rheumatoid arthritis (RA) have increased atherosclerosis that is associated with insulin resistance and higher IL-6 concentrations. Thus, a unifying mechanism underlying accelerated atherosclerosis in RA may be that increased IL-6 concentrations are associated with increased FFA concentrations resulting in insulin resistance and atherosclerosis.

Methods: Clinical variables, concentrations of non-esterified FFA and inflammatory cytokines, homeostasis model assessment for insulin resistance (HOMA), and coronary artery calcium (CAC) were measured in 166 patients with RA and 92 controls. We compared FFA concentrations in RA and controls using Wilcoxon rank sum tests and a multivariable linear regression that adjusted for age, race, sex and BMI. Among RA patients, we assessed the relationship between FFA and inflammatory cytokines, HOMA, and CAC scores using Spearman correlation and multivariable regression analysis.

Results: Patients with RA and controls were of similar age, race, sex and BMI. HOMA was significantly higher in RA (median [IQR]: 2.34 units [1.16–4.27]) than controls (0.83 units [0.54–1.79], $p<0.001$), as was CAC score (2.7 units [0.0–150.4] and 0.0 units [0.0–18.7], $p=0.016$). Triglyceride concentrations were similar ($p=0.18$), but LDL cholesterol was lower in RA than controls (111.0 mg/dL [88.0–135.0] and 122.0 mg/dL [104.0–145.0]) ($p=0.016$). FFA concentrations did not differ significantly in RA and controls (0.56 mmol/L [0.38–0.75] and 0.56 mmol/L [0.45–0.70], $p=0.75$). In RA, FFA concentration was positively correlated with CRP (rho=0.25, $p=0.001$), BMI (rho=0.16, $p=0.046$), HOMA (rho=0.20, $p=0.011$), triglycerides (rho=0.15, $p=0.048$), insulin (rho=0.18, $p=0.024$) and Framingham risk score (FRS) (rho=0.22, $p=0.005$); FFA were not correlated with IL-6 ($p=0.48$), TNF-α ($p=0.29$) or CAC score ($p=0.62$). After adjustment for age, race, sex and BMI, FFA remained associated with HOMA ($p=0.011$), insulin ($p=0.023$), CRP ($p=0.009$), triglycerides ($p=0.004$) and FRS ($p=0.048$).

Conclusions: FFA concentrations do not differ significantly in patients with RA and controls. In patients with RA, FFA concentrations are correlated with obesity, insulin resistance, CRP concentrations and FRS, but not with IL-6, TNF-α and CAC score. FFA may contribute to insulin resistance, but do not provide a mechanistic link between inflammation, insulin resistance and coronary atherosclerosis in RA.

Gene-Environment Interaction Determines Interstitial Lung Disease in Rheumatoid Arthritis. Jose Felix Restrepo[2], Inmaculada del Rincon[4], Ricardo Zuniga[3], Samvel Pogosian[4] and Agustin Escalante[1]. [1]Univ of Texas HSC San Antonio, San Antonio, TX, [2]Univ of Texas HSC, San Antonio, San Antonio, TX, [3]University of Texas HSC, San Antonio, TX, [4]UTHSCSA, San Antonio, TX

Background: Interstitial lung disease (ILD) is a progressive fibrotic process of unknown cause that may affect rheumatoid arthritis (RA) patients. We examined the role of gene-environment interaction as a determinant of the presence of ILD in RA patients.

Method: We performed a cross sectional study of prevalence and factors associated with ILD in a cohort of RA patients. ILD was diagnosed using chest X-ray, CT scan, MRI, or lung biopsy. Patients with ILD were compared to RA patients without ILD or other pulmonary diseases. We used the following independent variables: age, gender, rheumatoid factor (RF), disease duration, DAS 28, ESR, smoking status, SF36 general health, global assessment of disease severity and activity, Steinbrocker functional class, modified HAQ, current or past use of metothrexate and current use of prednisone. HLA-DRB1 shared epitope (SE) was assessed using sequence-specific DNA primers. We used t-test for continuous variables; chi square and odds ratio (OR) for categorical variables and logistic regression for multivariable analyses, adjusting for confounders.

Results: The sample included 779 RA patients. Sixty nine of them (8.8%) had ILD. We compared them to the 563 patients without pulmonary disease. We excluded 147 patients who had other pulmonary conditions. Significant differences between the two groups included (mean in ILD vs non-ILD patients): age 60.2 vs 52.9 ($p<0.0001$), age of RA onset: 47.5 vs 42.7 ($p<0.004$), SF36 general health: 68 vs 62 ($p<0.01$), ESR: 58 vs 39 ($p<0.0001$),DAS28: 5.96 vs 5.37 ($p<0.002$), modified HAQ 2.04 vs 1.87 ($p<0.05$), diseases severity: 3.76 vs 2.77 ($p< 0.0004$)and Steinbroker functional capacity 2.40 vs 2.06 ($p<0.001$). For categorical variables, ILD was associated with nodules, OR (95% CI) = 1.85 (1.05, 3.2; $p<0.001$); rheumatoid factor,OR = 3.15 (1.32,9.10, $p<0.006$); male gender, OR = 3.33 (1.93, 5.7, $p<0.000001$), current prednisone, OR = 2.02 (95% CI, 1.17–3.5), smoking OR = 2.19 (1.23,4.04, and the SE, OR = 1.98 (0.99, 4.32). In multivariate analysis, male gender, OR = 3.08 (1.74, 5.44), RF, OR = 2.58 (1.04, 6.39), prednisone,OR = 1.77 (1.007–3.13); DAS28, OR 1.42 (1.17, 1.73) showed significant, independent association with ILD.

We tested the SE for interaction with smoking using product terms in logistic regression. Smoking was strongly associated with ILD in the presence, but not in the absence of the SE. (Table)

Shared Epitope	Smoking OR for ILD (95% CI)	p value
Negative	0.54 (0.15–1.9)	0.152
Positive	2.19 (1.1–4.5)	0.033

Conclusion: ILD is frequent in RA, and is associated with aging, male gender, nodules, active disease, positive RF and current use of prednisone. The SE was necessary for smoking to be associated with ILD, providing an example of gene-environment interaction. Further research should focus on the use of variables associated with ILD for early identification of patients at risk for ILD. Mechanistic research into the SE x smoking interaction would be of great interest.

Glucocorticoid Use Is Not Associated with an Increased Risk of Cerebrovascular Accidents in Patients with Rheumatoid Arthritis. A Population-Based Study. Antonio Avina-Zubieta[1], Michal Abrahamowicz[2], Hyon K. Choi[4], M. Mushfiqur Rahman[1], Marie-Pierre Sylvestre[3], John Esdaile[1] and Diane V. Lacaille[1]. [1]Arthritis Res Centre of Canada, Vancouver, BC, Canada, [2]Department of Epidemiology and Biostatistics, McGill University, Montreal, QC, Canada, [3]Samuel Lunenfeld Research Institute, [4]Univ of British Columbia, Vancouver, BC, Canada

Purpose: While it has been shown that RA patients treated with glucocorticoids (GC) have an increased risk of coronary artery disease, the data available for cerebrovascular accidents (CVA) are scarce and controversial. We examined the effect of GC on risk of CVA in patients with rheumatoid arthritis (RA).

Methods: Using population-based administrative health data we assembled a cohort of 7,051 incident RA cases with disease onset between 1997 and 2001 with no history of CVA and no GC use prior to RA onset. Follow-up was until 2006. GC exposure was evaluated using four time dependent variables updated monthly: GC use, mean daily dose, total cumulative dose and total cumulative duration of use. CVA outcomes included acute thrombotic and hemorrhagic strokes, but not transient ischemic attacks, and were ascertained using ICD-9 codes (431, 434 and 436) from hospitalization and vital statistics data. To control for confounding by indication, wherein GC would be given to cases with more severe disease and/or less adverse cardiovascular profiles, we calculated propensity scores to control for the observed differences between GC users and non-users. We performed Cox-regression models to estimate the relative risk (RR) for CVA, adjusting for demographics, cardiovascular risk factors, RA characteristics, propensity scores and time-dependent prescription medications (methotrexate, Cox-2 inhibitors and other non-steroidal anti-inflammatory drugs).

Results: The mean age of the cohort was 56 yrs (57 and 54 for GC users and non users respectively) and 66% were females (70% and 64% for GC users and non-users respectively). Over a mean of 6 years of follow-up

(43,354 person-years), we identified 178 incident CVA cases (61 were fatal cases). The unadjusted stroke incidence rate was 4.1 per 1000 person-year in the RA cohort, 3.7 during GC exposure and 2.6 during non GC exposure. The directionality of the point estimates suggests a small non-significant effect in all adjusted models. The simplest time-dependent model that ignores dose and duration of exposure showed that GC use [yes/no] was not significantly associated with CVA (HR = 1.40, 95% CI; 0.83 – 2.37). Similarly, the model that accounts for current mean daily dose showed that current dose was not significantly associated with CVA (HR=1.01, 95% CI; 0.99 –1.04, for each mg increase in the current mean daily dose). In addition, cumulative duration of of use and total past cumulative dose were not significantly associated with CVA (RR = 1.01, 95% CI; 0.99 – 1.02 per month of use, and RR= 1.001, 95% CI; 1.000 – 1.002 per each gram accumulated in the past respectively).

Conclusions: This large population-based study indicates that GC use is not significantly associated with an increased risk of CVA in cases with RA. Our results may have important implications for people with RA and their treating physicians, when weighting the risks and benefits of using GC to treat RA.

Heptavalent Conjugate Pneumococcal Vaccine (Prevenarâ) Elicits Similar Antibody Responses as 23-Valent Polysaccharide Vaccine (PPV) in Adult Patients with Established Arthritis. Meliha C. Kapetanovic[1], Carmen Roseman[2], Göran Jönsson[1], Lennart Truedsson[3], Tore Saxne[1] and Pierre Geborek[1]. [1]Dept of Clinical Sciences Lund, Section of Infectious Diseases, Lund University, Lund, Sweden, [2]Dept of Clinical Sciences Lund, Section of Rheumatology, Lund University, Lund, Sweden, [3]Dept of Laboratory Medicine, Section of Microbiology, Immunology and Glycobiology, Lund University, Lund, Sweden

Background: The immunogenicity of 23-valent polysaccharide vaccine (PPV) is debated. Heptavalent conjugate pneumococcal vaccine (Prevenarâ) has been shown to elicit better immune responses compared to PPV in children and healthy adults. Corresponding data in patients with inflammatory rheumatic diseases receiving immunosuppressive treatments is lacking.

Aim: To study immune response after vaccination with A) Prevenarâ in immunosuppressed patients with rheumatoid arthritis (RA) and patients with spondylarthropathy including psoriatic arthritis (SpA) not receiving immunosuppressive treatment compared to B) immunosuppressed RA patients and healthy controls vaccinated with PPV.

Patients and Methods: In total, 254 patients with RA on methotrexate alone, TNF-blockers as monotherapy or methotrexate +TNF blockers and 86 patients with SpA not treated with immunosuppressive drugs received a single dose (0.5 ml) of Prevenarâ. Altogether, 149 patients with RA receiving corresponding immunosuppressive treatments and 47 healthy controls were vaccinated with 0.5 ml of a single lot of PPV, as previously reported (ref). Levels of serotype specific IgG to 23 F and 6B were measured prior to vaccination and 4–6 weeks after vaccination using standard ELISA. Pre- and postvaccination antibody levels for each serotype and immune response (IR), defined as ratio between post- and prevaccination antibody levels, were compared between the groups. Differences in IR were analysed using univariate analysis of variance (ANCOVA) adjusted for age, gender, prevaccination antibody levels, and concomitant methotrexate /prednisolone treatment when appropriate.

Results: Pneumococcal vaccination resulted in significant increase in post-vaccination antibody levels in all groups compared to baseline levels for both serotypes. RA patients vaccinated with Prevenarâ gained in general similar postvaccination antibody levels and IR as those receiving PPV (Table1). SpA patients had better IR for serotype 23F compared to healthy controls who received PPV vaccine. Among Prevenarâ vaccinated RA patients, IR was similar in the respective treatment modalities as those receiving PPV.

Conclusion: Pneumococcal vaccination using conjugate vaccine elicits similar immune response as 23-valent polysaccharide vaccine in patients with established RA receiving immunosuppressive treatments. Pneumoccal conjugate vaccine did not give better immune response in general but may be better for some serotype.

Table 1. Demographic characteristics and immunization response (IR) for serotype 23 F and 6B in different groups vaccinated with Prevenarâor 23-valent polysaccharide vaccine (PPV).

	Prevenar		PPV	
	RA patients (N=254)	Spondylarthropathy patients (N=86)	RA patients (N=149)	Healthy controls (N=47)
Age (years) (mean)	60 (13)	52 (12)	55 (13)	36 (12)
Female (%)	80%	45%	72%	75%
Disease duration at vaccination (years)	16 (12)	12 (12)	16 (11)	–
Immunization response (IR) for 23F (median; min-max)	1.99 (0.51–740)	4.96 (0.17–120)*	2.02 (0.25–67)	2.28 (0.18–91)
Immunization response (IR) for 6B (median; min-max)	1.38 (0.38–100)	2.1 (0.24–129)	2.13 (0.8–280)	2.22 (0.40–75)

* p=0.005 between SpA and healthy controls (univariate analysis of variance; ANCOVA, adjusted for age, sex and prevaccination antibody levels)

Higher Prevalence of Coexisting Papillary Thyroid Cancer as Well as Autoimmune Thyroid Diseases in Patients with Rheumatoid Arthritis. Yeon-Ah Lee[3], Sang-Hoon Lee[1], Ran Song[2], Kyoung Min Son, Hyung-In Yang and Seung-Jae Hong[4]. [1]Seoul, Korea, Republic of, [2]Korea, Republic of, [3]Division of Rheumatology, Department of Internal Medicine, School of Medicine, KyungHee University, Seoul, Korea, Republic of, [4]Division of Rheumatology, Department of Internal Medicine, School of Medicine, KyungHee University

Background & Objectives: Although the exact pathophysiologic mechanisms of autoimmune diseases in various organs remain unclear, an accumulation of autoimmune diseases in individual patients has been observed. It has been well documented that rheumatoid arthritis (RA) is the most common autoimmune disease coexisting with autoimmune thyroid diseases(ATD) such as Graves' disease or Hashimoto's thyroiditis. However, few studies have been performed to investigate the incidence of thyroid cancers and nodules in RA patients. The goal of our study was to investigate the prevalence of concurrent thyroid diseases (ATD, thyroid nodules and thyroid cancers) in patients with RA compared to the control group involving age and sex matched subjects.

Methods: A case-control study was done in 110 RA patients and 101 osteoarthritis (OA) patients. We screened consecutive patients by thyroid ultrasonography (USG), regardless of the presence of palpable nodules. Patients with nodule(s) of 7 mm or greater were evaluated by fine-needle aspiration (FNA). Serum T3, free T4, thyroid stimulating hormone (TSH), anti-thyroglobulin antibodies (anti-TG), and anti-peroxidase antibodies (anti-TPO) were measured.

Results: The mean age was 55.2 ± 8.9 years in the RA patient group and 56.6 ± 8.5 years in the OA group. Thyroid nodule(s) were detected in 47.3% (52/110) among 110 RA patients, and in 56.4% (57/101) among 101 OA patients by USG. Among patients with thyroid nodule(s), 59 patients had nodule(s) of 7 mm or greater in size and 54 cases of them (92.0%) underwent FNA. Seven cases of thyroid cancer were histologically confirmed and all of them were papillary type. Six cases of 7 papillary thyroid cancers were RA patients. So, the cancer prevalence of sonographically detected thyroid nodules was at least 11.5 % (6/52) in RA patients and this was higher than in OA patients (11.5% vs 1.8%, P=0.052). Most of thyroid cancers(5/7) had a solid and hypoechoic pattern in USG. The positivity of anti-TG was significantly higher in RA (6% vs 0%, P=0.039) and the prevalence of ATD tended to be higher in RA patients than in controls (14.7% vs. 7.8%), although the difference was not statistically significant. Concurrent ATD comprised Hashimoto's thyroiditis (7 in RA, 4 in OA), and Grave's diseases (4 in RA). The most common thyroid dysfunction observed in both groups was subclinical hypothyroidism (9 in RA, 5 in OA). Other types of thyroid dysfunctions included overt hypothyroidism (3 in RA, 4 in OA), hyperthyroidism (4 in RA), and sick euthyroid disease (2 in RA).

Conclusions: In this study, concurrent thyroid diseases were relatively common in patients with RA and more interestingly, papillary thyroid cancers were detected dominantly in RA patients. Therefore, an extended diagnostic screening for accumulating thyroid diseases, especially Graves's disease and thyroid cancer, seems reasonable in patients with RA.

Hospital-Based Surgical Procedures and the Risk of Perioperative Cardiovascular Events: A Comparison Study of Rheumatoid Arthritis and Diabetes Mellitus Using the National Inpatient Sample of the Healthcare Cost and Utilization Project. Ali Yazdanyar[2], Mary C. Wasko[3], Kevin L. Kraemer[3] and Michael M. Ward[1]. [1]National Institute of Arthritis and Musculoskeletal and Skin Diseases, [2]St Luke's Hospital, Bethlehem, PA, [3]University of Pittsburgh

Background: The association of rheumatoid arthritis with increased atherosclerotic burden has led some to equate the cardiovascular risk of rheumatoid arthritis (RA) with that of diabetes mellitus (DM). We compared the risk of perioperative cardiovascular outcomes among patients with RA, DM, both conditions, and neither.

Methods: This is a cross-sectional analysis of the National Inpatient Sample of the HealthCare Utilization Projects using data from years 1998 to 2002. We abstracted the diagnoses of RA, DM, potential confounding comorbidities and the principal surgical procedure using *International Classification of Diseases*, ninth revision codes. The principal surgical procedure was categorized into Low, Intermediate, and High risk according to established guidelines. The study endpoint was a composite cardiovascular outcome including an acute myocardial infarction, acute stroke, non-ST elevation MI, and/or congestive heart failure with pulmonary edema. Logistic regression accounting for survey design provided the adjusted magnitude of association between the covariates and the study endpoint.

Results: The total weighted frequency of hospitalizations with Low, Intermediate, and High risk principal procedures was 1 003 904, 6 011 950, and 277 010, respectively. The weighted frequency for individuals with RA without DM was 7 831, 92 005, and 1 767 for Low, Intermediate, and High risk surgical procedures, respectively. The weighted frequency of composite cardiovascular events in Low, Intermediate, and High surgical risk levels were 9 542, 38 542, and 31 772, respectively. The proportion of composite cardiovascular events was higher in DM as compared to RA patients for Low (1.63% vs. 0.81%), Intermediate (1.03% vs. 0.44%), and High (18.53% vs. 6.61%) risk surgical procedures. Relative to individuals without RA or DM, the adjusted odds of composite cardiovascular event in patients with RA without DM was 0.73 (95% confidence interval [CI]: 0.41, 1.30), 0.68 (95% CI: 0.54, 0.85), and 0.76 (95% CI: 0.47,1.22) for Low, Intermediate, and High risk surgical procedures, respectively. Relative to individuals without RA or DM, diabetics without RA undergoing a Low, Intermediate, and High risk surgical procedures had an adjusted odds of composite cardiovascular endpoint of 1.30 (95% CI: 1.16,1.45), 1.23(95% CI: 1.15,1.32), and 1.67(95% CI: 1.53,1.83), respectively.

Table. Odds of In-hospital Composite Cardiovascular Event by Risk Category of Principal Procedure

	Surgical Risk Category		
	Low OR (95% CI)	**Intermediate OR (95% CI)**	**High OR (95% CI)**
Characteristics			
Non-RA, Non-DM	1.00	1.00	1.00
RA, Non-DM	0.73 (0.41,1.30)	0.68 (0.54,0.85)	0.76 (0.47,1.22)
Non-RA, DM	1.30 (1.16,1.45)	1.23 (1.15,1.32)	1.67 (1.53,1.83)
RA, DM	1.48 (0.59,3.70)	0.91 (0.50,1.64)	0.84 (0.34,2.05)
Age, y			
18–50	1.00	1.00	1.00
50–75	2.61 (2.11,3.24)	12.53 (10.23,15.36)	3.10 (2.69,3.57)
>75	4.41 (3.45,5.63)	33.46 (27.54,40.66)	4.34 (3.74,5.03)
Gender

Hypogonadism in Males with Rheumatoid Arthritis. Dannette S. Johnson and Robert W. McMurray. G.V. (Sonny) Montgomery VA and University of Mississippi Medical Center, Jackson, MS

Background: The pituitary-gonadal axis has significant immunoregulatory effects on autoimmune diseases and a role in the pathogenesis or modulation of rheumatoid arthritis (RA) has been suggested. We investigated the role of sex hormones on disease activity of male RA patients.

Methods: Levels of testosterone (T) and prolactin (PRL) were examined in male patients with a diagnosis of RA (n=67) from a Jackson subpopulation of the Veterans Affairs Rheumatoid Arthritis (VARA) registry. Serum T and PRL were determined by RIA in a blinded fashion and the correlation with disease activity and severity calculated.

Results: Patients had the following demographics (age=68.3 yrs (range 40–91 yrs), disease duration =14.5 yrs (range 1.7–32.5 yrs), RF positive =79%, CCP positive = 70%, mean DAS 28 = 3.2 ± 1.4). Although mean PRL levels were within normal limits with 5 patients being hypoprolactinemic and 3 with high PRL, hypogonadal patients had significantly higher prolactin levels (mean=8.02 ng/ml vs. 5.55 ng/ml, p=0.39) than patients with normal T. Mean T levels were 302 ± 121 ng/dl and there was no relationship to age or DAS28. A surprisingly high number (n=24; 36%) of male RA patients in this study were hypogonadal (T < 250 ng/dl) which was associated with higher BMI (p=0.001). There was no statistical relationship between low serum total testosterone and age, disease activity and severity, and corticosteroid or narcotic use. However, patients with hypogonadism had a trend toward higher CRP (mg/l) (mean= 14.96) that was >40% higher than those patients with normal T levels (CRP 8.95; p=0.08).

Table. Characteristics of male patients with RA.

	Low Testosterone (T < 250 ng/dl)	**Normal Testosterone (T ≥ 250 ng/dl)**	**P-value**
Testosterone (ng/dl)	183.5 ± 50	368.7 ± 94	
Prolactin (ng/ml)	8.02 ± 8	5.55 ± 2	0.039
Age	69.8 ± 10	67.5 ± 9	0.17
BMI	30.4 ± 6	26.1 ± 5	0.003
RF (+)	79%	79%	0.76
ACCP (+)	71%	70%	0.85
CRP (mg/l)	14.96 ± 24	8.95 ± 11	0.08
DAS28	3.3 ± 1.3	3.1 ± 1.4	0.28
Erosion on hand X-ray	58.3%	56.7%	0.95
Nodules	58.3%	44.2%	0.39

Conclusion: There was a high prevalence of hypogonadism in our male RA population. Hypogonadal men had higher prolactin levels and BMI and a trend toward higher CRP levels. These findings suggest hypogonadal men may fare worse overall and consideration should be given to screening testosterone in older men with RA.

Il-17 as a Novel Predictor of Vascular Damage in Rheumatoid Arthritis. Wendy Marder[2], Shokoufeh Khalatbari[3], James D. Myles[3], Rita P. Hench[2], Susan Lustig[1], Robert D. Brook[1] and Mariana J. Kaplan[2]. [1]Division of Cardiology, University of Michigan, [2]Division of Rheumatology, University of Michigan, Ann Arbor, MI, [3]Michigan Institute for Clinical and Health Research, Ann Arbor, MI

Background: The enhanced risk of premature cardiovascular risk is well recognized in patients with inflammatory diseases such as rheumatoid arthritis (RA). In addition to overt atherosclerosis, a significant proportion of RA patients have subclinical vascular disease, manifested as impaired endothelial function and increased arterial stiffness. While pro-inflammatory cytokines, particularly TNF-α, have been linked to the development of atherosclerosis and endothelial dysfunction in RA, the roles of other proinflammatory mediators such as IL-17 have not been systematically assessed. We analyzed candidate variables that could determine conduit and microvascular endothelial function and arterial compliance in a cohort of RA patients with low Framingham risk factors and overall low disease activity.

Methods: RA patients with stable disease and stable therapy for at least 3 months underwent flow-mediated dilatation (FMD) of the brachial artery, assessment of arterial compliance with SphygmoCor, and endothelium -dependent microvascular function with the Endo-PAT2000 device. Circulating biomarkers of CV damage were quantified by ELISA (ICAM-1, VCAM-1, MCP-1 and IL-17). Insulin resistance was quantified by HOMA2 and RA disease activity was quantified by DAS-28 score. Analysis was performed on 57 patients who were stratified into 2 subsets: 31 patients were on biologic therapy (with or without DMARDS) at the start of the study, and 26 patients were not on biologic therapy (with or without DMARD) at the start of the study. The RA group as a whole was also analyzed.

Results: Microvascular function for the overall group of RA patients negatively correlated with ESR (-0.40, $p=0.003$) and VCAM-1 (-0.40, $p=0.003$). In the group of patients on biologics, IL-17 was the factor that most strongly showed a negative association with microvascular endothelial function. Indeed, there was a significant negative correlation of serum IL-17 with reactive hyperemia pulse amplitude tonometry (-0.39, $p=0.03$), which persisted in multivariate regression analysis adjusting for known confounders. In contrast, arterial stiffness, which was assessed by aortic pulse wave velocity (PWV), was associated primarily with traditional CV risk factors. PWV significantly correlated with age and systolic blood pressure in the biologic-treated patients, the non-biologic treated patients, and the group as a whole (age: 0.53, $p=.004$, 0.63, $p=0.001$, 0.61, $p<.001$; SBP: 0.47, $p=.01$, 0.53, $p=0.01$, 0.54, $p<.001$ respectively). Higher levels of rheumatoid factor negatively correlated with microvascular and conduit endothelial function among patients on biologics (-0.40, $p=0.03$, -0.43, $p=0.02$ respectively), and conduit function among the group as a whole (-0.29, $p=0.04$).

Conclusion: The factors that are associated with alterations in microvascular function in RA patients differ from those that are associated with large vessel arterial stiffness, and are primarily related to the inflammatory milieu rather than to traditional risk factors. This study suggests that IL-17 may play a significant role in the development of microvascular dysfunction in RA, potentially leading to premature vascular damage.

1042

Incidence of Progressive Interstitial Pneumonia in Patients with Rheumatoid Arthritis. Yuko Takahashi, Hiroyuki Yamashita, Yo Ueda, Yuji Yoshida, Hiroshi Kaneko and Akio Mimori. Division of Rheumatic Diseases, National Center for Global Health and Medicine, Shinjyuku-ku, Tokyo, Japan

Objective: Rheumatoid arthritis (RA) often involves interstitial pneumonia (IP), and chronic IP is common in RA patients in the course of their disease. However, few reports have examined the incidence of progressive RA-IP needing steroid therapy. This study estimated the incidence based on our hospital records.

Methods: We used our complete database containing all 550 RA patients registered from 1990 to 2010; we obtained the number of inpatients that received steroid therapy for RA-IP during this period and the total observation years for each outpatient during the same period. As most registered RA patients are followed in our hospital, and not by family physicians, and they are almost always admitted to our hospital when they need hospitalization including treatment for pulmonary complications, the method met our purpose. Patients with IP that developed outside our observation of the RA, *i.e.*, patients referred because of IP, were excluded from the study.

Results and Discussion: During the 21-year study period, 127 cases of RA were treated for pulmonary complications accompanied by an interstitial shadow on a chest x-ray. Of these, 113 cases were excluded from the study for the following reasons: 59 cases of pulmonary infection and existing chronic IP or exacerbation of chronic IP due to infection; 10 cases of drug-induced pneumonia, including four of methotrexate-induced pneumonia; and 44 patients referred because of pulmonary complications, including infection, drug-induced pneumonia, and RA-IP. Of these last 44 cases, nine had progressive IP, which was a clue to diagnosing their RA. After excluding these 113 cases, the remaining 14 cases (14 patients) had progressive RA-IP during our observation and were treated successfully with steroid therapy. Of these, diagnoses based mainly on radiological findings indicated that four had nonspecific interstitial pneumonia (NSIP) and 10 cases had organizing pneumonia (OP, formerly called bronchiolitis obliterans with organizing pneumonia (BOOP)). From the total observation period of 3833 person-years, the calculated incidence of progressive RA-IP was 0.37%/year (14/3833).

Before this study, we estimated the incidence as 0.30–0.39%/year (8/2031–2635) based on our hospital records up to 2005, which included some ambiguity because of dropped-out patients. This study gave a similar incidence using additional patients enrolled up to 2010 and more precise information on the observation periods of the outpatients. Our RA patients had rarely been treated with biologics before 2005, whereas 38% of the patients had received at least one biologics therapy up until the present. Therefore, the incidence of progressive RA-IP may not be influenced by differences in antirheumatic therapy.

Conclusion: The incidence of progressive interstitial pneumonia caused by rheumatoid arthritis was calculated as 0.37%/year (14/3833).

Infertility in Women with RA and Pregnancy Loss in Women with SLE Contribute to Smaller Than Desired Family Size. Megan E. B. Clowse[3], Eliza F. Chakravarty[1], Karen H. Costenbader[2], Christine D. Chambers[5] and Kaleb D. Michaud[4]. [1]Mountain View, CA, [2]Brigham & Women, Boston, MA, [3]Duke Univ Med, Durham, NC, [4]Univ of Nebraska Med Ctr, Omaha, NE, [5]University of California, San Diego

Purpose: Past studies have suggested that women with RA and SLE have diminished fecundity. We sought to understand the role of underlying RA or SLE upon family size.

Methods: A comprehensive reproductive history questionnaire was mailed to women diagnosed by a physician with RA (n=870) or SLE (n=237) participating in a US longitudinal observational study of rheumatic diseases. By disease, participants were divided into 2 main groups: those who had finished having children prior to diagnosis and those still interested in further children at the time of diagnosis. This second group was divided into 2 subgroups: those who had the same number of children that they wanted and those who had fewer children than they originally wanted. Comparisons were made by disease between the finished and not finished groups, as well as the women who had the same or fewer children than they wanted. Statistical analyses were performed using t tests and Fisher's exact tests in STATA.

Results: The response cohort consisted of 578 RA patients (66% response rate) and 114 SLE patients (48% response rate). Over 60% of women had finished childbearing at the time of diagnosis; these women were approximately 20 years older than women still interested in childbearing (see Tables 1 & 2). More than half of the women not finished with childbearing at the time of diagnosis ended up with a smaller family than they wanted.

Women who reported that they had fewer children than they desired had, on average, 1 less child than either women who had their children despite disease or had completed their family prior to diagnosis. For women with RA, those with fewer than desired children had significantly fewer pregnancies (2.2 vs. 3.2, $p < 0.01$) and a 1.5-fold higher rate of reported infertility compared to women with all of the children they desired. In contrast, women with SLE who had fewer children had a similar number of pregnancies but a 3-fold higher rate of miscarriage than those who completed their family despite SLE.

Concern about her ability to care for a child was the most common reason cited for limited childbearing (47%), followed by the risks of medications to a baby (38%) and physician guidance to avoid pregnancy (17%).

Conclusion: Young women diagnosed with RA and SLE are likely to have fewer biologic children than they wanted. Patient choice to avoid pregnancy may play a part, but much of this difference appears to be due to infertility in women with RA and pregnancy loss in women with SLE.

Table 1. Results from women with Rheumatoid Arthritis

	Not finished having children at time of diagnosis		Finished having children at time of diagnosis
	Fewer than desired children	Expected number of children	
Number of women (%)	120 (21%)	95 (16%)	363 (63%)

Interstitial Lung Disease in Rheumatoid Arthritis: Effect on Physical Function, Disability, Mental Health and Survival over a 10-Year Period. Inmaculada Del Rincon[2], Jose Felix Restrepo[3], Mrisa Sahai[2], Daniel F. Battafarano[1], L. Ricardo Zuniga-Montes[2] and Agustin Escalante[2]. [1]Brooke Army Medical Ctr, San Antonio, TX, [2]UTHSCSA, San Antonio, TX, [3]UTHSCSA, Bogota, Colombia

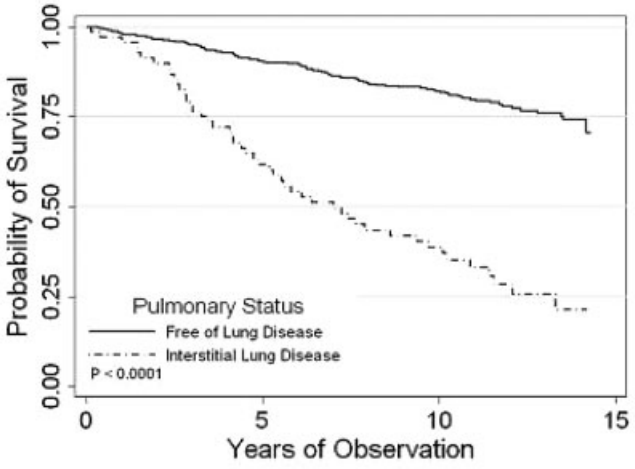
Introduction: Interstitial lung disease (ILD) is a serious complication of rheumatoid arthritis (RA), for which there are few therapeutic options. Moreover, information about how ILD affects the outcome of RA patients is limited. We examined the effect of ILD on physical function, disability, mental health and survival in a cohort of RA patients.

Patients and Methods: We studied patients with RA from rheumatology clinics. At the time of recruitment and yearly thereafter, medical records were reviewed thoroughly. ILD was diagnosed clinically using X-rays, CT scans, MRIs or biopsies of the lungs. At each yearly study visit, we performed tender, swollen and deformed joint counts, and measured the erythrocyte sedimentation rate (ESR). Patients also completed the SF36 questionnaire, the Center for Epidemiological Studies Depression (CESD) scale, timed tests of walking velocity over 50-feet and shirt button fastening, and a test of grip strength. We followed patients until they died, reached a censoring date, or were lost to follow-up. We compared outcome between patients with and without ILD using generalized estimating equations (GEE), adjusting for age, gender, follow-up time, the joint counts and ESR. To study the influence of ILD on survival, we plotted Kaplan Meier curves and used Cox proportional hazards to adjust for potential confounders.

Results: We studied 779 RA patients. Sixty nine of them (8.8%) had ILD, 147 (18.9%) had other pulmonary diagnoses, and 563 patients were free of lung diseases. Mean (95% CI) of the outcome measures in patients with ILD and patients free of lung disease, adjusted for demographics, joint findings and ESR are shown in the table.

	Velocity (ft/min)	Buttons/ minute	Grip (lbs)	Physical Function (SF36)	CESD
ILD	178 (162, 194)	7 (6, 8)	13 (11, 14)	55 (51, 58)	15 (14, 16)
No Lung Dz.	204 (199, 209)	8 (7, 8)	15 (14, 16)	60 (59, 61)	16 (14, 18)
P-value	0.002	0.03	0.02	0.006	0.3

Median observation time was 10.3 years per patient. Among ILD patients, 48 deaths occurred in 482 patient-years (9.9 deaths per 100); in patients free of lung disease, 113 deaths occurred in 5,444 person-years (2.1 per 100), hazard ratio 4.92 (3.51, 6.92). Mortality remained elevated in ILD patients, HR 3.14 (2.04, 4.85), even after adjusting for age, sex, joint findings and ESR.



Conclusion: We have provided detailed estimates of the influence of ILD on multiple aspects of RA outcome. ILD had a significant, independent negative impact on the physical function, disability and survival of patients with RA, but not on measures of mental health. A better understanding of the causes and pathogenesis of ILD in RA is needed to find ways to prevent and treat this complication.

Lower Extremity Ulcers in Rheumatoid Arthritis. David M. DeMaria[2], Christopher E. Attinger[1] and Victoria K. Shanmugam[2]. [1]Center for Wound Healing, Georgetown University Medical Center, Washington, DC, [2]Division of Rheumatology, Immunology and Allergy, Georgetown University Medical Center, Washington, DC

Lower extremity ulcers are a known complication of rheumatoid arthritis (RA). They are associated with longstanding uncontrolled RA. However, their prevalence has not been assessed since the advent of more effective biologic and non-biologic disease modifying anti-rheumatic therapies (DMARDs). The purpose of this study was to establish the prevalence of lower extremity ulcers in a modern day consecutive cohort of RA patients, and to report the features associated with ulcer development.

Methods: Consecutive patients evaluated in the Georgetown University Hospital Division of Rheumatology between June 2007 and June 2010 and fulfilling the ACR criteria for rheumatoid arthritis were identified using an ICD-9 diagnosis code search of the electronic medical record (Centricity, GE). Charts were reviewed for the presence of lower extremity ulcers during the study period. Demographic characteristics, rheumatoid factor (RF) and anti-cyclic citrullinated peptide (CCP) positivity, presence of comorbidities including venous and arterial disease, presence of other vasculitic manifestations of RA such as neuropathy and nodulosis, complement levels, inflammatory markers, biopsy findings and prothrombotic screen were noted.

Results: In the three years of this study 366 RA patients were evaluated, and 16 had active leg ulcers, giving a prevalence of 4.37%. Patients with ulcers were predominantly female (81.25%) and 56.25% were African American. All patients had erosive disease, and 62.5 % were RF or CCP positive. Ulcers were bilateral in 43.75%. The mean age at first ulcer was 64.81 $\pm$3.533 years. In 3 patients RA had previously been undiagnosed. In the remaining 13 patients the mean duration of RA at the time of ulcer development was 25.92 $\pm$ 4.944 years. In 37.5% of patients, the joint disease was in remission at the time of ulcer development. However at the initial visit mean ESR was elevated at 56.63 $\pm$ 7.591mm/hr, mean CRP was 5.928 $\pm$ 1.561 mg/dL and DAS-28 score was 3.836 $\pm$ 0.5460 suggesting ongoing inflammation. All patients had normal complement levels and negative SSA and B antibodies. Biopsy specimens were available in 12 cases. Only 3 had clear evidence of vasculitis, the biopsy was inconclusive in 5, 3 patients had gangrene and one had cholesterol emboli. Size of the initial ulcer ranged from 0.01 to 800 cm2. None of the patients in this study had significant titers of antiphospholipid antibodies, and the frequency of genetic prothrombotic states was similar to that reported in the general population. The mean duration of follow-up was 22.6 months but only 31.25% of ulcers were healed at the last follow-up visit. Due to the small sample size we were unable to

show a significant association between ulcer healing and use of biologic or non-biologic DMARDs.

Conclusions: Even in the era of biologic and non-biologic DMARD therapy, the prevalence of lower extremity ulcers in RA is 4.37%. We found healing rates of only 31.25% in 22.6 months of follow-up. Larger studies are warranted to evaluate the role of small vessel vasculitis in chronic wounds and to investigate the role of aggressive immune suppression even when the joint disease is in remission.

Lower Prevalence and Severity of "Vulnerable" Coronary Plaque in a-TNF-Exposed Asymptomatic Patients with Rheumatoid Arthritis (RA). George A. Karpouzas[1], Naser Ahmadi[2], Tae-Young Choi[2], Fereshteh Hajsadeghi[2], Silvia Munoz[2] and Mathew Budoff[2]. [1]Harbor-UCLA, Long Beach, CA, [2]Harbor-UCLA

Background: Tumor necrosis factor-a inhibitors (TNFi) have been recently reported to decrease the risk of myocardial infarction (MI) in patients (pts) with RA. The exact mechanisms, however, as well as the effects on coronary plaque quantity and composition are largely unknown. We prospectively evaluated the presence, total burden, and differences in the quality of coronary plaque in asymptomatic RA pts treated with TNFi vs. DMARDs alone.

Methods: We report on the first 74 of 150 recruited pts from a single center. Pt characteristics, including traditional risk factors and treatments are shown in table 1. Pts underwent 64+ slice cardiac Computed Tomography Angiography (CTA); this non-invasive modality includes an initial non-contrast phase assessing coronary calcium, followed by a contrast scan that detects plaque with equal accuracy to conventional angiography, and is superior in the assessment of non-calcified, lipid-rich, non-obstructive or "vulnerable" plaque. Individual coronary trees were evaluated for plaque volume and composition by standard methods (American Heart Association). Non-parametric tests were used for data analysis; regression models for plaque prevalence ratios (PR) and relative risk for plaque burden in TNFi vs. DMARD treated pts, adjusted for conventional risk factors were constructed.

Results: TNFi treated individuals had significantly longer disease duration (table 1). Despite that, they had significantly lower extent and severity of total plaque compared to DMARD treated pts; they exhibited lower numbers of affected coronary segments ($p=0.009$) and less total plaque burden score ($p=0.03$). More importantly, they displayed lower prevalence and severity of "vulnerable" plaque; TNFi exposed pts had significantly fewer segments harboring NC/ mixed plaque ($p=0.01$) and significantly lower NC/ mixed plaque burden score ($p=0.04$). TNFi treated pts had 76% less risk for the presence of "vulnerable" plaque ($p=0.006$) and 16% lower burden of NC/ mixed plaque risk vs. DMARD treated pts, adjusted for age, sex and Framingham RF ($p=0.03$).

n	DMARDs=27	TNFi=47	p-value
Age (yrs)	53 ± 12	53 ± 10	0.9
Gender (% female)	85	91	0.5
Disease duration (yrs)	7 ± 5.6	12 ± 7.6	*0.0004*
Diabetes (%)	11	9	0.6
Hypertension (%)	48	43	0.7
Smoking (%)	19	25	0.5
Family history of CAD (%)	4	4	0.9
Statin therapy (%)	41	35	0.6
DAS28-3v-ESR	2.8 ± 0.8	3.3 ± 1.1	0.1
ESR (mm/hr)	25.3 ± 18.5	26 ± 16.3	0.8
CRP (mg/dl)	0.7 ± 1.1	1 ± 1.7	0.4
Time on TNFi (months)	NA	51.8 ± 25.9	–
n (%) with plaque	17 (63)	28 (60)	0.7
n (%) total evaluated segments	108 (100)	188 (100)	–
n (%) diseased segments	34 (31.5)	33 (17.6)	*0.009*
Non-calcified/mixed calcified	27 (25)	24 (12.8)	*0.01*
	7 (6.5)	9 (4.8)	0.6
Total plaque burden score	3.9 ± 3.2	2.3 ± 3.3	*0.03*
Non-calcified/mixed calcified	3.6 ± 3.2	2.1 ± 2.8	*0.04*
	2.2 ± 3.1	3 ± 2.6	0.2
Prevalence Ratio for any plaque	1 (ref)	0.83 (CI:0.4–2.6)	0.67
non-calcified/mixed calcified	1 (ref)	0.24 (CI:0.09–0.6)	*0.006*
	1 (ref)	1.28 (CI:0.7–2.04)	0.49
Relative Risk-total burden score*	1 (ref)	0.85 (CI:0.74–0.99)	*0.03*
Non-calcified/mixed calcified	1 (ref)	0.84 (CI:0.09–0.6)	*0.03*
	1 (ref)	1.37 (CI:0.8–1.6)	0.38

*relative risk regression analysis: per standard deviation increase in burden score

Conclusion: TNFi-exposed asymptomatic RA pts have significantly lower prevalence and severity of total, but more importantly, "vulnerable" coronary plaque compared to DMARD treated pts, despite significantly longer disease duration. These findings insinuate additional favorable effects of TNFi on plaque homeostasis and stabilization and may reflect less future cardivascular morbidity.

Measuring Therapeutic Adherence in Rheumatoid Arthritis (RA) Using a Medication Event Monitoring System (MEMS®). Christian A. Waimann, Maria F. Marengo, Sofia de Achaval, Vanessa L. Cox, Araceli Garcia Gonzalez, Marsha N. Richardson and Maria E. Suarez-Almazor. The University of Texas MD Anderson Cancer Center, Houston, TX

Background: Treatment adherence is an important aspect in RA. Multiple methods of measuring adherence have been proposed, with electronic monitoring considered one of the most accurate measures. The objective of our study was to electronically quantify adherence to oral disease modifying antirheumatic drugs (DMARDs) and prednisone in patients with RA.

Methods: This study was part of a 2– year prospective cohort of 201 patients from 2 publicly-funded county hospitals, in which 110 patients agreed to have their RA drug therapies electronically monitored with MEMS® caps (AARDEX). These are medication bottle caps with a microchip that records the time and date of bottle openings. Adherence to daily medications was determined as the percentage of days with correct number of doses taken. Adherence to weekly methotrexate (MTX) was determined as the percentage of doses taken within an interval of 7 ± 1.75 days. We also estimated percentage of prescribed doses taken (not considering dosing interval). MEMS® data was downloaded with each refill. Patient outcomes were assessed at baseline, 3, 6, 12, 18 and 24 months including functional status, Disease Activity Index 28 (DAS28), SF-12, Medical Outcome Study social support (MOS), Center for Epidemiologic Studies Depression Scale 10 items (CDES-10) and sociodemographic variables. 91% of the patients completed 2 years follow-up; for the remainder we used the last observation for analysis. The statistical analysis was carried out using SAS.

Summary of Results: 86% were female, 67% Hispanic, and 21% African-American; mean age was 49y(±11), disease duration 7y(±5), DAS28 4.1(±1.4),MHAQ 1.8(±0.5); 47% received monotherapy, 39% two DMARDs, 12% three DMARDs and 56% biologics (not oral, therefore not electronically monitored). Adherence of 5 drugs was electronically monitored (table). Adherence for doses taken on schedule (day/wk) was 59% for DMARDs and 61% all drugs. Only 21(20%) of patients had an average adherence ≥ 80%. At 2 years, these patients showed better patient self-reported disease activity and pain by VAS ($p<0.029$; $p<0.008$). No differences were observed for DAS28. Percent prescribed doses taken was greater than % days or weeks with correct doses taken, especially for MTX, suggesting lack of adherence with appropriate prescribed intervals. Patients with self-reported worse global status by visual analogue scale (VAS), and those with better mental health by SF12 MCS were statistically more likely to be adherent ($p<0.03$; $p<0.003$). Patients living alone, and those separated or widowed were less adherent ($p<0.008$; $p<0.003$). Social support (MOS) showed a borderline positive correlation ($r=0.18$, $p<0.06$).

Drug	N	Mean dose	Total days monitored	% prescribed doses taken on schedule	% prescribed doses taken
Methotrexate	69	16 mg/week	479 (±244)	56.1 (±24)	121.8 (±78)
Leflunomide	36	17 mg/day	389 (±266)	69.1 (±18)	80.7 (±17)
Hydroxychloroquine	31	243 mg/day	494 (±256)	58.5 (±22)	75.8 (±21)
Sulfasalazine	6	891 mg/day	394 (±344)	50.5 (±27)	73.0 (±28)
Prednisone	58	6 mg/day	437 (±274)	65.1 (±20)	79.1 (±30)
Average DMARDs	101	–	–	59.1 (±22)	101.1 (±65)
Average all drugs	110	–	–	61.1 (±21)	94.1 (±43)

Conclusion: On average, RA patients showed 61% correct medication intake, with only 1 in 5 taking oral therapies as prescribed at least 80% of the times. Long-term cohort studies should evaluate the impact of non-adherence on RA outcomes.

Polyautoimmunity and Autoimmune Aggregation in Rheumatoid Arthritis. Adriana Rojas-Villarraga[1], Ricardo A. Cifuentes[3], Diana Botello-Corzo[3], Antonio Iglesias-Gamarra[4], Ruben D. Mantilla[5] and Juan-Manuel Anaya[2]. [1]Center for Autoimmune Diseases Research (CREA), Universidad del Rosario, [2]CREA, Universidad del Rosario, Bogota, Colombia, [3]CREA, Universidad del Rosario, [4]Rheumatology Unit, Universidad Nacional, [5]Riesgo de Fractura-CAYRE IPS

Objectives: Characterization of the extent to which particular combinations of autoimmune diseases occur in excess of what could be expected as a result of chance may offer new insights into possible common pathophysiological mechanisms. The goal of this study was to investigate the spectrum of polyautoimmunity [i.e. autoimmune diseases (Ads) co-occurring within patients], familial autoimmunity (i.e. diverse Ads co-occurring within families) and aggregation in patients with rheumatoid arthritis (RA).

Methods: This was a cross-sectional study in which 304 consecutive patients with RA (ACR criteria) and their nuclear families were included. The history of 23 Ads was investigated. A multivariate logistic regression analysis was performed in a search for risk factors that were significantly associated with the presence of polyautoimmunity. Aggregation (λ_R) was obtained by the ratio between the prevalence of Ads in relatives and the current prevalence of Ads in the general population.

Results: There were 98 (32.3%) patients presenting with at least one other AD. A total of 116 Ads were observed in patients of which the most frequent were autoimmune thyroid disease (AITD), Sjögren's syndrome (SS) and antiphospholipid syndrome (APS), registered in 64 (21.1%), 36 (11.8%) and 8 (2.6%) cases respectively. Of the patients with polyautoimmunity, 16 (16.3%) presented with multiple autoimmune syndrome (i.e., two or more Ads in addition to RA). Female gender (AOR: 2.8, 95%CI:1.22–6.31), cardiovascular disease (AOR: 2.2, 95%CI: 1.17–3.94) and the presence of antinuclear antibodies (AOR: 2.0, 95%CI: 1.08–3.84) were risk factors for polyautoimmunity. Seventy-three families (24%) had at least one first degree relative (FDR) with an AD. Of the 571 FDR in these 73 families, 145 (25%) had one or more AD. The most frequent Ads registered in FDR were AITD (9.5%), RA (4%) and systemic lupus erythematosus (1.4%), with a λ_R of 3.5, 8 and 7 respectively.

Conclusion: Polyautoimmunity and familial autoimmunity are frequent in RA and influenced by clinical and immunological features. These findings support the hypothesis that clinically different autoimmune phenotypes might share common susceptibility variants.

Prediction of 10-Year Cardiovascular and All-Cause Mortality in Rheumatoid Arthritis Using the Ankle-Brachial Index. Carlos Ramirez[3], Agustin Escalante[2], Mrisa Sahai[3], Daniel F. Battafarano[1], Samvel Pogosian[3] and Inmaculada Del Rincon[2]. [1]Brooke Army Medical Ctr, San Antonio, TX, [2]UTHSCSA, San Antonio, TX, [3]UTHSCSA

Introduction: The ankle-brachial index (ABI) is a non-invasive test of lower limb arterial function that can be readily performed at the bedside. It provides information about arterial flow obstruction and also about arterial wall rigidity. The ABI is frequently abnormal in rheumatoid arthritis (RA) patients. However, this is not often recognized, and its clinical significance is underappreciated. We examined the association between the ABI and 10-year cardiovascular (CV) and all-cause mortality in an RA cohort.

Methods: We studied a cohort of RA patients recruited from private and public rheumatology clinics. We measured the ABI as the systolic pressure of the lower limb arteries divided by that of the brachial arteries. A normal ABI varies from 0.91 to 1.3; while ABI $\leq$ 0.9 is considered obstructed, and ABI $>$ 1.3 is incompressible. Vital status of patients was updated annually. All reports of death were confirmed by death certificate. CV deaths were defined by any mention of a CV condition in the death certificate. We plotted Kaplan-Meier survival curves, and used Cox proportional hazards regression to adjust for potential confounders.

Results: We measured the ABI in 644 RA patients, among whom it was normal in 489 (76%), obstructed in 83 (13%) and incompressible in 72 (11%). Observation time from enrollment until death or last follow-up was 6,498 patient years (a median of 10.4 years per patient). During this time, 160 deaths occurred, for a mortality rate of 2.5 per 100 patient-years (95% CI 2.1, 2.9). Of these deaths, 90 were due to CV causes, for a CV mortality rate of 1.5 per 100 patient-years (1.2, 1.9). CV mortality rates per 100 patient years among patients with a normal ABI was 1.1 (0.8, 1.4); among patients with obstructed ABI mortality was 2.1 (1.3, 3.5), hazard ratio (HR) 2.0 (1.1. 3.6); and in patients with incompressible ABI CV mortality was 5.5 (3.1, 6.7), HR 4.4 (2.7, 7.2). Multivariable adjustment for demographic variables, measures of RA activity and damage and CV risk factors, attenuated the association of mortality with arterial obstruction, but did not efface that with incompressible lower limb arteries. The Figure shows a Kaplan-Meier plot of the all-cause survival function according to ABI.

Conclusion: Incompressibility of the peripheral arteries in RA patients is associated with increased CV and all-cause mortality. The ABI, a non-invasive test performed at the bedside with readily available equipment, is a potentially useful method to stratify mortality risk in RA.

Prevalence and Predictors of Pain in Rheumatoid Arthritis Patients in DAS28 Remission. Yvonne C. Lee[1], Jing Cui[3], Bing Lu[2], Michelle Frits[3], Christine K. Iannaccone[3], Nancy A. Shadick[4], Michael E. Weinblatt[4] and Daniel Hal Solomon[4]. [1]Brigham & Womens Hospital, Boston, MA, [2]Brigham and Women's Hospital, Foxboro, MA, [3]Brigham and Women's Hospital, Boston, MA, [4]Brigham and Womens Hospital, Boston, MA

Background: Physicians often presume that inflammation is the stimulus for pain in rheumatoid arthritis (RA), but many patients have pain despite well-controlled disease. We assessed the prevalence of pain in RA patients in remission according to Disease Activity Score (DAS28) and examined the associations between baseline characteristics and ongoing pain despite remission.

Methods: One hundred and sixty-four RA patients in DAS28 remission (DAS28 $<$ 2.6) completed questionnaires and underwent physical examination, blood work and hand radiographs at baseline and one year. Pain severity was assessed using the pain score from the Multi-Dimensional Health Assessment Questionnaire (MDHAQ). The association between baseline clinical predictors and clinical pain severity at one-year was assessed using multivariable linear regression.

Results: Twenty-eight patients (18.7%) in DAS28 remission had an MDHAQ pain score $\geq$ 40 at baseline. Thirty-five (22.0%) had an MDHAQ pain score $\geq$ 40 at one year. In unadjusted analyses, baseline MDHAQ pain score, MDHAQ sleep score, MDHAQ fatigue score, Arthritis Self Efficacy score and smoking were significantly associated with MDHAQ pain score at one year. Baseline Sharp score, C-reactive protein level (CRP) and DAS28 were not significantly associated with MDHAQ pain score at one year. In multivariable linear regression analyses adjusted for age and gender, baseline MDHAQ pain ($P <$ 0.0001) and MDHAQ fatigue ($P = 0.002$) remained significantly associated with one-year MDHAQ pain score (see table).

Table. Association between baseline MDHAQ pain severity and baseline MDHAQ fatigue levels and MDHAQ pain at one year among rheumatoid arthritis patients in DAS28 remission (N = 164).

Clinical Factors	Mean One-Year MDHAQ Pain Score (95% CI)	*P**
Age		**0.04**
< 50	27.8 (21.8,33.9)	
50–59	30.8 (24.4,37.2)	
≥ 60	21.7 (16.1,27.3)	
Gender		0.18
Female	23.9 (20.7,27.2)	
Male	29.6 (21.8,37.4)	
Baseline MDHAQ pain (0–100)		**<0.0001**
< 10	16.6 (10.7,22.6)	
19–29	22.4 (16.7,28.2)	
> 30	41.2 (33.7,48.7)	
Fatigue (0–100)		**0.002**
< 20	19.0 (12.4,25.5)	
20–49	26.3 (19.7,32.9)	
≥ 50	35.0 (29.1,40.9)	

*P-values from multiple linear regression, adjusted for age and gender.

Conclusion: Despite being in DAS28 remission, many RA patients still experience pain. In this cohort, RA-associated factors (e.g., Sharp scores, CRP and DAS28) were not significantly associated with pain severity at one year, but baseline pain severity and fatigue were strongly associated with pain severity at one year. These findings suggest that physicians should consider non-inflammatory etiologies of pain, such as a central sensitivity/symptom intensification syndrome, when evaluating pain in RA patients in remission.

Rheumatoid Arthritis Patients in Clinical Remission Manifest Persistent Joint Inflammation on Histology and Imaging. Allen P. Anandarajah[1], Ralf G. Thiele[2], Johnny Monu[4], Gwy-Suk Seo[3], Aqiba Bokhari[3] and Christopher T. Ritchlin[5]. [1]Univ of Rochester Med Ctr, Rochester, NY, [2]University of Rochester, Rochester, NY, [3]University of Rochester, [4]University of Rochester Med Ctr, [5]University of Rochester Medical Center, Rochester, NY

Background: Disease remission in rheumatoid arthritis (RA) has been defined clinically as the absence of evidence of disease activity. Several studies have shown, however, that patients in remission have persistent synovitis on ultrasound (US) and Magnetic Resonance Imaging (MRI). A central question is whether abnormal imaging findings in remission represent active joint inflammation.

Objective: To examine if patients in American College of Rheumatology (ACR) remission have persistent inflammation on histological analysis of synovial tissues and abnormal findings on ultrasound (US) and/ or magnetic resonance imaging (MRI),.

Methods: 13 synovial (joints) specimens were obtained from 12 RA patients in clinical remission as defined by the revised ACR criteria. Synovial specimens were obtained during surgical procedures on knee (5), hip (2), elbow (1), wrist (3), shoulder (1) and thumb (1). Histological specimens were scored for hyperplasia of synovial lining and synovial stroma, inflammation, lymphoid follicles and vascularity on a scale of 0–4 (absent, minimal, mild, moderate and severe) and a total score calculated by adding the individual scores (0–20). The total scores were classified as minimal (0–5), mild (6–10), moderate (11–15) or severe (16–20) disease activity. Nine of 13 joints also had US and/or MRI done prior to surgery. US was assessed for effusion, tenosynovitis, synovitis on grey scale and Doppler signal. MRIs were evaluated for bone marrow edema (BME), synovial proliferation, effusion and erosion. The biopsy specimens were scored by a pathologist and the imaging studies scored by 2 radiologists and a rheumatologist who were blinded to other results.

Results: The 12 patients comprised 10 females and 2 males with median disease duration of 2 years (range 1–20). Four of 12 patients were on anti-TNF therapy, 5 on methotrexate (MTX) alone, 3 on MTX and hydroxychloroquine (HCQ) and 1 on HCQ and sulfasalazine. The median histology score for the 13 specimens was 12 (moderate disease activity). Three specimens had severe, 6 moderate, 2 mild and 2 minimal disease activity on histology. Thickening of the synovial lining and stroma was seen in all patients. Inflammatory tissue was comprised mainly of lymphoplasmacytic cells in all specimens and neutrophils were noted in 6. Vascularity was also noted in all specimens (median score of 3). Interestingly, the 3 of 4 specimens with minimal and mild disease were subjects on anti-TNF therapy while the other was on methotrexate. Synovitis on US (grey scale)was seen in all 9 joints. Doppler signal was present in 5 of 6, effusion in 7 of 9 and tenosynovitis in 2 of 3 joints examined. All 4 joints that had MR images revealed synovitis, erosion and BME and one was also with effusion

Conclusion: Despite clinical remission, histology and imaging studies documented a persistently active disease state that may benefit from more aggressive therapy. Anti-TNF therapy may be more effective at suppression of disease activity than traditional DMARDs. Future studies will determine if this state is associated with disease progression.

Rheumatoid Arthritis Patients Receive Less Frequent Acute Reperfusion and Secondary Prevention after Myocardial Infarction. Sharon Van Doornum[4], Caroline Brand[3], Vijaya Sundararajan[1], Andrew Ajani[3] and Ian Wicks[2]. [1]Monash University, [2]Royal Melbourne Hospital, Melbourne, Australia, [3]Royal Melbourne Hospital, [4]University of Melbourne, Victoria, Australia

Introduction: The 30-day case fatality rate after acute myocardial infarction (MI) for rheumatoid arthritis (RA) patients is twice that of the general population.[1] This study compared the frequency and timeliness of early reperfusion therapy and treatment with secondary prevention medications after acute MI in RA patients and controls.

Methods: We performed a structured medical chart review of RA patients and matched controls who had been admitted with acute MI to one of three hospitals in Victoria, Australia between 1995 and 2005. The administration and timing of acute reperfusion therapy and in-hospital treatment with secondary prevention medications was compared between the two groups. Acute reperfusion was defined as thrombolysis or percutaneous coronary intervention (PCI) within 12 hours of first symptom of MI.

Results: The medical charts of 90 RA patients and 90 matched controls were reviewed. Demographic details, cardiovascular risk factors and other co-morbidities of the RA and control patients are shown in Table 1.

Table 1. Demographic and clinical features of the RA and control patients acute MI

	RA (n = 90)	Controls (n = 90)
Female, n (%)	55 (61)	55 (61)
Age in years, mean (SD)	71 (10)	71 (10)
RA disease duration in years, mean (SD)	20 (13)	–
No. of DMARDs, mean (SD)	1.4 (1.1)	–
Taking NSAID at time of MI, n (%)	21 (23)	6 (7)*

*$p < 0.05$

Table 2 shows the treatment received by the RA and control patients after acute MI. The RA patients were significantly less likely to receive acute reperfusion compared with the controls (16% vs 37%: OR 0.27 (95% CI

0.10–0.64)), and this difference persisted after adjusting for type of MI, clinical setting of MI and prior MI (OR 0.2, 95% CI 0.05–0.6).

Table 2. Treatment received by RA and control patients following MI

	RA (n = 90)		Controls (n = 90)			
	n	%	n	%	Unadjusted OR§ (95% CI)	Adjusted OR¶ (95% CI)
Acute reperfusion*	14	16	33	37	**0.27 (0.10–0.64)**	**0.21 (0.07–0.62)**
Thrombolysis	8	9	22	24	**0.30 (0.10–0.77)**	**0.33 (0.11–0.96)**
PCI	10	11	30	33	**0.20 (0.06–0.53)**	**0.23 (0.09–0.63)**
PCA	39	43	52	58	**0.41 (0.16–0.92)**	0.54 (0.23–1.25)
CABGS	11	12	17	19	0.57 (0.21–1.46)	0.67 (0.27–1.65)

§McNemar's chi-squared test; ¶Conditional logistic regression, adjusting for type of MI (STEMI or NSTEMI), presence of prior MI and clinical setting of MI; PCI percutaneous coronary intervention (angioplasty ± insertion of stent); PCA percutaneous coronary angiography; CABGS coronary artery bypass graft surgery.

Urgent reperfusion is not necessarily indicated in all cases of MI, however in the event of STEMI early thrombolysis or PCI is considered the standard of care. Of the total study cohort, 29 of the RA patients and 39 of the controls were diagnosed with STEMI. Acute reperfusion was administered in 48% of the RA-STEMI patients versus 74% of the control-STEMI patients (p=0.027).

Table 3 shows the number of RA and control patients who received treatment with selected secondary prevention medications after MI. The RA patients received less frequent in-hospital treatment with beta blockers (71% vs 83%: OR 0.42 (95% CI 0.18–0.96)) and lipid-lowering agents (40% vs 70%: OR 0.21 (95% CI 0.09–0.46)).

Table 3. In-hospital treatment with secondary prevention medications received by RA and control patients following myocardial infarction

	RA (n = 90)		Controls (n = 90)		
	n	%	n	%	OR§ (95% CI)
Aspirin	85	94	89	99	0.20 (0.02–1.71)
Beta Blockers	64	71	75	83	**0.42 (0.18–0.96)**
ACE Inhibitors	61	68	57	63	1.18 (0.67–2.08)
Lipid-lowering agents	36	40	63	70	**0.21 (0.09–0.46)**

§McNemar's chi-squared test; PCI percutaneous coronary intervention; PCA percutaneous coronary angiography; CABGS coronary artery bypass graft Surgery

Conclusions: RA patients who experience acute MI receive acute reperfusion and secondary prevention medications less frequently than controls. This may contribute to higher case fatality rates after MI in RA patients.

Risk Factors for Coronary Heart Diseases in Japanese Patients with Rheumatoid Arthritis: From a Large Observational Study, IORRA.

Eiichi Tanaka[1], Eisuke Inoue[3], Toru Yamada[3], Ayako Nakajima[3], Atsuo Taniguchi[3], Shigeki Momohara[3] and Hisashi Yamanaka[2]. [1]Institute of Rheumatology, Tokyo Women's Medical University, Tokyo, Japan, [2]Institute of Rheumatology, Tokyo Women's Medical University, Shinjuku-ku, Tokyo, Japan, [3]Institute of Rheumatology, Tokyo Women's Medical University

Background: The incidence and mortality of coronary heart diseases (CHD) are lower among Japanese in comparison to individuals in Western countries based on population-based cohort study. However, we reported that the incidence of CHD was higher in Japanese RA patients compared to Japanese population, as previously indicated in Western countries.

Objectives: To investigate the risk factors of CHD in Japanese patients with RA, using a large cohort of RA patients.

Methods: Among 8,699 RA patients enrolled in an observational cohort study in our institute, IORRA (Institute of Rheumatology Rheumatoid Arthritis) study from October 2000 to October 2008, 8,387 RA patients without a history of CHD were selected as this study cohort (Female 82.5%, mean age 55.3 years, mean RA duration 7.5 years). All patients were of Japanese origin. The occurrence of first-ever CHD (myocardial infarction or angina pectoris) events were collected by the biannual patient self-reports and all cases were confirmed by their medical records. BMI and smoking status, and factors in relation to RA including disease activity (DAS28) and Japanese HAQ (J-HAQ) were collected. The multivariate adjusted hazard ratio (HR) for CHD events was calculated according to these factors using Cox proportional hazards model in order to identify the risks associated with CHD events in Japanese RA patients.

Results: During the observation period (38,297 person-years, the mean follow-up period 4.6 years), 34 first-ever CHD events (myocardial infarction: 16, angina pectoris: 18) in men, and 52 first-ever CHD events (myocardial infarction: 18, angina pectoris: 34) in women were observed. The age-adjusted incidence rates (per 100,000 person-years) of all CHD events were 238.5 and 92.1, and those of myocardial infarction were 134.8 and 35.5, and those of angina pectoris were 103.7 and 56.7 in men and women, respectively. DAS28 and Japanese HAQ (J-HAQ) scores at study entry were 4.3 and 0.96 in the CHD group, 4.0 and 0.77 in the non-CHD group, respectively. Cox proportional hazards after adjusting for age, gender and RA disease duration, confirmed that hypertension (HR: 2.7 [95%CI: 1.7–4.4]), hypercholesterolemia (HR: 2.6 [1.7–4.1]), current smoking (HR: 2.4 [1.3–4.4]) and DAS28 (HR: 1.2 [1.0–1.4]) were significant factors associated with CVD events.

Conclusion: Disease activity assessed by DAS28 is a risk for the excess incidence of CHD in Japanese RA patients, however traditional risk factors for CHD such as hypertension, hypercholesterolemia and smoking were more significant risk factors for CHD. These data suggest that not only controlling the RA disease activity but also managing the co-morbid diseases is important for the improvement of long-term prognosis of RA patients.

1054

Risk of Acute Coronary Syndromes in Relation to TNF-Inhibition in Early Rheumatoid Arthritis.

Lotta Ljung[5], Julia F. Simard[3], Lennart T. H. Jacobsson[4], Solbritt M. Rantapaa-Dahlqvist[1] and Johan Askling[2]. [1]Umea, Sweden, [2]Clinical Epidemiology Unit, [3]Clinical Epidemiology Unit, Stockholm, Sweden, [4]Malmo University Hospital, Malmo, Sweden, [5]Umea University Hospital

Background: The risk of ischemic cardiovascular disease (CVD) is increased in rheumatoid arthritis (RA) also in the early course of the disease. In established RA, myocardial infarction (MI) risks have been linked to response to anti-TNF-alpha therapies (anti-TNF).

Objectives: To study the risk of acute coronary syndromes (ACS) in patients with RA during the first years of disease in relation to treatment with, and response to, TNF-inhibitor treatment.

Methods: All patients with early RA (disease duration <12 months) diagnosed 1995–2007, was identified from the Swedish RA Register (n=8,746). Data on disease activity, laboratory variables and pharmacological treatment was extracted from the register. Through linkage with the National Patient Register and the Cause of Death Register, co-morbidity and hospitalisation with ACS (ICD-10: I20-I21) were identified. Hazard ratios (HR) comparing the risk of incident ACS among patients exposed or not to anti-TNF were estimated using a propensity-score adjusted Cox proportional hazards regression among patients (n=6,000) included 1999 or later, excluding patients with previous ischemic or congestive heart disease. The relationship between response to anti-TNF and risk for an ACS in the cohort was further analysed by conditional logistic regression using a nested case-control design; 24 cases with ACS (unstable angina or MI) after start of anti-TNF were identified, and 81 matched controls were randomly selected. Patient records were reviewed for ACS validation, disease activity, pharmacological treatment, co-morbidity, CVD risk factors and extra-articular disease. No significant differences between cases and controls were noted at start of anti-TNF regarding inflammatory activity, RA therapy, RF-positivity, or extra-articular disease. There was a tendency of more prevalent CVD among cases (37% vs.16 %, p=0.07).

Results: In the cohort, 1,271 of the 6,000 patients were exposed to anti-TNF during a follow-up time of 21,677 person-years at risk (pyar) with 4,231 anti-TNF-exposed pyar. The incidence of ACS was 9.1/1000 pyar (n incident ACS=198). HR for ACS associated with anti-TNF after stratification for age, sex and year of entry in the cohort was 0.96 (95%CI 0.61–1.49), and after further adjustment for the propensity score HR was 0.81(95%CI 0.52–1.24). In the nested case-control study EULAR response (good or

moderate) at 3 and 6 months after initiation of anti-TNF therapy was achieved in 51% (cases 65 %, controls 47 %, n.s.) and 67% (cases 79 %, controls 64 %, n.s.), of the patients respectively. Comparing cases to controls, a good or moderate EULAR response at 3 or 6 months was not associated with risk of ACS, OR 1.65 (0.54–5.05) and 1.48 (0.32–6.88) respectively, adjusted for disease activity before treatment start. Furthermore, no significant associations between response and risk of ACS were observed after adjustment for previous CVD.

Conclusion: In this study of patients with early RA, treatment with, or response to, anti-TNF could not be linked to any decrease in the risk of acute coronary events. Whether this is due to factors specific for this cohort or if TNF-inhibition have limited protective abilities is not possible to conclude.

Sonographic Guidance and the Injection of the Rheumatoid Joint. Courtney R. Johnson[4], Natalia Chavez Chiang[1], Suzanne Delea[1], Hilliary Norton, Wilmer L. Sibbitt[2] and Arthur D. Bankhurst[3]. [1]Albuquerque, NM, [2]University of New Mexico HSC, Albuquerque, NM, [3]University of NM Med Ctr, Albuquerque, NM, [4]UNM Carrie Tingley Hospital, Albuquerque, NM

Objective: The present randomized controlled study addressed whether sonographic needle guidance affected the outcomes of intraarticular injection of the rheumatoid joint.

Methods: 400 rheumatoid joints were randomized to injection by conventional palpation-guided anatomic injection, sonographic image-guided injection enhanced with a one-handed RPD (the reciprocating procedure device) syringe, or the RPD alone. A one needle, two-syringe technique was used. After intraarticular placement and synovial space dilation were confirmed by sonography, a syringe exchange was performed, and triamcinolone acetonide was injected with the second syringe through the indwelling intraarticular needle. Baseline pain, procedural pain, pain at outcome (2 weeks and 6 months), responders, therapeutic duration, reinjection rates, total cost, and cost per responder were determined.

Results: Relative to conventional palpation-guided methods, sonographic guidance for injection of the rheumatoid joint resulted in 45% reduction in procedural pain ($p<0.001$), a 19% reduction in pain scores at outcome, a 20% increase in therapeutic duration, and a 23% increase in time to next injection. The RPD syringe alone was also beneficial with results midway between the conventional syringe and tsonographic guidance using the RPD syringe.

Conclusions: Sonographic needle guidance can improve the performance, clinical outcomes, and cost-effectiveness of intraarticular injections of the rheumatoid joint.

Statin Discontinuation and Risk of Acute Myocardial Infarction in Rheumatoid Arthritis: A Population-Based Study. Mary A. De Vera[1], Hyon K. Choi[5], Michal Abrahamowicz[3], Jacek Kopec[1], Maria Victoria Goycochea-Robles[4] and Diane V. Lacaille[2]. [1]Arthritis Research Centre of Canada, Vancouver, BC, Canada, [2]Arthritis Research Ctr Canada, Vancouver, BC, Canada, [3]McGill University, Montreal, QC, Canada, [4]Research Unit of Clinical Epidemiology, Hospital Regional 1 IMSS, Mexico City, Mexico, [5]Univ of British Columbia, Vancouver, BC, Canada

Purpose: Screening for cardiovascular risk factors and treating hyperlipidemia with statins are recommended to reduce the significantly increased cardiovascular risk in individuals with rheumatoid arthritis (RA). However, poor compliance with statins may limit their therapeutic benefit. Our objective was to evaluate the impact of statin discontinuation on risk of acute myocardial infarction (AMI) among RA patients.

Methods: We conducted a retrospective longitudinal study of a population-based cohort of RA patients with incident statin use followed from May 1996 to March 2006 with administrative health data. Primary exposure was statin discontinuation for ≥3 months at any time during follow-up; primary outcome was combined hospitalized AMI and fatal AMI events occurring outside of hospitals. To evaluate the impact of statin discontinuation on AMI risk, we used Cox's proportional hazards analysis and modeled statin discontinuation as a time-varying exposure variable, updated monthly. Covariates included: age, gender, comorbidities (prior AMI, cerebrovascular accident, angina, use of diabetes, hypertension, and congestive heart failure medications), and use of medications known to influence cardiac risk (hormone replacement therapy, anticoagulants), assessed at baseline. As well, proxy measures of RA severity (use of RA medications [DMARDs, glucocorticosteroids, NSAIDs, methotrexate] and rate of RA-related medical visits) were included as time-dependent covariates.

Results: The cohort of incident statin users with RA comprised 4,102 individuals with mean age of 66 years and 60% female. Atorvastatin was the most commonly initiated statin in 48% of patients, followed by simvastatin and pravastatin, initiated in 22% and 12% of patients, respectively. Overall, 1,833 (45%) individuals in the cohort met the study definition for statin discontinuation. Over 15,669 person-years of follow-up, we identified 264 AMI events. Statin discontinuation was associated with a 67% increased risk of AMI (adjusted hazard ratio: 1.67; 95% CI: 1.24–2.25). Other significant predictors of increased AMI risk included older age, male sex, prior AMI, use of diabetes, hypertension and congestive heart failure medications, as well as current glucocorticosteroid use, and cumulative rate of RA-related medical visits measured as time-dependent covariates. In subgroup analyses, the association between statin discontinuation and AMI was not modified by timing of first statin prescription, prior AMI status, sex, and age (p-values for interactions: >0.17).

Conclusion: These population-based data indicate that RA patients who discontinue statins have an increased risk of AMI. To our knowledge, this is the first study to document the impact of statin discontinuation on cardiovascular outcomes in individuals with RA. Given the recent emphasis on the management of cardiovascular risk factors in RA, our findings have implications for the care of people with RA. Not only is it important to assess cardiovascular risk and initiate recommended statin therapy in patients, it is also essential to monitor and ensure patient compliance to the prescribed therapy regimen.

1057

Stroke in Rheumatoid Arthritis: (When) Is There an Increased Risk? Marie E. Holmqvist[1], Lennart T. H. Jacobsson[3], Lars Alfredsson[1] and Johan Askling[2]. [1]Karolinska Institutet, [2]Karolinska University Hospital, [3]Malmö University Hospital

We recently showed that the risk of ischemic heart disease, known to be elevated in established RA, increases rapidly after RA onset (1). Data on risk of cerebrovascular disease are conflicting and risks in relation to RA disease duration are lacking. Few have assessed the risk of ischemic and hemorrhagic stroke separately or stratified on serostatus.

Objective: To assess the risk of stroke in patients recently diagnosed with RA with short symptom duration at diagnosis, as a function of time since diagnosis, and stratified on serostatus.

Methods: From the Swedish RA register, ongoing since 1995, we

identified 7,176 patients with recently diagnosed RA (<18 months of symptoms at inclusion). As a comparator cohort, 5 individuals from the general population were selected for each RA patient, matched on age, sex, calendar year, residential area and marital status (n=35,171). Information on all hospitalizations listing stroke was retrieved from the nationwide Swedish Hospital Discharge Register (through 2006). We assessed stroke overall, as well as ischemic and hemorrhagic stroke separately. One individual could contribute first events to both subgroup outcomes, as well as to the overall outcome. Start of follow-up was date of RA diagnosis in RA patients. Comparators were given the same start date as their matched RA patient. Incidence rates were calculated. Relative risks (RR) and 95% confidence intervals (CI) of stroke after RA-diagnosis were estimated using Cox proportional hazards regression.

Results: Mean age at start of follow-up was 57 years. 70% were women. Follow-up amounted to 31,318 person-years in the RA cohort and 153,180 person-years in the general population cohort. Median follow-up was 3.9 years (range 12 years) in both cohorts. 2.6% of all patients with RA and of all comparators had any cerebrovascular event during follow up (incidence rate 6/1000 person-years in both cohorts) which corresponded to an overall RR of 1.0 (95% CI 0.9, 1.2). The incidence rates of ischemic (4.8/1000 person-years in RA and 4.1 in comparators) and hemorrhagic stroke (0.9/1000 person-years in RA and 1.2 in comparators) were similar in both cohorts, corresponding to RRs of 1.1 (95% CI 0.9, 1.3) and 0.7 (95% CI 0.5, 1.1) respectively. During this time-frame, no increased risk of stroke was observed, neither overall nor by stroke subtype nor time since RA-diagnosis. When stratified by serostatus no heterogeneities were detected (data not shown).

	<1 year since RA diagnosis	1–4 years since RA diagnosis	5–12 years since RA diagnosis
Cerebrovascular event	1.1 (0.7,1.5)	0.9 (0.8,1.2)	1.2 (0.9,1.6)
	34/154	96/489	60/255
Ischemic stroke*	1.3 (0.9,2.0)	1.0 (0.8,1.3)	1.1 (0.8,1.6)
	29/102	80/352	44/190
Hemorrhagic stroke*	0.3 (0.1,1.2)	0.6 (0.4,1.2)	1.4 (0.7,2.7)
	2/34	15/113	13/44

*The sum of ischemic and hemorrhagic strokes does not equal cerebrovascular events since some of the cerebrovascular events cannot be classified as neither ischemic nor hemorrhagic. *Cox proportional hazards model adjusted for age at diagnosis, sex, residential area, calendar year of inclusion, and marital status.

Conclusion: In contrast to the rapid increase in IHD risk, the risk of stroke, ischemic or hemorrhagic, is not elevated in RA within 12 years of RA duration. Stratification by serostatus did not alter these results. This does, however, not preclude an increased risk of stroke in RA patients with longer disease duration but may point to distinct aetiologies behind IHD and stroke in early RA.

1058

Subclinical Atherosclerosis in Patients with Rheumatoid Arthritis Is Associated with Decreased Activity of Lecithin Cholesterol Acyl: Transferase, a High Density Lipoprotein (HDL)-Associated Protein Involved in Reverse Cholesterol Transport. Christina Charles-Schoeman[2], Yuen Yin Lee[3], Sogol Amjadi[3], John D. FitzGerald[4], Veena K. Ranganath[2], Mihaela Taylor[3], Maureen A. McMahon[2], Harold E. Paulus[1] and Srinivasa T. Reddy[3]. [1]Encino, CA, [2]UCLA School of Medicine, Los Angeles, CA, [3]UCLA School of Medicine, [4]UCLA School of Medicine Rehabilitation, Los Angeles, CA

Purpose: Patients with rheumatoid arthritis (RA) have increased cardiovascular (CV) risk which is not explained by traditional CV risk factors. Lecithin cholesterol acyl:transferase (LCAT) is an HDL-associated protein which promotes reverse cholesterol transport from cells and has been shown to protect low density lipoproteins (LDL) from oxidative modification. We previously reported that LCAT activity is decreased in RA patients compared to healthy controls, and that decreased LCAT activity is associated with abnormal anti-oxidant function of HDL. The aim of the current work was to determine whether decreased LCAT activity is associated with subclinical atherosclerosis in RA.

Methods: Carotid artery ultrasound was performed in 110 patients with rheumatoid arthritis and fasting blood was collected for lipoprotein analyses. LCAT activity was measured in patient plasma as the change in ratio of the intact to hydrolyzed LCAT monomer substrate (470/390 nm of emission intensity) over time. Lipoprotein cholesterol levels were measured by standard methods and traditional cardiovascular risk factors, medication use, and RA disease characteristics were assessed for all patients.

Results: Carotid plaque was identified in 49% of the RA patients studied. LCAT activity was significantly lower in patients with plaque compared to patients without plaque (See table). After multivariate analysis, LCAT activity (OR 0.002, p=0.009), age (OR 1.1, p<0.0001), and gender (OR 9.0, p=0.005) were significantly associated with plaque in RA patients.

Group	LCAT Activity	Age (yrs)	F (%)	HSCRP (mg/L)	DAS28	HDL-C (mg/dL)	LDL-C (mg/dL)	HTN (% yes)	BMI (lb/in2)	HAQ-DI
Plaque n = 54	0.219 ± 0.038*	61 ± 11*	78*	7.3 ± 16.9	4.4 ± 1.9	62 ± 19	106 ± 32	59*	27.4 ± 6.6	0.95 ± 0.77
No Plaque n = 56	0.237 ± 0.043	49 ± 11	93	7.1 ± 14.1	4.7 ± 1.7	59 ± 15	104 ± 37	23	27.7 ± 7.8	1.05 ± 0.88

F = Female; HTN = hypertension; DAS28 = Disease activity score with 28 joint count; HAQ - DI = health assessment questionnaire disability index; *p value < 0.05.

Conclusions: Decreased LCAT activity is significantly associated with subclinical atherosclerosis in patients with rheumatoid arthritis. This data suggest that abnormalities in the reverse cholesterol transport pathway may contribute to the increased cardiovascular disease in RA. Further investigation of abnormalities in lipoprotein function including LCAT activity may be warranted as potential biomarkers and mechanisms for increased atherosclerotic risk in RA.

Symptomatic Heart Failure, NT-proBNP Levels, and Diastolic Dysfunction in RA-Patients with and without Anti-TNFa Therapy. A Prospective Consecutive Cohort Study. Michael Gottwald[1], Denio Ridjab[2], Stephanie Glocke[1], Kathrin Behring[1], Robert Lange[3], Christian Butter[1] and Michael Zaenker[1]. [1]EFKH and Heart Center Brandenburg, Bernau, Germany, [2]EFKH and Heart Center Brandenburg, Bernau, Germany, [3]Hospitalverbund and Rheumazentrum Nord-Brandenburg

Background: Incidence of HF is 2-fold higher for patients with RA compared to general population. Independent association of RA with diastolic dysfunction and increased NT-proBNP levels has been demonstrated. The chronic elaboration of inflammatory cytokines like TNFa is likely substantial contributor to myocardial dysfunction. However, there are still conflicting results of clinical trials whether TNFa inhibition does promote or prevent heart failure in RA patients.

Objective: To determine the rate of symptomatic heart failure, increased NT-proBNP and diastolic dysfunction among RA-patients with and without TNFa-inhibition.

Methods: In this prospective study all RA-patients were consecutively included, who showed up in a 3 months period for follow up. Inclusion criteria were written consent, and diagnosis of RA, fulfilling ACR-criteria. All patients were interviewed using a standardized questionnaire to asess cardiovascular (cv) risk factors, cv disease, and symptoms of heart failure. Clinical signs were evaluated based upon Framingham criteria. Laboratory tests included NT-proBNP levels for all patients. Technical investigations included chest x-ray, ECG, spirometry, and echocardiography.

Results: 133 patients with RA, 68% female, mean (SD) age 60.3 (±13.6) years, median disease duration 8.0 years, median DAS28 2.7, median HAQ 1.25 were included. 57% reported any dyspnoea, 42% dyspnoea according to NYHA-class II, 9% NYHA-III, 4% NYHA-IV, 50% reported any edema, whereas raised NT-proBNP levels >220 ng/ml were found in only 29% of patients. Diastolic dysfunction was found in 13.7 %, systolic dysfunction in 1.9%. Cardiovascular risc factors were hypertension in 52%, hypercholesterolemia in 24%, current smoker in 23%, diabetes in 17% of patients. Previous diseases included TIA/stroke in 4%, peripheral artery disease in 9%, CAD in 22%, MI in 8%. N=48 (36%) had anti-TNFa therapy, 64% other treatment with DMARDs, abatacept, or rituximab. Comparing the subgroups with and without anti-TNFa therapy no significant differences were found for mean age, DAS28, HAQ, ESR, CRP, rate of increased NT-proBNP (68.7 vs. 70.6 %), mean NT-proBNP (244 vs. 263 ng/ml, rate of dyspnoea (54.2 vs. 58.8%), rate of NYHA II (41.6 vs. 42.3%), NYHA III (10.4 vs. 8.2 %), NYHA IV (2.0 vs. 4.7 %), diastolic dysfuntion (14.6 vs. 12.5%). The patients with anti-TNFa therapy had longer disease duration (14.5 vs. 6.0 years, p<0.001), worse HAQ (1.5 vs. 1.0, p=0.044), higher rate of hypercholesterolemia (33.3 vs.

18.8 % p=0.033) but no significantly different rates of hypertension (58.3 vs. 48.2%), diabetes (22.9 vs. 14.1%), apoplex/TIA (0 vs. 6%), MI (6 vs. 9%). Both subgroups had comparable hospital admission rates and treatment with β-blockers, diuretics, ACE-I/ARB, and statines. In multivariate analysis age>60y (OR 8.5 (1.2–58.6) p=0.03) and NT-proBNP>220 (OR 30.3 (4.2–215.6) p<0.001) were independent risc factors for diastolic dysfunction.

Conclusion: There is high rate of heart failure in our RA-cohort, increasing with age. However, the patients with anti-TNFa therapy did not show higer rates of dyspnoea, raised NT-proBNP, or diastolic dysfunction than the patients with other treatment.

The Clinical Features of 13 Women with Microchimerism in Rheumatoid Nodules. Christopher J. Atkins[4], William F. N. Chan[1], David Naismith[6], Nicholas van der Westhuizen[6], Janet Woo[3], Valerie Cortez[5] and J. Lee Nelson[2]. [1]Fred Hutchinson Cancer Research Center, [2]Fred Hutchinson Cancer Research Center and University of Washington, [3]University of British Columbia, [4]University of Victoria, Victoria, BC, Canada, [5]University of Washington, [6]Vancouver Island Health Authority

Introduction: Non-caseating granulomatous nodules in the setting of an inflammatory symmetrical polyarthritis have a high degree of diagnostic specificity for rheumatoid arthritis (RA). The pathogenesis of the rheumatoid nodule (RN) is unknown, although its growth over pressure points suggests a role for trauma. An increase in microchimerism (Mc) has been reported in the blood of RA patients, therefore we reasoned that microtrauma triggers an allogenic response to michrochimeric cells in the formation of the RN.

Purpose: To investigate Mc in RNs from women by testing for male DNA.

Methods: 1. DNA extraction from 19 nodules collected from 15 female patients followed by quantitative PCR on the Y-chromosome specific sequence *DYS14*; 2. Review of clinical features of women whose RNs contained male DNA, including treatment with methotrexate and anti-TNF biologics, both of which have been associated with RN formation; 3. Comparison of the concentration of Mc in RN, expressed as genome equivalents (gEq) of male-specific *DYS14* DNA per 100,000 cells, to serum concentration of anti-cyclic citrullinated peptide (CCP) antibodies.

Results: Fourteen nodules from 13 patients were positive for Mc. Mean age of RA onset was 43 years (range 26–64). The most common source of male DNA in a woman is prior birth of a son. Eight of 13 patients had given birth to sons, seven with sons born before (mean time from birth 19 years; range 0–38) and one after RA onset. Blood transfusion is an alternative potential source of Mc. The patient whose son was born after RA onset had received blood transfusions 1 and 4 years before disease onset. Mc can also originate from a miscarriage. The 5 patients without sons but positive for Mc had no history of miscarriage or transfusion. Two had daughters and one received gamma globulin 2 years before disease onset.

All patients presented with a symmetrical inflammatory polyarthritis. Eleven of 13 patients had erosions on X-ray. Twelve patients received methotrexate, all of whom developed RN after therapy, with 6 patients following the addition of a biologic. Two developed accelerated RN formation with methotrexate, one after the addition of infliximab. Eleven of 13 patients tested positive for rheumatoid factor. Twelve of 13 patients had a concentration of anti-CCP that is above the reference range (0–5 U/ml), with 7 patients >100 U/ml. Eight patients with a concentration of anti-CCP >50 U/ml (range 58 to >100) had a Mc concentration of <1 gEq (range 0.08–0.78). In contrast, 4 of 5 patients with a concentration of anti-CCP <50 U/ml (range 3–34) had a Mc concentration of >1 gEq (range 1.57–7.51).

Conclusions: The clinical features of 13 women with RA whose nodules contained male DNA were typical of those usually associated with severe disease. In 7 patients, the nodules appeared several years after the birth of their male offspring, suggesting a fetal origin for the foreign DNA. Unrecognized miscarriage, induced abortion, or transfer of cells from an older male sibling are potential sources of male DNA in the 5 women who did not have sons, known miscarriages, or transfusions. Patients with the highest Mc concentrations had the lowest anti-CCP concentrations, suggesting an inverse relationship.

The Clinical Implication of Anti-Cyclic Citrullinated Peptide Antibody in Late Onset Rheumatoid Arthritis. Se Jin Jung[3], Yoon Kang[3], You-Jung Ha[3], Kwang-Hoon Lee[3], Sang Won Lee[3], Min-Chan Park[1], Soo Kon Lee[2] and Yong-Beom Park. [1]Gangnam Severance Hospital, Seoul, Korea, Republic of, [2]Yonsei Univ College of Med, Seoul, Korea, Republic of, [3]Yonsei Univ College of Med

Background: Late onset rheumatoid arthritis (LORA), onset of which is over 60 years old, has clinical features that are different from those of younger onset rheumatoid arthritis (YORA). While anti-cyclic citrullinated peptide antibody (anti-CCP) is known to be more disease-specific in RA, clinical implications of anti-CCP in LORA have not been reported to date.

Purpose: To investigate the association of anti-CCP and its titer with markers reflecting disease-activity of RA.

Methods: We retrospectively investigated medical records of 238 patients with RA, who visited Severance Hospital between January 2005 and May 2009. All patients were divided into two groups according to the age of 60 when they were diagnosed with RA (LORA (N=61) and YORA (N=177)). Rheumatic factor (RF) and anti-CCP were analyzed, and disease activity score (DAS) 28 at diagnosis was assessed at their first visit. Initial as well as accumulated erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP) levels were measured. Accumulated levels were obtained using the area under curve (AUC) during the first year after diagnosis. Patients having anti-CCP were evenly distributed in three groups according to the range of the titer of anti-CCP (low (>5), moderate (5~135) and high (>270) titer groups).

Results: The mean ages of patients with LORA and YORA were 67.1 ± 6.0 and 43.7 ± 10.5 years old, respectively. There were no significant differences in joint involvement, symptom duration, clinical manifestations, positivity of RF or anti-CCP, and medications between the two groups. However, patients with LORA had higher DAS28, anti-CCP titer and accumulated ESR and CRP levels than those with YORA. The titer of anti-CCP was well correlated with initial and accumulated levels of ESR in patients with LORA (r=0.416 and r=0.432, p<0.05), but not with patients with YORA.

Conclusions: In patients with LORA, but not with YORA, the titer of anti-CCP was significantly correlated with initial and accumulated levels of ESR, suggesting that initial titer of anti-CCP might be used as a value to predict the extent of inflammation during the first year after diagnosis in LORA patients.

The Effect of Calcium and Vitamin D Supplementation on the Incidence of Rheumatoid Arthritis in the Women's Health Initiative Randomized Study. Marius Racovan[10], Brian Walitt[10], Christopher Collins[10], Mary Pettinger[2], Christine Parks[4], James Shikany[6], Jean Wactawski-Wende[8], JoAnn E. Manson[1], Larry Moreland[9], Nicole Wright[7], Rebecca Jackson[5] and Barbara V. Howard[3]. [1]Brigham and Women's Hospital, Harvard Medical School, [2]Fred Hutchinson Cancer Research Center, [3]MedStar Research Institute, [4]National Institute of Enviromental Health Sciences, [5]Ohio State University, [6]University of Alabama, [7]University of Arizona, [8]University of Buffalo, [9]University of Pittsburgh, [10]Washington Hospital Center

Objective: To determine if calcium and vitamin D supplementation reduces the incidence of rheumatoid arthritis (RA).

Methods: 32,435 postmenopausal women enrolled in the WHI calcium plus vitamin D (CaD) randomized controlled trial were included in a study with primary endpoints of hip fracture or colorectal cancer. The participants were assigned in a randomized, double-blind manner to either daily 1000 mg of calcium carbonate plus 400 IU of vitamin D_3 or placebo. In a post-hoc analysis, a previously validated method was used to identify RA cases using participant self-report plus concomitant use of disease modifying anti-rheumatic drugs (DMARDs). Cox proportional hazards ratios and Kaplan-Meier curves were used to compare the incidence of RA in the treatment versus the placebo groups. Covariates, such as age, hormone therapy, smoking, duration of breastfeeding and geographic location, were considered in the model.

Results: 163 new RA cases were identified over 6 years. No significant differences were observed between the two groups in terms of demographics or non-experimental vitamin D intake (total vitamin D supplementation [p = 0.96], multivitamin intake [p = 0.07] and sun exposure [p= 0.85]). There was no difference between the two groups in RA incidence (p=0.82, Figure 1). Stratification of the results by age, regional solar irradiance and total vitamin D intake and adjustments for covariates such as smoking, hormone therapy, longer duration of breastfeeding did not alter the results.

Conclusions: Calcium and vitamin D intake as a dietary supplement did not have a statistically significant effect on the incidence of RA in the WHI randomized CaD trial. These results suggest that calcium and low dose vitamin D replacement had no effect on the development of RA in post-menopausal women. Further research is needed to assess the effect of supplementation with higher doses of vitamin D on the incidence of RA.

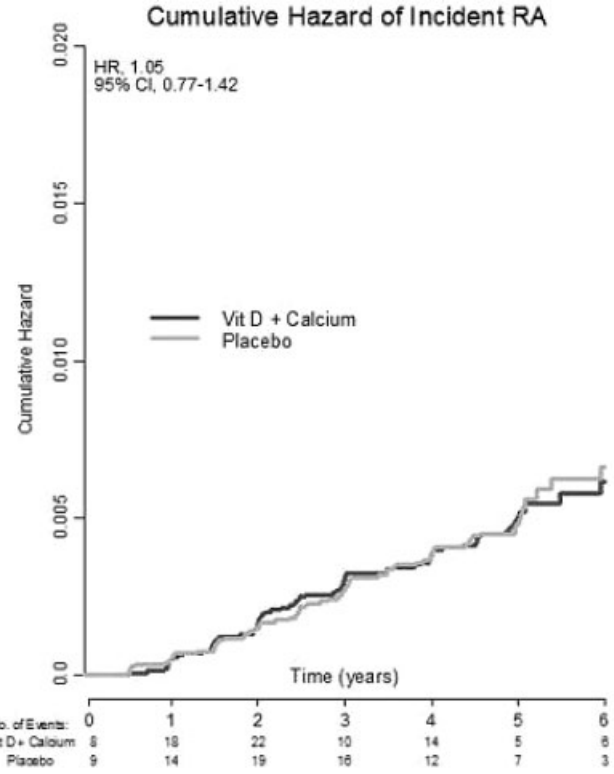

Figure 1. Cumulative hazard of incident RA.

The Impact of Rheumatoid Arthritis (RA) on Women: Focus on Pain, Productivity and Relationships. Vibeke Strand[2], Paul Emery[1], Scott Fleming[4] and Catherine Griffin[3]. [1]Chapel Allerton Hospital, Leeds, United Kingdom, [2]Division of Immunology and Rheumatology, Stanford University School of Medicine, Palo Alto, CA, [3]Echo Research, London, UK, [4]UCB, Slough, UK

Background: It is widely recognized that daily life-burdens associated with RA, including functional impairment, pain, inability to participate in desired family, social and leisure activities and reduced productivity at work and within the home, have a profound impact on the overall health-related quality of life (HRQoL) of RA patients. However, this impact on daily life in women, as well as on relationships and overall well-being, has not been well characterized.

Objective: To explore the impact of RA on women's daily lives and relationships.

Methods: Women with RA from 7 countries (USA, Canada, UK, France, Germany, Italy, and Spain) were recruited by an online research panel to complete an internet survey regarding how their lifestyle has been affected by RA. Eligible women were aged 25–65 years with a formal diagnosis ≥6 months; screening criteria were established to exclude those without a diagnosis of RA and/or who did not satisfy the age criteria. Respondents were queried regarding the physical, emotional and social impacts of RA on their lives. Mean responses to each question were computed for the overall patient population.

Results: 27,459 women were recruited via an online research panel. Of these, a total of 1958 women with RA (USA, UK, Germany, and Spain 300 patients each; Canada, 155; France, 301; Italy, 302) completed the survey between July 30 and August 31, 2009. No major regional differences were observed in any outcome measured. Mean age was 46 years, 75% had RA diagnosed >1 year and 69% self-reported moderate to severe disease. Among the 75% of respondents who were currently taking pain-relief medications, a high proportion still reported experiencing daily pain (72%). The majority of respondents felt they had to conceal pain (68%). Furthermore, 67% of respondents agreed/strongly agreed that they constantly look for new ideas to address pain, and nearly 9 out of 10 mentioned pain in discussions with their physicians. Another key finding of the survey was the negative impact of RA on productivity at work. Of those employed (n=1108), 71% reported they were less productive at work because of RA, 23% had to stop work altogether, and 17% had to switch to part-time employment. Respondents reported that the emotional impact of RA is high: many have feelings of detachment and isolation from their friends and family due to their condition; 26% felt isolated, and 32% that RA had affected their closest relationships for the worse. RA was also reported to negatively affect the most intimate aspects of patients' lifestyles, with 4 of 10 single women agreeing that RA makes it more challenging to find a partner, and 22% divorced/separated respondents indicating that RA had at least some role in their decision to separate.

Conclusions: Pain is a paramount issue for women with RA; the majority experience pain despite taking pain relief medication. In all countries evaluated, respondents indicated that RA had a negative impact on employment and caused them to feel isolated, negatively affecting intimate relationships. Optimization of treatment strategies to reduce pain, increase productivity, and manage the social aspects of the disease is thus needed.

There Are No Differences in Lipids between RA Patients and Their Siblings, Despite Higher Incidence of CHD in RA. Namita Kumar, Nicola J. Marshall, David J. Walker and Philip N. Platt. University Hospital of North Durham

Introduction: The interest in coronary heart disease (CHD) and cardiovascular risk remains high in our patients with inflammatory arthritis and especially Rheumatoid Arthritis (RA). The exact cause of the increased risk is still unclear with contradictory data regards the role of lipids and their response to treatment.

We looked at a cohort of RA patients and their siblings to assess this further.

Method: A population of RA patients and their same sex siblings were studied in Newcastle-upon-Tyne, UK. This population were matched for age and sex. Diagnosis of CHD and a number of risk factors were assessed and compared. Diabetics were excluded.

Results: Data from 79 pairs were available, Female:male ratio was 67: 12. There was a twofold increase in the amount of diagnosed CHD in the index cases compared to the siblings (Mann-Whitney test, (p less than 0.0001). There was a significant increase in CRP and ESR (p less than 0.0004) in the index cases and increased BMI in the siblings. Current and previous smoking status between the 2 groups was similar. There was no difference in the use of statins and other lipid lowering drugs between the 2 groups.

Linear regression showed no association between CRP, cholesterol: HDL, LDL apolipoprotein A or B and the incidence of CHD in our patients with RA. There was also no correlation with CRP and any of the lipids shown in Table 1.

N = 79 pairs	RA	Sibling	P-value
Age	61.9 (9.2)	59.4 (10.8))	*ns*
Diagnosed CHD	16 (20%)	9 (11%)	*<0.0001*
CRP mg/l median (range)	11 (3.232)	3 (0.21)	*<0.001*
BMI (kg/m^2) (mean SD)	25.7 (5.6)	27.3 (5.1)	x*0.016*
Cholesterol mmol/l (mean, SD)	5.5 (1.1)	5.9 (1.2)	*ns*
Triglycerides mmol/l	1.5 (0.6, 3.8)	1.3 (0.4, 4.1)	*ns*
HDL-cholesterol mmol/l	1.5 (0.4)	1.6 (0.4)	*ns*
Cholesterol: HDL mmol/l	3.8 (1.0)	3.9 (1.0)	*ns*
LDL mmol/l (mean, SD)	3.3 (1.0)	3.6 (1.1)	*ns*
Apolipoprotein A1 (mean, SD)	1.45 (0.3)	1.5 (0.3)	*ns*
Apolipoprotein B (mean, SD)	0.99 (0.25)	1.01 (0.3)	*ns*

In those pairs who had no CHD there was still no difference in cholesterol, triglycerides, cholesterol: HDL and apolipoprotein A and B levels, all of which were in the normal range.

Conclusion: RA patients have higher CHD than same sex siblings when matched for age, sex, diabetes and smoking status. They have lower BMIs and higher inflammatory markers. This data suggest that lipids within this RA population were not a major component of risk.

Disclosure: N. Kumar: None; **N. J. Marshall:** None; **D. J. Walker:** None; **P. N. Platt:** None.

Thigh Fat and Muscle in Rheumatoid Arthritis: Associations with Disease Features and Physical Functioning. Henry R. Kramer[1], Kevin R. Fontaine[1], Joan M. Bathon[1] and Jon T. Giles[2]. [1]Division of Rheumatology, Johns Hopkins University, Baltimore, MD, [2]Johns Hopkins Univ, Baltimore, MD

Background: Body fat is increased and lean mass decreased, on average, in rheumatoid arthritis (RA) patients. However, no studies have explored longitudinal predictors of thigh fat and muscle composition, an important anatomic site for physical functioning.

Methods: Participants in ESCAPE RA, a prospective cohort study of cardiovascular disease in RA, underwent mid-femur computed tomography (CT) scanning at study visit 3, occurring 3.2 ± 0.3 years from baseline. The associations of baseline and cumulative demographic, lifestyle, and RA disease and treatment characteristics with thigh fat area (TFA), thigh muscle area (TMA), and thigh muscle density (TMD) were explored using multivariate linear regression (MVLR). MVLR was also used to model associations of TFA, TMA, and TMD with disability, assessed using HAQ and with the components and summary score of the Short Physical Performance Battery (SPPB).

Results: A total of 152 RA patients (64% female; 88% Caucasian; mean age=63 years; median baseline RA duration=12 years, median DAS28 at visit 3=3.1) were scanned. Among RA characteristics, longer RA duration, higher tender joint count, higher cumulative IL-6, and current prednisone use were significantly associated with lower TMA, even after adjusting for demographics, smoking, physical activity, depression, and thyroid disease. RA characteristics accounted for 24% of the explainable variability in TMA. These same RA characteristics were also significantly associated with TMD, and accounted for 45% of the explainable variability. For TFA, longer RA duration and higher FACIT fatigue scores were significantly associated with higher TFA, and current prednisone use was associated with 28cm^2 lower TFA compared to non-use (p=0.001); however, cumulative prednisone dose was not associated with TFA. RA characteristics accounted for 28% of the explainable variability in TFA. Biologic and non-biologic DMARD treatment was not significantly associated with thigh composition. Lower TMD and higher TFA (but not TMA) were significantly associated with higher HAQ scores, after adjusting for exercise, DAS28, Sharp score, and FACIT score. These six characteristics accounted for 59% of the explainable variability. RA patients with the lowest SPPB scores had significantly lower TMA and TMD compared to those with the highest scores (Figure). TFA was not significantly associated with SPPB score.

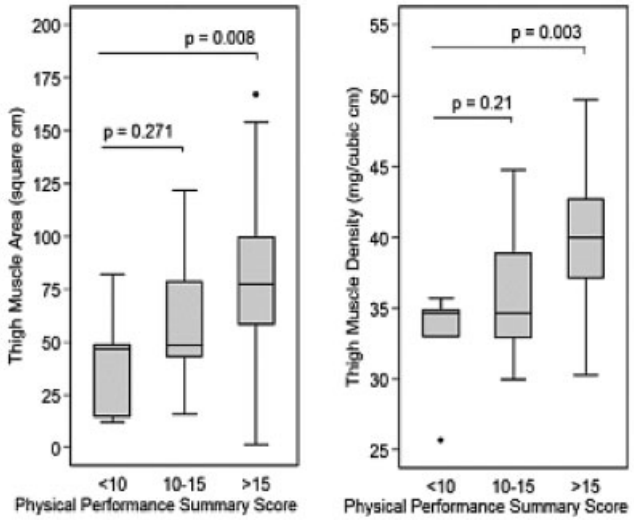

Figure. Thigh muscle area and density according to short physical performance battery summary score.

Conclusions: These findings suggest that: 1) the origins of altered muscle bulk and quality, and changes in fat distribution, are likely multifactorial in RA patients, with contributions from inflammation, joint damage, fatigue, and treatments (i.e. glucocorticoids) and 2) abnormal fat and muscle composition, in particular muscle quality, contribute substantially to physical functioning.

1066

TNF Inhibitors and the Risk of Fracture in Rheumatoid Arthritis. Daniel Hal Solomon[3], Seo Young Kim[1], Jun Liu[2], Claire Canning[2] and Sebastian Schneeweiss[2]. [1]Brigham and Women's Hospital, Boston, MA, [2]Brigham and Women's Hospital, [3]Brigham and Womens Hospital, Boston, MA

Background: Prior studies suggest an increased risk of fracture with RA. Potential causes include the underlying inflammation of RA as well as use of glucocorticoids. Several prior investigations demonstrate an improvement in bone mineral density associated with use of TNF inhibitors (TNFi). However, there are no studies comparing the risk of fracture related to different DMARDs in patients diagnosed with RA.

Methods: Our study cohort was drawn from two data sources—a population-based cohort from a Canadian province and a large US commercial insurance plan. Patients with at least 2 diagnoses of RA were eligible for the study cohort at the time of a DMARD addition or switch. DMARD additions or switches were categorized into three mutually exclusive groups: 1) TNFi, with or without other DMARDs; 2) methotrexate (MTX), without a TNFi; or 3) other DMARDs, without a TNFi or MTX. Group 3 (other DMARD) was considered the reference group. Subjects were followed until they experienced a hip, humerus, wrist, or pelvis fracture based on diagnosis and procedure codes identified in the health care utilization data. The composite of any of these fracture types was considered the primary outcome. Incidence rates for fractures were compared across exposure groups. In addition, adjusted hazard ratios were calculated in Cox regression with covariates including age, gender, Charlson comorbidity index, prior fractures, oral glucocorticoids, other fracture risk factors, and health services utilization. Secondary analyses focused on groups with oral glucocorticoid use and prior fractures.

Results: The study cohort consisted of 25,988 subjects with RA starting one of the three groups: 5,856 TNFi, 12,554 MTX, and 7,578 other DMARDs. Mean follow-up was 6 months. The three groups' characteristics were similar with respect to age, gender, and comorbidities, but differed with respect to oral glucocorticoid and opioid use, with higher rates for TNFi users. The incidence rates per 1,000 person-years for the composite fracture outcome were 5.11 (95% CI 3.50–7.45) for TNFi, 5.35 (95% CI 4.08–7.02) for MTX, and

6.38 (95% CI 3.78–10.77) for other DMARDs. Adjusted hazard ratios for the primary outcome and secondary analyses are shown in the Table. The risk of fracture was similar across DMARD exposure groups.

Table. Adjusted hazard ratio (95% CI) for fracture among subjects with RA

	Main analysis (n = 25,988)	No recent steroid use (n = 18,157)	No prior fracture (n = 25,752)
Other DMARDs	Reference	Reference	Reference
MTX	1.18 (0.60–2.34)	1.20 (0.62–2.34)	1.17 (0.46–2.98)
TNFi	1.07 (0.57–1.98)	1.25 (0.60–2.61)	1.21 (0.54–2.71)

Conclusions: Among subjects diagnosed with RA, the adjusted risk of fracture was similar across persons starting a TNFi, MTX, or other DMARDs. This result was robust across secondary analyses.

1067

Traditional and Novel Risk Markers for Atherosclerosis but Not Clinical Measures of Inflammatory Disease Are Associated with Atheromatous Plaque Presence in Early Inflammatory Polyarthritis—Results from the Norfolk Arthritis Register (NOAR). Hoda Mirjafari[3], Suzanne M. M. Verstappen[2], Diane Bunn[6], Helena Edlin[5], Valentine Charlton-Menys[4], Philip Pemberton[5], Tarnya Marshall[6], Paddy Wilson[6], Mark Lunt[2], Deborah P. Symmons[7] and Ian N. Bruce[1]. [1]Arthritis Research UK Epidemiology Unit, Stopford Building, The University of Manchester, Manchester, United Kingdom, [2]Arthritis Research UK Epidemiology Unit, Stopford Building, The University of Manchester, [3]Arthritis Research UK Epidemiology Unit, The University of Manchester, [4]Cardiovascular Research Group, The University of Manchester, [5]Manchester Royal Infirmary, [6]Norfolk and Norwich University Hospital, [7]Univ of Manchester, Manchester, United Kingdom

Purpose: Patients with inflammatory polyarthritis (IP) have an excess risk of cardiovascular (CVD) mortality due to accelerated atherosclerosis. Markers identifying individuals with subclinical atheromatous plaque may allow for attenuation of CVD risk. The objective of this study was to identify risk markers associated with atheromatous plaque in an incident cohort of patients with early IP.

Methods: Consecutive patients with early IP (> or equal to 2 joints swollen for > or equal to 4 weeks) aged 18–65 years, who were within 24 months of symptom onset were recruited as part of a primary-care based inception cohort between 2004–2008. Patients underwent assessment of classic risk factors, completion of a health assessment questionnaire (HAQ) and a 28 joint count for calculation of disease activity score (DAS28). Blood was taken for rheumatoid factor (RF), anti-citrullinated protein antibody (ACPA), C-reactive protein (CRP), high sensitivity CRP (hs-CRP), fasting glucose, novel and traditional lipid levels (LDL, HDL, triglycerides, paroxonase 1 (PON1) apolipoprotein (Apo) A1 and B), markers of vascular damage (E-selectin, vascular adhesion molecule (VCAM)) and adipocytokines (leptin and adiponectin). All patients underwent B mode Doppler ultrasound examination of the carotid arteries to assess for the presence of plaque. In univariate analyses we identified factors that were associated with plaque presence after age and gender adjustment. An additive stepwise multivariable logistic regression model investigated the independence of any associations.

Results: Of the 316 patients studied 93 (29%) patients were male. The median (IQR) age and symptom duration at study entry was 51 (42–58) years and 6.6 (4.2–11.2) months respectively. The patients had a mean (SD) blood pressure of 134/82 (17/10) mmHg, 71(23%) were smokers and 149 (47%) had detectable plaque. From the univariate analysis; age, smoking, total cholesterol, triglycerides, Apo B, hs-CRP, adiponectin and E-selectin were significantly associated with plaque presence. There was no significant association found between HAQ score, DAS28, exposure to steroid therapy and DMARDs, RF and ACPA status and plaque presence at baseline (OR (95% CI); 0.97 (0.68, 1.40), 1.06 (0.85, 1.32), 0.77 (0.39, 1.51), 0.98 (0.58, 1.64), 1.54 (0.92, 2.57), 1.39 (0.81, 2.39)). In an additive stepwise multivariable logistic regression model age, smoking, systolic blood pressure, Apo B, hs-CRP and adiponectin remained significant independent predictors of plaque (Table).

Table. Multivariable logistic regression association with plaque

Variable	Odds Ratio (95% CI)
Age (years)	1.11 (1.07, 1.16)
Smoker (Y/N)	2.91 (1.28, 6.64)
Systolic blood pressure (/mmHg)	1.02 (1.00, 1.04)
Apo B (/g/l)	7.63 (2.28,25.51)
hs-CRP (/mg/L)	1.04 (1.01, 1.07)
Adiponectin (/mg/l)	1.19 (1.05, 1.36)

Conclusion: Markers known to be associated with atherosclerosis in the general population including smoking, higher systolic blood pressure and Apo B are associated with early atherosclerosis in this population. The association with hs-CRP and adiponectin suggests that low grade inflammation, even in early disease, may contribute to atherogenesis in early IP.

Unaffected First-Degree Relatives of RA Patients Exhibit a High Prevalence of Joint Symptoms That Is Not Explained by the Presence of RA Autoantibodies: Studies in a Predisposed North American Native Population. Irene Smolik[3], Qier Tan[3], Xikui Wang[3], Donna Hart[3], Marianna Newkirk[1], Charles N. Bernstein[3], David B. Robinson[3] and Hani S. El-Gabalawy[2]. [1]McGill University, [2]University of Manitoba, Winnipeg, MB, Canada, [3]University of Manitoba

Purpose: We have previously shown that in a North American Native (NAN) population in Central Canada, the prevalence of RA is 2–3 times higher than that seen in most other populations, with a particularly high frequency of familial disease. We have also demonstrated a high prevalence of anti-citrullinated protein antibodies (ACPA), rheumatoid factor (RF), and of RA-like joint symptoms in the first-degree relatives (FDR) of RA probands from this population. We sought to get a better understanding of the relationship between joint symptoms and RA autoantibodies in disease-free NAN individuals who may be at risk for developing future RA.

Methods: The prevalence of joint symptoms was compared in three distinct groups: 1) FDR of NAN RA patients (n=306), 2) NAN controls (NC, n=330), and 3) Caucasian controls (CC, n=293). The two control groups had no family history of RA or related autoimmune diseases, and NC were from the same geographic areas as FDR. All study subjects completed a questionnaire which included demographic data, health related habits, family health history, and six questions probing into whether they experience pain, swelling, or stiffness of the hands or of other joints. Anti-CCP2 antibodies were tested by ELISA and RF by nephelometry in FDR (n=287), NC (n=198), CC (n=100).

Results: The mean age of FDR= 35±13, NC= 33±11, CC= 42±13, $p<0.0001$. The percentage of females was FDR=69%, NC=63%, and CC=63%, p=ns. In all groups, females reported more joint pain, swelling, and stiffness, and overall had an OR=1.6, $p<0.01$ for having any joint symptom. Compared to both control groups, FDR were more likely to report joint symptoms in the hands: pain (54%, 35%, 18%); swelling (36%, 16%, 7%); stiffness (40%, 23%, 14%); and in other joints: pain (57%, 34%, 32%); swelling (30%, 17%, 11%); stiffness (39%, 24%, 25%) for FDR, NC, CC, respectively; all comparisons $p<0.0001$. The high prevalence of joint symptoms in FDR was confirmed after matching FDR to NC by age and sex. Compared to CC, NC had more joint symptoms ($p<0.01$ for all hand joint symptoms). There was a higher prevalence of joint symptoms in FDR living in urban vs. rural locations (79% vs. 60%, $P<0.0001$). The prevalence of anti-CCP2 was: FDR = 8.3%, NC = 1%, and CC = 1%, $p<0.0001$, and RF was: FDR = 4.5%, NC = 1%, and CC= 1%, $p<0.05$. Logistic regression modeling demonstrated that age and FDR status were strong independent predictors of having any joint symptoms ($p<0.0001$ for both), while gender, RF, and ACPA status were not significant predictors in the model. Similar results were obtained when modeling the individual joint symptoms, although gender was found to be a predictor of hand symptoms.

Conclusion: RA-like joint symptoms are more common in FDR of NAN RA patients than in either NAN or Caucasian individuals having no

family history of RA, a finding that is not explained by the higher prevalence of ACPA and RF in FDR. This finding, combined with the overall higher frequency of joint symptoms seen in NAN compared to Caucasian controls, and in urban compared to rural FDR raises the possibility that pre-clinical joint symptoms based on biological and psychosocial factors may be part of the risk profile for developing future disease in high risk individuals and populations.

'Shared' T-Cell Clones Identified in Lymph Nodes and Synovial Tissue of Early Rheumatoid Arthritis Patients Using a Novel High Throughput Sequencing Technology. Paul L. Klarenbeek[4], Marjolein J. de Hair[4], Stefano Alivernini[4], Marleen G. van de Sande[4], Marieke E. Doorenspleet[4], Barbera D. van Schaik[3], Ferco H. Berger[2], Rebecca E. Esveldt[4], Antoine H. van Kampen[3], Danielle M. Gerlag[4], Frank Baas[5], Paul P. Tak[1] and Niek de Vries[4]. [1]Academic Med Ctr/Univ of Amsterdam, Amsterdam, The Netherlands, [2]Dept of Radiology, Academic Medical Center-University of Amsterdam, [3]Dept. of Clin. Epidemiology, Biostatistics and Bioinformatics, Academic Medical Center-University of Amsterdam, [4]Div of Clin Immunology & Rheumatology, Academic Medical Center-University of Amsterdam, Amsterdam, The Netherlands, [5]Lab. For Genome Analysis, Academic Medical Center-University of Amsterdam

Background: T-cells are likely to play important roles in the pathogenesis of rheumatoid arthritis (RA), but the role of T-cell clones remains to be elucidated. Although the synovial tissue (ST) is the primary target tissue in RA, previous observations from our group suggested that other sites might also be involved in the early phases. As a primary site for adaptive immune responses the lymph node (LN) is a likely candidate. Previously, we demonstrated, using newly developed High Throughput Sequencing (HTS) technology, that T-cell clones are present in the ST of RA-patients, and that the T-cell repertoire in the ST is markedly different from that in the peripheral blood (PB). Here, for the first time, we analyzed paired samples from LN, ST and PB to study T-cell clones in early RA.

Objectives: Investigate paired LN, ST, and PB samples of early RA patients for presence of T-cell clones to analyze the relation between these compartments with regard to adaptive immune responses.

Methods: mRNA was isolated from paired LN, ST and PB samples of 2 DMARD-naive anti-CCP+ RA-patients (pt) (fulfilling ACR-criteria at inclusion; disease duration < 1 year) after arthroscopic ST sampling of an arthritic ankle and ultrasound guided needle biopsy sampling of a regional lymph node. A linear amplification with primers for all V(ariable)-genes of the T-cell receptor β-chain was performed. The amplified products contain the Complementarity Determining Region 3 (CDR3), which can be used as 'fingerprint' for each clone. The samples were processed using a Genome Sequencer (454/Roche) analyzing up to 1 million receptors at once. The frequency of each clone was determined by the CDR3 using bioinformatics algorithms. Clones with a frequency of ≥1% were arbitrarily considered as highly expanded.

Results: The LN samples showed only few highly expanded clones when compared to the ST (2 vs. 25 clones (pt1) and 1 vs 24 (pt2) in LN and ST respectively). Few expanded clones were detected in PB as well (0 (pt1) and 2 (pt2)). Evidence of circulation between the compartments was seen in both patients. E.g. of the 24 highly expanded clones in pt2 9 clones were found in the PB and 8 were found in the LN. Of these, 4 were found both in the LN and the PB. Whereas these shared clones were highly expanded in the ST, they were of low frequency in the PB and LN (0.01–0.09% in LN and 0.01–0.52% in PB). Little overlap was seen in the T-cell repertoire between ST and PB/LN. In pt1 only 6% and 8% of the ST clones were shared with the LN and PB respectively. In pt2 this was 9% for both LN and PB.

Conclusions: This is the first analysis of T-cell clones in LN samples compared to ST and PB, using the HTS technology. In these patients we found T-cell clones in both the regional LN and the ST. Only few highly expanded clones were found in the LN while multiple highly expanded clones were found in the ST, perhaps due to epitope spreading in the ST. Many of the highly expanded ST clones could be found back in LN and/or PB. The frequencies of these clones in LN/PB were very low suggesting local retention and/or proliferation of these clones in the inflamed ST. Additional studies are underway to further characterize the roles of T- and B-cell clones in early RA and to investigate the role of the LN in RA.

Anticitrullinated Peptide Antibodies (ACPAS) in the Sera of Heavy Smokers without Arthritis. A Differential Role of Associated Pulmonary Disease? Virginia Ruiz-Esquide[3], María José Gómara[4], Víctor Peinado[1], José Alfredo Gómez Puerta[3], María Victoria Hernández[2], Joan A. Barberà[1], Julio Ramírez[3], Juan de Dios Cañete[3], Isabel Haro[4] and Raimon Sanmartí[3]. [1]Pneumology Service, Hospital Clínic of Barcelona, Barcelona, Spain, [2]Rheumatology Service, Hospital Clínic of Barcelona, Barcelona, Spain, [3]Rheumatology Service. Hospital Clínic of Barcelona, Barcelona, Spain, [4]Unit of Synthesis and Biomedical Applications of Peptides, IQAC-CSIC, Barcelona, Spain

Background: Anti-citrullinated peptide antibodies (ACPAs) are the most specific serological markers of rheumatoid arthritis (RA). An increased risk of RA has been described in smokers, but only in ACPA-positive RA patients. The frequency of ACPAs in serum of heavy smokers is not known.

Objectives: To analyze the frequency and levels of ACPAs in the serum of heavy smokers subjects, with and without lung disease, and to compare them with a healthy control group.

Methods: Serum samples of 110 heavy smokers (39% women, mean age 56.9 ± 10 years) were obtained. Subjects were selected, from a Pneumology Service data base and from hospital health workers, regardless of wheather they had chronic obstructive lung disease (COPD) or not. Study subjects were compared with a healthy control group who had never smoked (51% women, 41.8 ± 12 years) (n=209). Both groups were tested for two different antibodies against citrullinated proteins, a commercial CCP2 test and a home-made chimeric fibrin/filaggrin citrullinated synthetic peptide (anti-CFFCP). The frequency of positive results and autoantibody levels were compared between groups.

Results: Of the 110 heavy smokers, 54 had COPD and 56 were healthy smokers. None had RA. Mean pack-years were 44.3 ± 36 (53 ± 28 in COPD disease and 36 ± 16 in healthy smokers, $p<0.01$).

The percentage of positive results together with the mean serum levels of the two citrullinated autoantibodies in all the study groups are shown in Table 1.

The prevalence of positive anti-CFFCP was higher in the heavy smoker group than in non smokers, although the difference was not significant. The highest prevalence of positive anti-CFFCP was seen in patients with COPD (7.4%); the difference was at the limit of statistical significance compared with the control group (2.4%) (OR 3.26 95% CI 0.85–12.6 p=0.07). There was no significant difference in the frequency of positive anti-CCP antibodies between groups.

The differences in the mean serum levels of anti-CFFCP and anti-CCP antibodies in heavy smokers compared with never smokers were not statistically significant. Heavy smokers with COPD had significantly higher levels of both autoantibodies than those without pulmonary disease, although almost all patients had serum levels bellow the cut-off values.

Table 1. Frequency (%) of patients with positive autoantibodies and mean serum levels of antibodies in the study groups.

	HEAVY SMOKERS			NON SMOKERS
	A TOTAL n = 110	B COPD n = 54	C NON COPD n = 56	D n = 209
CFFCP+ (%)	5 (4.5%)	4 (7.4%)*	1 (1.7%)	5 (2.4%)*
CFFCP mean ± SD	0.12 ± 0.06	0.15 ± 0.7†	0.09 ± 0.5†	0.10 ± 0.12
CCP2+ (%)	2 (1.8%)	2 (3.7%)	0 (0%)	4 (1.9%)
CCP2 mean ± SD	15.62 ± 4.25	16.2 ± 5.97‡	15.05 ± 0.9‡	16.9 ± 2.78

*B vs D: p = 0.07
†B vs C: p = 0.013
‡B vs C: p = 0.003

Conclusion: ACPAs are rarely seen in the sera of non-arthritic heavy smokers. However the production of these autoantibodies seems to be higher in heavy smokers patients with associated COPD disease. Larger series

studies are necessary to confirm these findings and to ascertain the relationship between ACPAs and inflammatory lung disease.

Anti-Citrullinated Protein Antibodies (ACPA) in Unaffected Siblings of ACPA-Positive Rheumatoid Arthritis Patients. Lillian Barra[1], Elizabeth Wilson[1], Matthias Scinocca[1], Kelly Summers[1], Ewa Cairns[2] and David A. Bell[2]. [1]The University of Western Ontario, [2]The University of Western Ontario, London, ON, Canada

Background: We have previously reported that ACPA purified from RA patients injected intra-peritoneally (ip) into FcgRIIB-deficient mice induced inflammatory arthritis; whereas, ip injections of IgG devoid of ACPA from the same RA patients did not. ACPA has been shown to be positive in some unaffected first degree relatives of patients with RA (approximately 2% prevalence in a predominantly Caucasian population and 17% in a North American Native population) and its prevalence increases with the presence of the shared epitope (SE).

Objective: To determine whether unaffected siblings of ACPA positive RA probands have RA features and whether their ACPA can induce inflammatory arthritis experimentally.

Methods: Patients were included if they met ACR criteria for RA, had IgG anti-CCP2>50 and had unaffected siblings (confirmed after assessment by a physician). A questionnaire detailing medical history and risk factors for RA was completed. ACPA was affinity purified using a proprietary synthetic citrullinated peptide (JED) and administered ip to pre-autoimmune FcγRIIb deficient mice. IgG and IgM anti-JED and anti-CCP2 were measured by ELISA. All subjects were tested for the presence of the SE; levels of 27 cytokines were determined by Luminex®.

Results: Twelve families were recruited for a total of 33 siblings (32 were unaffected with RA); there were two monozygotic twins discordant for RA. All subjects were Caucasian. Mean age of RA probands was 60, mean age of disease onset was 44, 10/12 (83%) were smokers, and 10/12 (83%) were in complete remission. Mean age of siblings was 51 and 14/29 (48%) were smokers, which was significantly less than RA probands ($p=0.024$). 9/12 probands were also IgG anti-JED positive and 7/12 were IgM anti-JED positive. One sibling was IgG anti-JED and anti-CCP2 positive. 10/31 siblings were IgM anti-JED positive; whereas, all normals ($n=9$) were negative. The monozygotic twins were also discordant for the presence of anti-JED and anti-CCP2. The results of HLA-typing and ip ACPA transfers are pending. Pro-inflammatory cytokines were elevated in RA patients compared to siblings and normals ($p<0.05$). Siblings did not have higher levels of pro-inflammatory cytokines than normals; however, the levels in smokers were higher than non-smokers ($p<0.05$).

Conclusions: Siblings of IgG anti-CCP2 postive RA probands had an increase in IgM anti-JED, but rarely had IgG anti-JED and IgG anti-CCP2 and also lacked elevation of pro-inflammatory cytokines characteristic of RA. Interestingly, monozygotic twins discordant for RA were also discordant for the presence of anti-CCP2 and anti-JED antibodies. Future work aims to determine whether IgM and IgG anti-JED isolated from these unaffected siblings is pathogenic in a mouse model of inflammatory arthritis.

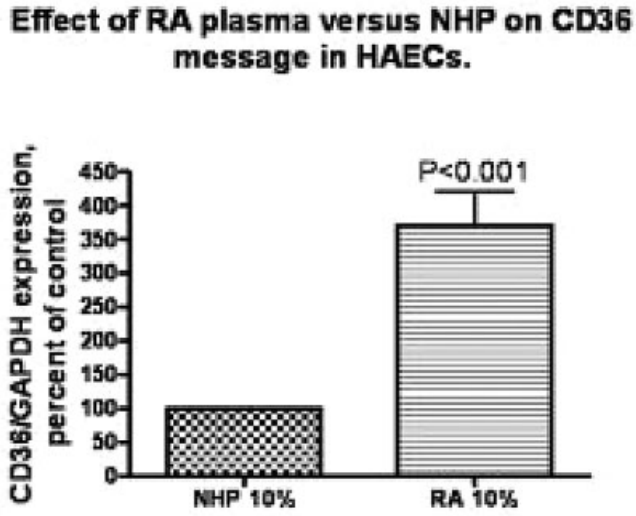
Atherogenic Properties of Rheumatoid Arthritis Plasma: Effect on Cholesterol Transport Genes. Allison B. Reiss[1], Iryna Voloshyna[1], Michael Littlefield[1], Elise Belilos[1], Kristina Belostocki[2], Lois A. Bonetti[1], Gary C. Rosenblum[1] and Steven E. Carsons[1]. [1]Winthrop University Hospital, Mineola, NY, [2]Winthrop University Hospital, Jamaica, NY

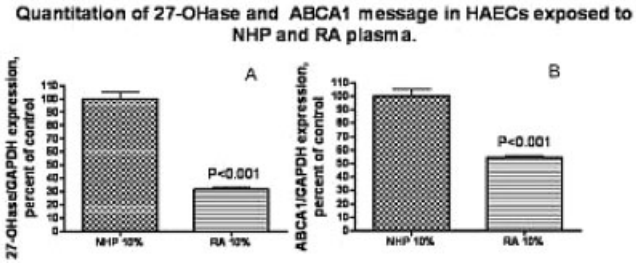
Purpose: The risk of cardiovascular (CV) morbidity and mortality is profoundly increased in patients with systemic lupus erythematosus (SLE) and rheumatoid arthritis (RA). We have reported that SLE patients manifest a pattern of disturbance in expression of genes involved in lipid transport that is atheroma-promoting. When THP-1 human monocytes/macrophages are exposed to lupus plasma, the cholesterol efflux proteins 27-hydroxylase (27-OHase) and ATP binding cassette transporter (ABC)A1 are suppressed while the scavenger receptor CD36 that facilitates cholesterol uptake is augmented, leading to cholesterol overload and foam cell formation (FCF). This study examines whether RA patients exhibit comparably atherogenic plasma. In addition to the genes already mentioned, we look at the nuclear hormone receptor liver X receptor (LXR), which stimulates cholesterol efflux and induces expression of ABC transporters.

Methods: CD36, ABCA1, 27-OHase and LXR expression were evaluated in THP-1 human monocytes and human aortic endothelial cells (HAEC), cell types relevant to atherogenesis. Cells were incubated for 18h and 24h in medium containing 0, 10 or 25% of either RA patient plasma or normal human plasma (NHP). Following the 18h incubation, mRNA was isolated and reverse transcribed. The resulting cDNA was subjected to quantitative PCR using specific primers for each gene. Cellular extracts were prepared for Western immunoblotting after 24h.

Results: Pooled plasma from RA patients in this study population was compared to NHP. The presence of 10% RA plasma upregulated CD36 message by 270.8 ± 88.0% in HAEC ($n=3$, $P<0.001$) above NHP (Figure 1).



In THP-1 and HAEC, 27-OHase message level fell by 46.23 ± 12.5% and 69.1 ± 4.12% (Figure 2A) ($n=3$, $P<0.001$) below NHP, respectively and ABCA1 fell by 50.6 ± 15.0% ($n=3$, $P<0.001$) and 45.6 ± 8.7% (Figure 2B) ($n=3$, $P<0.01$) below NHP, respectively. LXR levels fell concomitantly: by 26.6 ± 3.9% and 56.6 ± 7.4% % ($n=3$, $P<0.001$) below NHP, respectively. Western blot analysis confirmed PCR results.



Conclusion: Traditional CV risk assessment is inadequate in RA. This study demonstrates pro-atherogenic properties of RA plasma that may promote atherosclerosis by increasing vulnerability to cholesterol overload. Demonstration of disrupted cholesterol homeostasis in this select group of patients provides further evidence of the involvement of the immune system in atherogenesis. Our findings may lead to the use of a cholesterol transport gene profile for evaluation of CV risk in this susceptible population.

1073

Circulating Cytokines Influence the Fetal Growth in Pregnant Women with Rheumatoid Arthritis. Florentien D. O. de Steenwinkel[2], Johanna M. W. Hazes[1], Yaël A. de Man[1], Anita C. S. Hokken[2], Yolanda B. de Rijke[2] and Radboud J. E. M. Dolhain[1]. [1]Erasmus Medical Center, Rotterdam, The Netherlands, [2]Erasmus Medical Center/Sophia Children's Hospital, Rotterdam, The Netherlands

Background: High RA disease activity during pregnancy is associated with lower birth weight. Lower birth weight, even within the normal range, has been linked with cardiovascular diseases and metabolic syndromes later in life. Outside pregnancy, active RA is associated with high levels of circulating cytokines.

Purpose: To asses the levels of IL-10, IL-6 and TNFa in pregnant women with RA and to evaluate correlations between these levels, disease activity, and birth weight.

Methods: Current study is embedded in the PARA-study, a prospective study on RA and pregnancy. 134 pregnant RA patients are enrolled in first and 168 in third trimester. 33 healthy pregnant women served as control. We analyse data using birth weight standard deviation scores (bwsds), a measure for birth weight adjusting for gestational age and sex of the child. Maternal disease activity is based on DAS28. IL-10, IL-6 and TNFa are determined by Immulite 1000.

Results: Levels of IL-10, IL-6 and TNFa decrease during pregnancy. Strong correlations are found between these cytokines in first and third trimester and between DAS28 and IL-10, IL-6.

First trimester patients with detectable IL-10 (n=12) show a higher disease activity than the IL-10 negative patients, a mean DAS28 4.4 (SD 1.2) and 3.6 (SD 1.1) respectively. To diminish the influence of disease activity on birth weight we match the IL-10 positive to an IL-10 negative group. Matching is on disease activity, parity and prednisone use. Mean bwsds is significantly higher ($p=0.02$) in the IL-10 positive group 0.92 (SD 0.7), than in the IL-10 negative match, 0.15 (SD 0.7). No such association is found in third trimester.

To determine the additional effect of IL-6 to disease activity on bwsds stratification is done. In first trimester we stratify IL-6 and DAS28 in high and low group based on their median, resulting in 4 groups. In the two high DAS28 groups (defined median over 3.8), bwsds is significantly lower in high IL-6 than in low IL-6 ($p<0.05$). In the high IL-6 group bwsds is −0.19 (SD 1.12) in the low IL-6 group bwsds is 0.36 (SD 0.93). No such association is found in third trimester.

TNFa is stratified the same way. In third trimester, only in patients with low disease activity, bwsds is lower in the low TNFa group than in the high TNFa group, bwsds of 0.05 (SD 0.97) and 0.52 (SD 0.96) respectively ($p<0.05$). Same trend is seen in the healthy cohort group, although not significant. No such association is found in first trimester or in patients with high RA disease activity.

Conclusion: Circulating cytokines influence fetal growth in pregnant women with RA. In first trimester elevated IL-10 seems to protect against the negative influence of RA disease activity on birth weight, IL-6 seems to amplify this negative influence. Both cytokines create a bwsds deviation of more than 0.50 which is considered clinically relevant. In third trimester there is no influence suggesting an early critical window.

Finally, our data might indicate a physiological role of TNFa in fetal growth during third trimester in healthy controls and patients with low disease activity. Underscoring that TNF-blockers should be used with caution during pregnancy.

This study was supported by the Dutch Arthritis Association.

1074

Citrullination and Peptidylarginine Deiminase (PAD) Expression Is Detected in the Oral Mucosa and Periodontium in the Absence of Rheumatoid Arthritis. Clifton O. Bingham[1], Mark A. Reynolds[3], Jon Giles[2], Felipe Andrade[2], Joan M. Bathon[2], Karen Fox-Talbot[2] and Marc K. Halushka[2]. [1]Johns Hopkins, Baltimore, MD, [2]Johns Hopkins, [3]University of Maryland Dental School

Background: There is growing interest in the association of periodontal disease (PD) and rheumatoid arthritis (RA). It has been proposed that *P. gingivalis*, an important periodontal bacteria with an endogenous PAD enzyme (Pg-PAD), is responsible for oral citrullination leading to a break in tolerance with attendant anti- citrullinated peptide antibody (ACPA) formation in RA. There is limited data on the protein citrullination and endogenous PAD expression in the oral cavity.

Methods: Using immunohistochemistry, we have examined formalin-fixed, paraffin-embedded gingival tissue from 4 patients with PD. Additional oral tissues examined included buccal mucosa and tonsil. All samples were from patients without known inflammatory arthritis. We used an anti-modified citrulline kit (Upstate) to detect citrullination. Expression of PAD2, PAD3, PAD4, and PAD6 were evaluated with rabbit-anti human polyclonal antibodies using an avidin-biotin complex detection system with DAB as the chromogen and with appropriate controls.

Results: Citrullination was detected in keratinized epithelium in gingiva and in normal buccal mucosa. Variable levels of citrullination were also detected in blood vessels and inflammatory cells in normal mucosa and periodontitis. Expression of PAD2 was abundant in buccal mucosa and periodontal tissues in epithelium, vascular endothelium, and inflammatory cells. PAD3 was similarly localized in the epithelium, endothelium, and inflammatory cells. PAD4 was only minimally expressed in the epithelium and weakly in the endothelium, but seen in some infiltrating cells including neutrophils and in inflammatory cells in tonsil. PAD6 was seen in the epithelium and endothelium with variable expression in inflammatory cells. In some tissue with skeletal muscle, bundles were variably stained with PAD2 and PAD6 with concomitant citrullination. Studies to examine PAD1 expression and additional diseased and control tissues are in progress.

Conclusions: This is the first comprehensive examination of protein citrullination and PAD expression in oral tissues. Citrullination is ubiquitously present in multiple oral locations and is not limited to inflamed periodontium. Similarly, PADs 2, 3, 4 and 6 are all localized in oral tissue in the presence or absence of inflammation. Our studies indicate that there are multiple potential pathways responsible for post-translational citrullination in the oral mucosa: endogenous PAD expression, upregulated PADs at inflammatory foci, in addition to Pg-PAD providing an exogenous source. Additional studies are necessary to determine the specific substrates of different human and bacterial PADs in the periodontal microenvironment and to establish their relationship with ACPA formation, and disease initiation or propagation in RA.

1075

Common Genetic Background for Rheumatoid Arthritis and Systemic Lupus Erythematosus. Gisela Orozco, Steve Eyre, Anne Hinks, Wendy Thomson, Jane Worthington and Anne Barton. Arthritis Research Campaign Epidemiology Unit, The University of Manchester

Background: Evidence is beginning to emerge that there may be susceptibility loci for rheumatoid arthritis (RA) and systemic lupus erythematosus (SLE) that are common to both diseases.

The aim of this study was to investigate single nucleotide polymorphisms (SNP) that have been reported to be associated with SLE in a UK cohort of RA cases and controls.

Methods: 3,962 RA patients and 9,275 controls were included in the study. Of the SLE loci identified to date (1), eleven SNPs mapping to confirmed SLE loci were investigated. These mapped to the *TNFSF4, BANK1, TNIP1, PTTG1, UHRF1BP1, ATG5, JAZF1, BLK, KIAA1542, ITGAM* and *UBE2L3* loci. Genotyping was undertaken using a Sequenom platform with iPlex chemistry. Genotype frequencies were compared between RA cases and controls using the trend test implemented in PLINK software. *P*-values <0.0045 were regarded as significant after correcting for multiple testing.

Summary of Results: The SNPs mapping to the *BLK* and *UBE2L3* loci showed significant evidence for association with RA (rs2736340, $P = 3.0 \times 10^{-4}$, OR 1.11 95% CI 1.05–1.17; rs5754217, $P = 2.4 \times 10^{-3}$, OR 1.11 95% CI 1.04–1.19). Two other SNPs, mapping to *ATG5* and *KIAA1542*, showed nominal evidence for association with RA ($P=0.02$ and $P=0.02$, respectively) but these were not significant after applying a Bonferroni correction. Additionally, we found a significant global enrichment in carriage of SLE alleles in RA patients compared to controls ($P=$

9.1×10^{-7}). Meta-analysis of this and previous studies confirm the association of the *BLK* and *UBE2L3* gene with RA at genome-wide significance levels ($P<5\times10^{-8}$). Together, we estimate that, after excluding *HLA-DRB1* alleles, the overlapping loci identified so far explain ~5.8% of the genetic susceptibility to RA as a whole.

Conclusions: The findings confirm the association of the *BLK* and *UBE2L3* loci with RA thus adding to the list of loci showing overlap between RA and SLE, which currently include *HLA-DRB1, PTPN22, STAT4, TNFAIP3, FCGR2A, PRDM1, IRF5* and *PXK*.

1076

Confirmation of the Especial Interaction of Autoimmunity Against Citrullinated α-Enolase with Genotypes Predisposing to Rheumatoid Arthritis. Antonio Gonzalez[1], Ariana Montes[2], Rebeca Dieguez-Gonzalez[2], Manuel Calaza[2], Eva Perez-Pampin[2], Antonio Mera[2] and Juan J. Gomez-Reino[2]. [1]Hospital Clinico Universitario de Santiago, Santiago de Compostela, A Coruña, Spain, [2]Hospital Clinico Universitario de Santiago

Background: Autoimmunity against citrullinated α-enolase has been proposed as a major component of the anti-citrullinated proteins response characterizing rheumatoid arthritis (RA) patients with worse spontaneous disease evolution. This claim was based on the extraordinary interaction between the presence of antibodies against the immunodominant peptide of α-enolase (CEP-1) and genetic and environmental susceptibility factors for RA.

Methods: DNA and serum samples from 451 patients with RA and 277 healthy controls of Spanish ancestry were obtained. Antibodies to CCP-2 and CEP-1 were measured by ELISA. HLA-DRB1 was genotyped by the sequencing-based-typing method (SBT) and the R620W SNP of PTPN22 by a Taqman genotyping assay. Interactions between factors were evaluated as departures from additivity of the individual effects.

Results: Anti-CEP-1 antibodies were detected in 26.8 % of the RA patients whereas 71.2 % were anti-CCP positive. Most of the patients with anti-CEP-1 antibodies, 86.6 %, were also positive in the anti-CCP2 test. This group of patients with RA positive for the two antibodies were disproportionally associated with the SE (Fig. 1), especially with the DRB1*04 allele (not shown), and with the 620W risk allele of PTPN22 (Fig. 2).

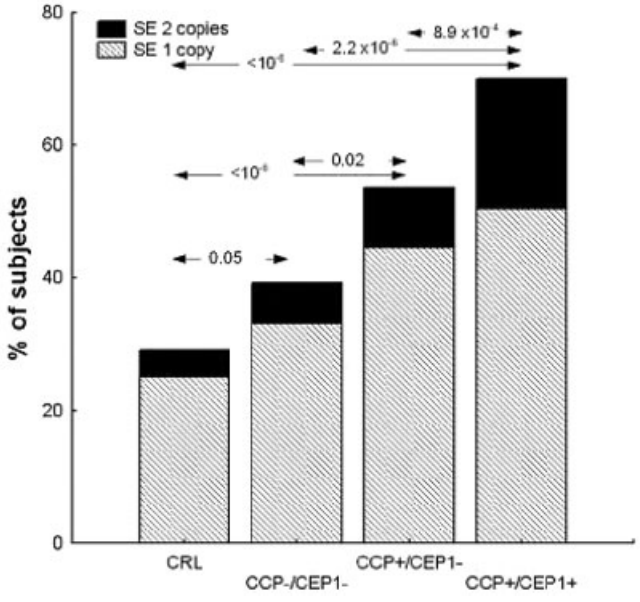

Figure 1.

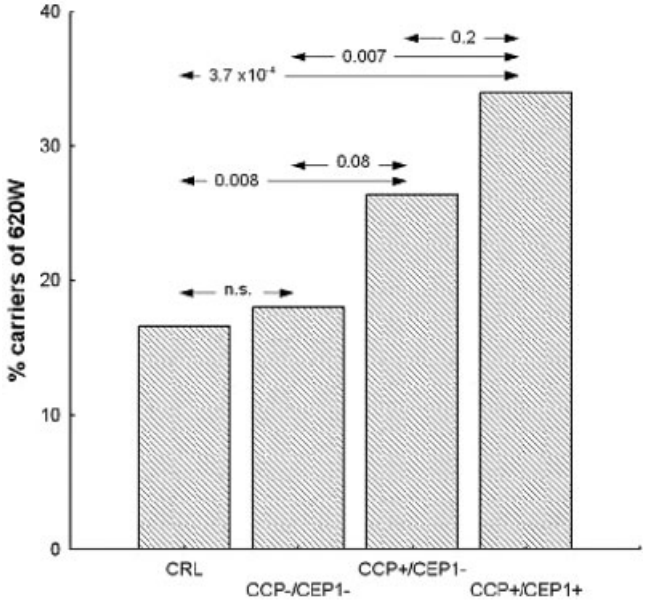

Figure 2.

There was significant evidence of epistasis between the two genetic factors only when considering the patients that were positive for the two antibodies (p = 0.002, Fig. 3).

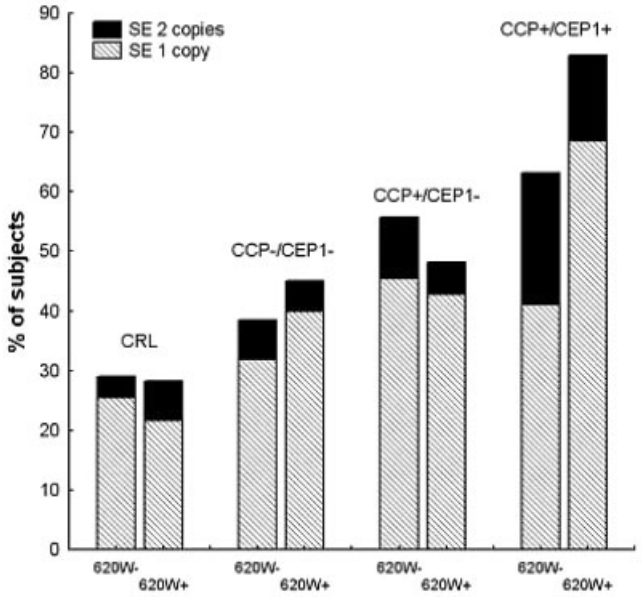

Figure 3.

The patients that were anti-CCP+ but anti-CEP-1- showed also association with these susceptibility genetic factors although of a lower magnitude and without significant interaction.

There was not association of any of the subgroups of patients with the smoking habit, probably in relation with the much lower prevalence of this habit among our patients (18.7 %) than in other published series.

Conclusions: We have confirmed that autoimmunity against citrullinated α-enolase accounts for a disproportionally large part of the effect of the genetic susceptibility alleles of HLA-DRB1 and PTPN22 among patients positive for anti-CCP antibodies. However, other citrullinated proteins seem to be also important targets in RA pathogenesis. In contrast with a previous report, we did not find any evidence of association with the smoking habit, but we have a small percentage of smokers among our patients.

C-Reactive Protein (*CRP*) Single Nucleotide Polymorphisms (SNPs) Are Associated with Radiographic Damage and Plasma CRP Levels in African Americans (AAs) with Early Rheumatoid Arthritis (RA). Maria I. Danila[6], Lang Chen[5], Desiree M. Van Der Heijde[2], Doyt L. Conn[1], Beth L. Jonas[7], Leigh F. Callahan[8], Edwin A. Smith[3], Richard Brasington[10], Larry W. Moreland[9], S. Louis Bridges[6] and Laura B. Hughes[4]. [1]Emory Univ Schl of Med, Atlanta, GA, [2]Leiden University Medical Center, Meerssen, The Netherlands, [3]Med Univ of South Carolina, Charleston, SC, [4]Univ of Alabama Birmingham, Birmingham, AL, [5]Univ of Alabama-Birmingham, [6]Univ of Alabama-Birmingham, Birmingham, AL, [7]Univ of N Carolina-Chapel Hill, Chapel Hill, NC, [8]Univ of North Carolina, Chapel Hill, NC, [9]Univ of Pittsburgh Med Ctr, Pittsburgh, PA, [10]Washington Univ Schl of Med, St Louis, MO

Background: Plasma CRP levels are associated with disease activity in RA and influence clinical management. *CRP* SNPs correlate with plasma CRP levels and cardiovascular events. There are large differences in minor allele frequencies (MAF) of some clinically relevant *CRP* SNPs between Caucasians and AAs.

Objective: To test the hypotheses that, after accounting for other variables, *CRP* SNPs are associated with radiographic severity or plasma CRP levels in AAs with early RA (< 2 years disease duration).

Methods: Genotyping of *CRP* SNPs (rs3093058, rs3093059, rs2794521, rs3093061, rs3093062, rs3091244, rs1417938, rs1800947, rs3093066 rs1205, rs2808630), baseline plasma CRP level measurement and baseline radiographs of hands/feet scoring (Sharp/van der Heijde score) were performed on 357 AA RA patients and 150 AA controls enrolled in the CLEAR study. Differences in MAF were analyzed using chi square analysis. Univariable and multivariable negative binomial regression was used to evaluate the association of *CRP* SNPs with baseline radiographic erosions scores and CRP levels. Other relevant variables examined in univariable analyses were: HLA-DRB1 shared epitope, RF, anti-CCP antibody, age, gender, disease duration, body mass index (BMI), use of DMARDs, biologic agents, and corticosteroids. Those obtaining a p value < 0.1 in the univariable analyses were included as covariates in the multivariable analyses.

Results: 40% of RA subjects had radiographic erosions at baseline. Mean age of RA onset was 49 years, median disease duration was 1.5 years, 82.4% were female, mean BMI was 31.2; DMARD use (62.8%), corticosteroid use (77.7%), biologic use (4.0%), and mean baseline plasma CRP was 17.9 mg/L.

There were no significant differences in the distribution of the *CRP* SNPs between RA cases and controls. In the multivariable analysis, significant associations were found between 5 *CRP* SNPs and plasma CRP levels: rs3093058 (p=0.0002), rs3093061 (p=0.0042), rs3093062 (p=0.002), rs3091244 (p=0.0212), rs1205 (p=0.0425) after adjusting for BMI, age at RA onset, and biologic use (Table 1a). The majority of the observed effect was due to the rs3091244 T and rs1205 T alleles (Table 1a). In the multivariable analysis of radiographic erosions, 5 CRP SNPs demonstrated significance: rs3093059 (p=0.0096), rs2794521 (p=0.0238), rs3091244 (p=0.0026), rs3093066 (p=0.0090), rs2808630 (p=0.0081) after adjusting for disease duration and biologic use (Table 1b). The majority of the observed effect was due to the rs2794521G allele (Table 1b). There was no association between baseline plasma CRP levels and radiographic erosions.

Table 1a. Multivariate analysis of *CRP* SNPs and CRP levels, adjusted for factors found to be significant in the univariate analysis: BMI, age at RA onset, and biologic use.

Differential Association of IL23R Genetic Variants with Anti-CCP Positive and Negative Rheumatoid Arthritis Patients. Antonio Gonzalez[6], Aida Ferreiro[5], Eva Perez-Pampin[5], Manuel Calaza[5], Francisco J. Lopez-Longo[13], Jose Luis Marenco[12], Francisco J. Blanco[9], Rafael Caliz[14], Javier Narvaez[10], Federico Navarro[15], Juan Cañete[3], Arturo R. de la Serna[8], Isidoro Gonzalez-Alvarez[11], Gabriel Herrero-Beaumont[1], Jose Luis Pablos[2], Alejandro Balsa[7], Benjamin Fernandez-Gutierrez[4] and Juan J. Gomez-Reino[5]. [1]Fundacion Jimenez Diaz. Madrid, [2]Hospital 12 de Octubre, Madrid, [3]Hospital Clinic. Barcelona, [4]Hospital Clinico San Carlos, Madrid, [5]Hospital Clinico Universitario de Santiago, [6]Hospital Clinico Universitario de Santiago, Santiago de Compostela, Spain, [7]Hospital La Paz. Madrid, [8]Hospital Santa Creu e San Pau. Barcelona, [9]Hospital Universitario A Coruña, [10]Hospital Universitario de Bellvitge. Barcelona, [11]Hospital Universitario de la Princesa, [12]Hospital Universitario de Valme. Sevilla, [13]Hospital Universitario Gregorio Marañon, Madrid, [14]Hospital Universitario Virgen de las Nieves, Granada, [15]Hospital Universitario Virgen Macarena, Sevilla

Background: Several polymorphisms in the interlekin-23 receptor gene (IL23R) have shown strong association to autoimmune diseases including ankilosing spondylitis, Crohn's disease and psoriasis. There have been also some less convincing reports of association with rheumatoid arthritis (RA). These associations are interpreted as highlighting a significant involvement of the IL23/IL17 pathway in disease pathogenesis and, therefore, are of great interest for the understanding of disease pathogenesis.

Methods: We have examined 5 SNPs in the IL23R gene (rs11209026, rs1343151, rs7530511, rs2201841, rs11209032) that were strongly associated with other autoimmune diseases in 1655 patients with AR and 1601 healthy controls of Spanish ancestry. Genotyping was done by minisequencing. Statistical analyses were done with the Statistica software. Haplotype estimation was conducted with PHASE2.

Results: One of the SNPs was rejected due to lack of Hardy-Weinberg equilibrium. Comparison of allele frequencies of the other 4 SNPs in patients with RA and healthy controls revealed no differences in the distribution of IL23R allele frequencies. However, there were differences between anti-CCP$^+$ and anti-CCP$^-$ patients and between the two subgroups of patients and the controls (Table 1).

	anti-CCP$^+$	**anti-CCP$^-$**	**CRL**	**anti-CCP$^+$ vs CRL p-value**	**anti-CCP$^-$ vs CRL p-value**	**anti-CCP$^+$ vs anti-CCP$^-$ p-value**
rs11209026	6.7% (80/1188)	10.2% (89/870)	8.0% (255/3200)	0.2	0.034	0.0043
rs1343151	33.8% (401/1188)	41.6% (362/870)	37.3% (1193/3200)	0.031	0.02	0.00027
rs2201841	32.3% (384/1188)	27.3% (237/868)	31.1% (995/3198)	0.4	0.03	0.014
rs7530511	12.8% (152/1188)	13.0% (113/868)	12.6% (402/3198)	0.8	0.7	0.9

Conditional logistic regression analysis showed that rs1343151 could account for all the associations in the locus, both in anti-CCP$^+$ and anti-CCP$^-$ patients, but with a stronger effect in the latter. Haplotype analysis also indicated that this SNP was able to explain all association in the locus.

Conclusions: Our results showed evidence of a differential effect of polymorphisms in the IL23R gene in anti-CCP$^+$ and anti-CCP$^-$ patients with

RA. The effect was of an increased risk for the anti-CCP$^-$ phenotype in the patients bearing the minor allele of rs1343151, and of an opposed trend for the anti-CCP$^+$ phenotype. These contrasting associations may explain previous results of genetic studies of this locus in RA that have shown a predominant effect of the rs1343151 SNP but some variation between patient cohorts. They also rise the intriguing possibility of their contribution to the differentiation of these two major subgroups of RA patients. This possibility together with the evidence of multiple independent associations in other diseases increase the interest in the dissection of the mechanisms affected by the IL23R polymorphisms.

DNA Damage, T Cell Lymphopenia and Immunosenescence in Rheumatoid Arthritis. Lan Shao[1], Hiroshi Fujii[2], Jorg J. Goronzy[1] and Cornelia M. Weyand[1]. [1]Stanford University School of Medicine, Stanford, CA, [2]Tohoku University School of Medicine, Sendai, Japan

Background/Purpose: In RA, immune aging is accelerated by 25–30 years. The immune system is homeostatically controlled; lymphocyte regeneration/proliferation compensates for cell attrition. Lymphocytes age prematurely if they proliferate excessively; imposed by too much loss or too little cell input. We have examined whether RA patients have higher T cell loss than age-matched controls by focusing on naive CD4 T cells which have not yet been recruited into any immune response. Specifically, we have examined signals and molecular mechanisms regulating survival of naive T cells that build the immune reserve.

Methods: Naive CD4 T cells from sero-positive RA patients and demographically matched controls were tested ex vivo for their susceptibility to apoptosis by cytometric analysis of 7AAD and Annexin V with and without T cell receptor stimulation. The load of damaged DNA was quantified by Comet assay and telomeric length was measured by modified qPCR. Repair mechanisms for telomeric and non-telomeric DNA were assessed through the analysis of three enzymatic systems involved in DNA repair/telomeric maintenance; telomerase and the phosphoinositide-3-kinase-related protein kinases Ataxia-telangiectasia mutated (ATM) and DNA-dependent protein kinase catalytic subunit (DNA-PKcs). DNA damage sensing enzymes were knocked down by si-RNA technology or forcefully overexpressed by transfection.

Summary of Results: Naive human CD4 T cells, both resting and triggered with anti-CD3/CD28, died through the intrinsic death pathways, regulated by pro- and anti-apoptotic Bcl-2 family members. RA CD4 T cells freshly isolated from patients or kept without stimulation ex vivo were highly susceptible to apoptosis with doubling of death rates (28.2% RA T cells vs. 15.1% control T cells; p=0.01). Increased apoptotic susceptibility coincided with accumulation of DNA double strand breaks (p=0.0001), suggesting that unrepaired DNA and telomeres shorten survival of naive T cells. Induction of the telomere repair enzyme telomerase was impaired in RA T cells (p=0.0001). Also, RA T cells insufficiently upregulated the damage-sensing enzyme ATM (p=0.008) but expressed high levels of DNA-PKcs transcripts and protein (p=0.03). Forced overexpression of telomerase or ATM and blockade of DNA-PKcs rescued RA T cells from apoptosis (p=0.008, 0.001 and 0.005, respectively). The shift in apoptotic threshold setting was not a consequence of therapy but was equally present in untreated RA patients (p=NS, Tx vs. non-Tx).

Conclusions: Naive CD4 T cells in RA patients are under genotoxic stress. Telomeres are shortened and insufficiently repaired and DNA doubles strand breaks accumulate. Repair pathways involving the enzyme ATM are suppressed. Chronic repair activity signaled by the DNA-PKcs pathway sustains cell-internal stress signals that harm the cells and lead to apoptosis. Excessive T cell loss strains homeostatic mechanisms and, by depleting the proliferative reserve of long-lived T cells, leads to premature immune aging. Mechanisms regulating intactness of telomeric and non-telomeric DNA should be considered in attempts to reset the dysfunctional immune system of RA patients.

Do Patients with Rheumatoid Arthritis Exhibit Differential Cellular Responses to Implant Wear Debris and Do the Implant Failure Mechanisms Differ from Non-RA Patients? Anant Vasudevan[5], Edward F. DiCarlo[3], Timothy Wright[2], Dan Chen[2], Steven R. Goldring[1] and Lisa A. Mandl[4]. [1]Chief Scientific Officer, Hospital for Special Surgery, [2]Department of Biomechanics, Hospital for Special Surgery, [3]Department of Pathology and Laboratory Medicine, Hospital for Special Surgery, [4]Hospital for Special Surgery, New York, NY, [5]Yale School of Medicine, New York, NY

Background: Peri-implant osteolysis is the major reason total elbow replacements (TER) fail. Osteolysis is caused by implant wear debris, and evidence exists that patients with rheumatoid arthritis (RA) may respond differently to foreign material compared to patients without RA. This study was performed to determine whether TER patients with RA exhibit differential cellular responses to implant wear debris compared to TER patients without inflammatory joint disease.

Materials and Methods: Thirty-eight patients who had their first TER revision for osteolysis were reviewed. All had similar prosthetic devices removed between 1996 and 2008. Twenty-five had RA, and thirteen had no autoimmune disease. Histopathology, clinical data, and gross wear of the removed prostheses were evaluated and compared in RA and non-RA patients.

Results: Structural evaluation of the retrieved prostheses showed increased material loss was significantly associated with the generation of more, large polyethylene particles (p-value < 0.01) and a trend towards more metal particles (p-value $= 0.05$). The amount of wear debris in the tissue was similar regardless of underlying diagnosis (p-value > 0.65). In the presence of large particulate polyethylene debris, RA patients not on anti-TNF therapy showed a trend towards more plasma cell infiltration within lymphocytic aggregates in the periprosthetic tissue compared with non-RA patients (p-value $= 0.07$). This difference was attenuated in RA patients who had received anti-TNF therapy (p-value $= 1.0$). Among patients with high levels of plasma cells within lymphocytic aggregates, non-RA and RA patients on anti-TNF inhibitors showed similar perivascular patterns of lymphocytic aggregation, whereas RA patients not on anti-TNF inhibitors showed no perivascular aggregates (p-value $= 0.01$).

Conclusion: RA patients exhibit a distinct pattern of cellular response to implant wear debris when compared with non-RA patients, which was not due to differences in the type or amount of particulate debris. The increased number of plasma cells within lymphoid aggregates indicates that RA patients mount an adaptive immune response to implant wear particles, which is mitigated by anti-TNF therapy. These observations provide insights into the pathogenic link between the innate and adaptive immune systems in RA and have implications for future approaches to treating osteolysis in RA patients.

1081

Dual Roles of Heme Oxygenase-1 on Rheumatoid Arthritis: Anti-Inflammation Versus Angiogenesis. Kaoru Takase[2], Shigeru Ohno[1], Mitsuhiro Takeno[3] and Yoshiaki Ishigatsubo[4]. [1]Center for Rheumatic Diseases, Yokohama City University Medical Center, [2]Department of Internal Medicine and Clinical Immunology, Yokohama City University Graduate School of Medicine, Japan, [3]Department of Internal Medicine and Clinical Immunology, Yokohama City University Graduate School of Medicine, Japan[4]Yokohama City Grad Sch of Med, Yokohama, Japan

Objectives: Heme oxygenase 1 (HO-1) plays cytoproptective roles on various pathological conditions including inflammatory disorders. However, the roles of HO-1 in development of rheumatoid arthritis (RA) have been controversial. We and others have demonstrated an anti-inflammatory role of HO-1 in synovitis *in vitro* and *in vivo*, whereas hemin, a potent HO-1 inducer, is not necessarily beneficial for animal model arthritis. Some studies have suggested the protein promotes angiogenesis, leading to exacerbation of arthritis. We here examined relationship between HO-1 expression and angiogenesis in synovial tissues from RA patients and animal arthritis model.

Materials and Methods: 1) Human samples of synovial tissues were obtained form 10 RA patients and 5 OA patients during knee surgery. Expression of HO-1, and CD31 as a marker for endothelial cells, and CD68,

a marker for macrophages, in the tissues were semiquantitatively determined by immunohistochemistry using a digital image analyzer.

2) Arthritis was induced by cocktails of anti-type II collagen antibody in CB57/B6 mice (CAIA). Mice were pretreated with an HO-1 inducer, hemin or PBS, followed by induction of arthritis. Macroscopic arthritis score (0–3) and thickness of foot pad were evaluated.

Results: 1) HO-1 expressing cells were significantly more abundant in synovial tissues from RA than those from OA.

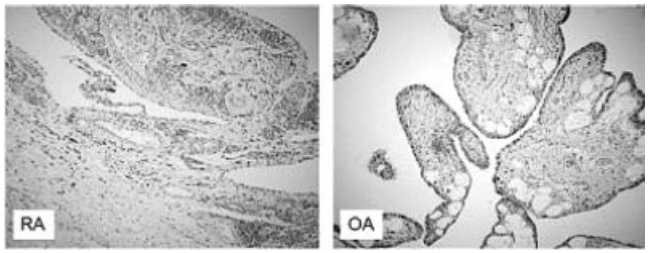

Figure 1. Expression of HO-1 proteins in synovial tissue.

While HO-1 expression was localized in the lining layer of OA synovium, analysis of serial sections revealed that HO-1 expression was detected in CD68+ synovial sublining macrophages and CD31+ vascular endothelial cells of RA synovium. Number of HO-1 expressing cells was correlated with those of CD68+ cells (r=0.81) and those of CD31+ cells (r=0.78), respectively.

2) Arthritis score and thickness of foot pad were significantly higher in CAIA mice pretreated with hemin than controls. In concordant with the clinical score, more abundant HO-1 expressing cells and angiogenesis were found in synovial tissues of hemin-treated group than controls.

Conclusions: The present study demonstrates HO-1 is associated with angiogenesis which potentially promotes development of arthritis in both human RA and arthritis in animal models, whereas HO-1 suppresses inflammatory responses by the innate immune systems including RA synoviocytes. Both features of HO-1 should be considered in the clinical application for inflammatory arthritis.

Epstein Barr Virus Serologies and Future Risk of Rheumatoid Arthritis among Women. Barbara L. Goldstein[2], Lori B. Chibnik[2], Elizabeth W. Karlson[2] and Karen H. Costenbader[1]. [1]Brigham & Women, Boston, MA, [2]Brigham and Women's Hospital, Boston, MA

Background: Exposure to EBV and/or the humoral immune response it creates may be involved in the pathogenesis of rheumatoid arthritis (RA). Several past studies suggest an association between EBV and RA, but no study has examined EBV serologies prior to RA onset.

Methods: We studied the association between EBV serologies and future RA risk in a nested case-control sample among women enrolled in the Nurses' Health Study (NHS). We confirmed 93 incident RA cases with blood collected prior to RA symptoms by questionnaire and medical record review, excluding all self-reports not confirmed as RA. In a nested case-control design, each incident RA case was matched to a participant without RA by time of day and date of blood collection, year of birth, menopausal status and postmenopausal hormone use. Immunofluorescence assays were used to measure IgG serologic responses to EBV peptides: viral capsid antigen (VCA), early-antigen-diffuse and early antigen-restricted (EA-D and EA-R-D), EA-complex, Epstein Barr nuclear antigen (EBNA)-1, EBNA-2, and BZLF-1 (an EBV immediate early protein); all of which were reported as titers, except for BZLF-1 which was reported as positive or negative. Six ANA positive samples and their matched controls were excluded. We employed conditional logistic regression analyses of the risk of RA associated with two-fold elevations in the geometric mean titer (GMT) of the viral antibodies or presence/absence of BZLF-1. Multivariate models further adjusted for age and smoking.

Results: Mean time to RA after blood draw was 5.2 years (range = 0.3–12 years) among 87 incident RA cases, who were matched to 87 healthy female controls. Mean age at RA diagnosis was 60.5 ± 9.7 years. Forty-seven (54%) cases were RF positive at diagnosis. In unadjusted and multivariate models, two-fold elevations in EBV antibody GMTs, as well as anti- BZLF-1 positivity, were not associated with increased RA risk.

Table 1. Risk of RA associated with EBV Serologies

IgG Serology	Unadjusted OR* (95% CI)	MV** OR* (95% CI)
VCA	1.01 (0.87, 1.18)	1.02 (0.87, 1.18)
EBNA-1	1.02 (0.87, 1.20)	1.03 (0.88, 1.21)
EBNA-2	1.03 (0.89, 1.19)	1.02 (0.89, 1.18)
EA-D	2.68 (0.73, 9.81)	2.88 (0.75, 10.99)
EA-R-D	0.98 (0.82, 1.16)	0.98 (0.82, 1.18)
BZLF-1 (+)	0.75 (0.36, 1.59)	0.72 (0.34, 1.55)

VCA: viral capsid antigen, EA-D and EA-R-D: early-antigen-diffuse and early-antigen-restricted EA-complex, EBNA: Epstein Barr nuclear antigen, BZLF-1: an EBV immediate early protein
*Odds ratio of a 2-fold elevation in the IgG geometric mean titer, or presence of IgG antibody to BZLF-1.
**Multivariate conditional logistic regression model controlling for age and smoking.

Conclusions: Two-fold elevated anti-EBV GMTs, and BZLF-1 positivity, were not associated with future risk of RA, diagnosed a mean of 5.2 years later, in these women.

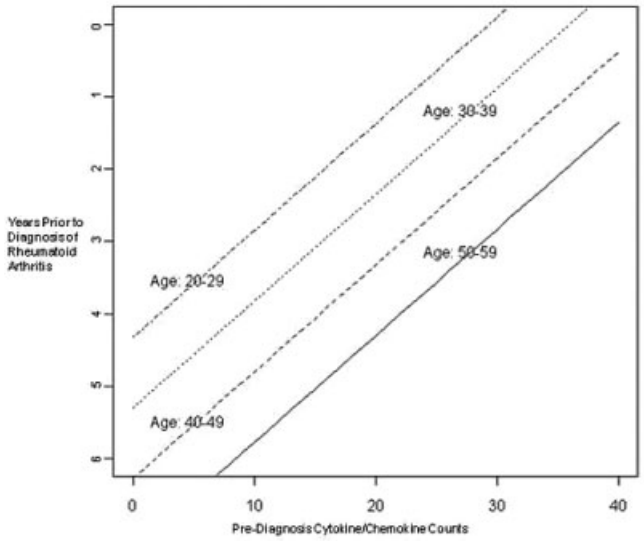
Expanded Cytokine/Chemokine Testing Improves Prediction of Time to Future Diagnosis of Seropositive Rheumatoid Arthritis (RA) in an Age-Dependent Manner. Kevin D. Deane[8], Colin I. O'Donnell[2], Lezlie A. Derber[3], Jess D. Edison[10], William R. Gilliland[1], Wolfgang Hueber[4], Jeremy Sokolove[6], Piyanka E. Chandra[7], Jill Norris[9], William Robinson[5] and V. Michael Holers[8]. [1]Department of Medicine, Rheumatology Section, Walter Reed Army Medical Center, Washington, DC, [2]Department of Preventive Medicine and Biometrics, University of Colorado Denver, Denver, CO, [3]Division of Rheumatology, University of Colorado School of Medicine, Aurora, CO, [4]Novartis Institutes for BioMedical Research, Basel, Switzerland, [5]Stanford Univ School of Med, Stanford, CA, [6]Stanford University School of Medicine, Palo Alto, Mountain View, CA, [7]Stanford University School of Medicine, Palo Alto, CA, [8]Univ of Colorado School of Med, Aurora, CO, [9]University of Colorado Denver, Aurora, CO, [10]Walter Reed Army Med Ctr, Washington, DC

Purpose: We have previously shown using testing for 14 cytokines/chemokines that the number of elevated cytokines/chemokines predicted time to diagnosis of future RA in an age-dependent manner. However, with this limited number of cytokines/chemokines, accurate prediction was limited to <5 years prior to RA diagnosis. Herein we examine the effect of testing for increased numbers of cytokines/chemokines (N=48 current versus 14 prior) on the prediction of time to diagnosis of future RA.

Methods: For this analysis we selected 101 stored pre-RA diagnosis serum samples from 51 military cases (69% male, mean age at RA diagnosis 39) that would develop future rheumatoid factor (RF) and/or CCP positive RA. These pre-diagnosis samples were selected based on positivity for anti-CCP and/or 2 or more RF isotypes, an autoantibody profile shown prior to have 74% sensitivity and >96% specificity for future RA. Each of these pre-diagnosis samples was tested for 48 cytokines/chemokines using a magnetic bead-based assay. Cytokine/chemokine positivity was established using additional military post-RA diagnosis case versus matched control samples (N=43 each group), with cutoff levels selected for positivity >90% specific for RA. The time from pre-diagnosis sample collection to RA diagnosis was analysed using mixed-model regression analysis, with predictor variables age-at-diagnosis (stratified by decade) and cyotkine/chemokine counts.

Results: The number of elevated cytokines/chemokines (cytokine/chemokine counts) increased as the time of diagnosis of RA approached, with the highest cytokine/chemokine counts present <2 years prior to RA diagnosis. Increasing cytokine/chemokine counts predicted time to diagnosis in an age-dependent manner (Figure). The regression coefficients for age-at-diagnosis (by decade) and cytokine/chemokine counts were respectively beta1= −0.975 ($p<0.01$) and beta2= 0.147 ($p<0.01$). In contrast to prior analysis with 14 markers, testing for 48 markers allowed for accurate prediction of time of onset of future RA more than 6 years prior to diagnosis as well as allowing for finer prediction of time to diagnosis in times <3 yrs prior to diagnosis.



Increasing Cytokine/Chemokine Counts Predict Time to Future Diagnosis of Seropositive Rheumatoid Arthritis. All subject samples (N=101 from 51 RA cases) included in this analysis were positive for anti-CCP and/or 2 or more RF isotypes, an autoantibody profile >96% specific for future RA. In regression analysis, time to diagnosis for future RA was the outcome, and cytokine/chemokine counts and age (by decade) were predictor variables. For example, in a subject 45 years-old at assessment, a cytokine/chemokine count of 30 positive predicts a time to diagnosis of future RA of ~2 years.

Conclusions: In pre-clinical case samples positive for autoantibodies highly specific for future RA, increasing cytokine/chemokine counts from a panel of 48 cytokines/chemokines predicts time-to-diagnosis in an age-dependent manner, improving a prior model using 14 cytokines/chemokines. These findings provide insight into the biology of pre-clinical RA as well as provide a methodology for identification of currently arthritis-free subjects at risk for imminent RA who may be candidates for intervention studies.

Background: Targeting of B cells using rituximab, a monoclonal antibody directed against the B cell marker CD20, is one of the options for treatment of rheumatoid arthritis (RA). Despite the fact that rituximab depletes the B cells in all the patients treated, the fact that not all patients show a favorable clinical response raised questions about the mechanism of action. In order to provide insight in the biological basis of the clinical response to rituximab we evaluated the pharmacological effects of rituximab using genome-wide gene expression technology on whole blood of RA patients

Methods: RNA was isolated from peripheral blood (PB) samples collected from 13 RA patients before, three and six months after start of treatment with rituximab. Gene-expression profiling was performed using Illumina HumanHT 12-vs bead chips. Clinical responder status was determined after three and six months using ΔDAS28 (7 responders and 6 non-responders) and EULAR (4 responders, 5 moderate responders and 4 non-responders) response criteria. Hierarchical cluster analysis, Significance Analysis of Microarrays and MetaCore pathway level analysis were used for data analysis and interpretation. Differences in type I IFN response gene expression levels between responders and non-responders were analyzed using Student's unpaired t-test.

Results: Pharmacogenomic analyses demonstrated that despite the overall decrease in the expression of B cell markers RA patients exhibited interindividual differences in their pharmacological responses towards rituximab therapy. Genes that were differentially regulated between patients after rituximab treatment represented the following biological processes: humoral immunity, cytotoxic T and NK cell mediated immunity, type I Interferon (IFN) response, IL17 signalling, granulocyte development, chemotaxis and adhesion, and genes related to the ubiquitin proteosomal pathway and Activin A signaling.

When we investigated the pharmacological differences between patients in relation to clinical response we observed that only the cluster of IFN type I response genes correlated with the treatment response to rituximab as defined by ΔDAS28 and EULAR response measurements. Good responders exhibited a selective induction of the expression of type I IFN response genes after three months of treatment, whereas non-responders showed no induction under the influence of rituximab ($p=0.0397$ and $p=0.0478$ for ΔDAS28 and EULAR respectively). The increase in IFN type I activity in the good responders correlated with a low baseline level IFN type I activity and returned to baseline values at 6 months after the start of therapy. These results indicate that the pharmacological induced change in type I IFN response gene activity correlates with the clinical response of rituximab treatment in RA.

Conclusions: An increase in IFN-response activity during rituximab treatment is associated with a favorable response and may provide insight in the biological mechanism underlying the therapeutic response. Moreover, this information could be used to develop surrogate markers to monitor efficacy of rituximab.

Heterogeneity in the Bone Marrow B Cell Compartment: Implications for Pathogenesis of Human RA. Arumugam Palanichamy, Chris Cistrone, Jennifer Hossler, Chungwen Wei, James Kobie, Inaki Sanz and Jennifer Anolik. University of Rochester Medical Center

Purpose: Recent studies suggest that the bone marrow (BM) may be an active compartment in the development of autoimmune responses in RA. However the precise phenotype, function and regulation of mature B cells in BM remain largely unexplored in humans. Investigation of BM compartment may provide critical insights into the role of B cells in the pathogenesis of RA

Methods: B cells in BM and matched peripheral blood (PB) samples from 10 subjects (5 RA and 5 normal controls (NC)) were analyzed by 11 color flow cytometry. For analysis DAPI+ dead, CD3+ T and CD24hi/CD38hi early B cells were negatively gated and CD19+ mature B cells were divided into memory subsets (switched (SM): IgD-, CD27+; unswitched (USM): IgD+, CD27+; double negative (DN): IgD-, CD27-) and true naïve (N: IgD+, CD27-) population and expression of markers associated with activation and differentiation including FcRH4 and B220 were examined. In 2 NC, single B cells from memory subsets were sorted, reverse transcribed, Ig-VH3 genes amplified by nested PCR, sequenced and mutational imprints compared between BM (n=58) and PB (n=57).

Results: Frequency of CD27+ memory B cells in RA BM remained lower compared to matched PB or normal BM (18.24±2.9 v 29.04±13.2 or 25.16±13.0; RA BM v RA PB or normal BM) which reflected in a reduction of SM B cells (7.87±3.0 v 16.86±13.6; RA BM V NC BM). Examination of expanded markers, such as B220 (which is previously shown to be expressed on a majority of CD27- and a subset of CD27+ B cells) revealed an increased number of B220 expressing BM mature naïve and USM cells in RA as opposed to NC ($P<0.05$). Furthermore elevated levels of B220 expressing cells were noticed in naïve and memory subsets in RA PB compared to BM suggesting tissue specific differential expression. Analysis of the FcRH4 (an inhibitory FcR homolog,) showed a slightly higher number of USM and naïve B cells from RA PBL that was FcRH4+ compared to the BM. On the molecular level, Ig gene analysis of memory subsets between BM and PB of normal controls showed no differences in the overall mutational frequencies between BM and PB. However significant changes were noted in the pattern of mutational targeting in Ig-VH framework (FR1–3) and hypervariable regions (CDR1 and 2). Of note, SM B cells from BM exhibited a 2 fold higher mutations in FR2 compared to PB, whereas in USM B cells, a 2 fold increased mutations were seen in CDR1 compared to PB. Both SM and USM had higher numbers of G mutations in hotspot motifs in PB. Mutational analyses of RA BM and PB memory subsets are underway.

Conclusion: Molecular analysis of BM and matched PB hints increased AICDA enzymatic activity in PB revealed by G mutations and tissue specific generation/selection of distinctly targeted B cell subsets. Distinct mature B cells with consistent heterogeneity in RA BM suggest that these cells may

play a role in the mounting autoimmune responses. Further analyses are needed to elucidate the functionality of these cells.

High Level of Serum Matrix Metalloproteinase-3 Could Be Implicated in the Pathogenesis of Rheumatoid Interstitial Lung Disease. Yoshinobu Koyama[3], Kosuke Tsuruno[1], Toshiyuki Ota[2] and Kenji Fujii[1]. [1]Center for Rheumatic Diseases, Iizuka Hospital, [2]Department of Laboratory and Transfusion Medicine, University of Occupational and Environmental Health, [3]Iizuka Hospital, Iizuka, Japan

Background: Pulmonary complications such as interstitial lung disease (ILD) are common in patients with rheumatoid arthritis (RA) even in the absence of symptoms. Presentation of ILD has been reported to associate with seropositive and erosive joint disease. Although the etiology of ILD in RA is still unclear, matrix metalloproteinase (MMP)s are believed to play important roles in the pathogenesis of idiopathic pulmonary fibrosis recently. Among them, MMP-3 is known to be one of the most established markers indicating RA activity. However, the correlation between ILD and level of serum MMP-3 in RA has not been well discussed.

Objectives: To identify whether serum MMP-3 level has implication for the pathogenesis of ILD in RA.

Methods: Newly diagnosed RA patients (n=86) were enrolled in this study. As a loss of carbon monoxide diffusing capacity (DLCO) is quantitative and one of the most sensitive marker for ILD, correlations between a loss of DLCO and serum indices for diagnosis of RA were evaluated. Before the patients were exposed to medication, the activity of RA (DAS-28) and the level of laboratory data such as erythrocyte sedimentation rate (ESR), C-reactive protein (CRP), matrix metalloproteinase-3 (MMP-3), serum amyloid A protein (SAA), rheumatoid factor (RF), anti-cyclic citrullinated peptide (CCP) antibody and %DLCO were evaluated. RA patients were classified in three groups by the %DLCO based on the criteria of the American Thoracic Society (group A; DLCO>70%; normal to slight decrease, group B; 50%<DLCO<70%; moderate decrease, group C; DLCO<50%; severe decrease). Statistical analysis was performed to identify the characteristic pattern of serum markers in the three groups.

Results: At the time of diagnosis for RA, the titer of RF and anti-CCP antibody seemed to be no significant influence on a loss of DLCO. Although DAS28, CRP or SAA seemed to be no direct impact on %DLCO, a weak association between high ESR and the loss of DLCO was found (P<0.05). The serum level of MMP-3 was the most significant index correlating with a loss of DLCO (P<0.01). The significant negative correlation between MMP-3 and %DLCO was also detected (P<0.05). If the level of MMP-3≥450ng/ml, the relative risk of severe decrease of DLCO (DLCO<50%) was 6.1.

Conclusion: Although the elevation of inflammatory markers such as ESR or CRP is known to be associated with the elevation of serum MMP-3, we found the MMP-3 was the most significant index correlating with a loss of DLCO. In our study, titer of RF or CCP antibody seems no significant association with rheumatoid ILD at the time of diagnosis for RA. As MMPs are believed to play important roles in the pathogenesis of idiopathic pulmonary fibrosis recently, our finding suggests that MMP-3 is possible to play an important role in the developing of ILD associated with RA. The novel approach such as the correction of inappropriate expression of MMP-3 would be worth to discuss for preventing progression of ILD in RA patients.

Identification of Genes Associated with Erosion in Cohorts of Patients with Early Arthritis. Amir Kadi[5], Brigitte Izac[5], Jean-Philippe Jais[3], Thierry Lequerre[4], Olivier Vittecoq[4], Xavier Le Loet[4], Philippe Dieude[1], Corinne Miceli[3], Maxime Breban[2] and Gilles Chiocchia[5]. [1]AP-HP, Paris, France, [2]AP-HP, Boulogne-Billancourt, France, [3]AP-HP, [4]CHU Rouen, [5]Inserm U1016/CNRS UMR8104, Paris, France

Background: Rheumatoid arthritis (RA) is a complex disease influenced by both genetic and environmental factors. Several studies showed a large number of polymorphisms associated with this disease. Here, we selected a subset of 137 of these single nucleotide polymorphisms (SNP) to dissect and identify genes implicated in disease susceptibility and structural severity.

Objectives: The aim of this work was to evaluate the predictive SNP, and to test the value of their combination as susceptibility markers for RA diagnosis and as markers of structural severity in two different cohorts of patients with early arthritis (VErA and ESPOIR).

Methods: VeRA cohort: 244 European Caucasian who had persistent swelling of at least two joints for more than 4 weeks with evolution lasting for less than 6 months before inclusion. The erosion was evaluated and classified at 3 separate time-points (1, 2 and 5 years of follow up) according to ACR criteria 1987. ESPOIR cohort: Patients were recruited if they had undifferentiated arthritis or rheumatoid arthritis, of less than 6 months disease duration. TRhe erosion was evaluated and classified at 3 separate time-points (0, 1, 2 years of follow up) according to ACR criteria 1987. SNP genotyping was performed using the SNPlex platform from Applied Biosystems. The association studies were performed using standard chi-square tests implemented in PLINK program. Correction for the significance level of statistical tests was applied to account for the multiplicity of tests. Genotype and allele frequencies did not deviate significantly from those expected under Hardy-Weinberg Equilibrium (HWE) either in RA or in non RA patients.

Results: Seventeen SNPs were discarded because insufficient quality control. The analysis was performed on the 120 remaining SNPs. In the VeRA cohort, we found that there was a significant association of 4 SNPs lying in 4 distinct genes with the presence of erosion. The strongest association was observed for Ficolin (collagen/fibrinogen domain containing) 1 (rs2989727) (P = 2×10-3, OR, 0.41, 95% CI, 0.23–0.73), at 1 year. The second most significant association was with Tumor necrosis factor type 2 gene (rs1061622) (P = 7×10-3, OR, 2.12, 95% CI, 1.21–3.70), at all time-points. Two others polymorphisms (CTLA4 rs3087243 and IL-1F8 rs1900287) were also significantly associated with the first year of erosion ($p < 0.05$). We are now in the replication step of these results in the independent French cohort "Espoir" including 810 early rheumatoid arthritis

Conclusion: Our findings suggest that at least four SNPs are associated with erosion in RA and that combining detection of these SNPs could be useful to predict early progression of structural damage in patients with very early arthritis.

1088

In Early RA, Serum Increase of IL-21 Is Associated with Serum Level of IL-6, Autoantibody Secretion, Markers of B-Cell Activation, and Radiographic Progression. Jacques-Eric Gottenberg[4], Pascale Roux-Lombard[2], Alain Cantagrel[5], Alain Saraux[1], Cedric Lukas[3], Jean-Michel Dayer[2] and Xavier Mariette. [1]Brest Hospital, [2]Geneva Hospital, [3]Montpellier Hospital, [4]Strasbourg Hospital, [5]Toulouse Hospital

Rationale and Objectives: IL-21, a cytokine mainly expressed by CD4 T cells, was recently suspected to play a pathogenic role in rheumatoid arthritis (RA). However, levels of serum IL-21 have never been assessed in a prospective cohort of early RA. We recently reported that IL-6 and serum markers of B-cell activation were correlated and increased in early RA. IL-6 is a strong inducer of IL-21. We therefore investigated serum IL-21 level in early RA.

Patients and Methods: In the ESPOIR early arthritis cohort (at least 2 swollen joints for more than 6 weeks but less than 6 months), serum IL-21 and diagnosis of RA using the new 2010 ACR/EULAR criteria were assessed at enrollment in 723 patients with early arthritis, naïve to corticosteroid and DMARD treatment. Results for serum levels of IL-1beta, IL-1Ra, IL-2, IL-4, IL-6, IL-10, IL-17, TNF-alpha, IFN-gamma, MCP1, BAFF and markers of B-cell activation (beta2-microglobulin, total IgG, IgA, IgM and free light chains of Igs) were previously reported. Radiographic progression was defined as an increase of total Sharp/van der Heijde score (SHS) greater or equal to 1 between inclusion and 1 year.

Results:

- Higher levels of IL-21 in patients with early RA compared to other early arthritides

There was a trend in favor a higher frequency of detection (21.5% vs 15.3%, p=0.07) and a higher level of serum IL-21 (391.3 pg/ml [181.9–593.9] versus 191.6 pg/ml [142.5–543.4], p= 0.08) in the 523 patients with early RA versus the other patients with undifferentiated arthritis.

- Association between baseline IL-21 and autoantibody secretion, markers of B-cell activation and IL-6 in patients with early RA

IL-21 was significantly more frequently detected in RF-positive patients (30.2% vs 7.5% in RF-negative patients, P< 0.0001) and in anti-CCP-positive patients (28.5% vs 13.5%, P< 0.0001). Serum IL-21 could be detected in 33.3% of patients with detectable IL-6 levels compared to 14.6%

in patients without detectable IL-6 (P= 0.02). No association was observed between IL-21 and BAFF, or the other 9 assessed cytokines.

Patients with detectable IL-21 had significantly higher levels of serum beta-2 microglobulin, IgG, kappa and lambda free light chains (P= 0.003, 0.02, 0.0003, 0.0003, respectively).

- Association between baseline IL-21, early RA erosions and radiographic progression

Patients with early RA and erosions at enrollment had significantly more frequently detectable IL-21 (29.6% of patients with detectable IL21 compared to 19.6% in patients without erosions, P= 0.05).

Radiographic progression after 1 year of follow-up was significantly higher in patients with detectable IL-21 at enrollment (mean increase in SHS of 2.9±0.6 compared to 1.3±0.2 in patients without detectable IL-21, P= 0.005).

Conclusion: In early RA, increase in serum IL-21 is strongly correlated with autoantibody secretion, B-cell biomarkers levels, IL-6 increase and radiographic progression. This suggests that IL-21 could be the intermediate between IL-6 overexpression and B-cell activation. This study suggests that targeting IL-21 might be a useful therapeutic strategy in early RA.

Strong Activation of Dopamine Pathway in Synovial Tissue from Rheumatoid Arthritis Patients: New Target of Pathology? Silvia Capellino[1], Christine Wolff[2], Franca Marino[3], Alessandra Luini[3], Marco Cosentino[3] and Rainer H. Straub[1]. [1]University Hospital Regensburg, Dept. of Internal Medicine I, Regensburg, Germany, [2]University Hospital Regensburg, Dept. of Internal Medicine I, Regensburg, Germany, [3]University of Insubria, Varese, Italy

Introduction: Synovial cells produce catecholamines in osteoarthritis (OA) and rheumatoid arthritis (RA) patients. Dopamine (DA) is the most abundant catecholamine locally produced during arthritis. However, expression of DA receptors in synovial tissue and role of DA on synovial inflammation are still unknown. Aim of this study is to investigate the presence of DA receptors and DA transporter (DAT) on synovial cells in OA and RA and to study their role on immune response.

Material & Methods: Synovial tissue was collected from 10 OA and 10 RA patients. Control synovial tissue samples were obtained by 5 joint trauma patients. For immunofluorescence analysis D1, D3, D4, D5 and DAT were analyzed alone or in combination with CD45 (lymphocyte marker), CD163 (macrophages) or prolyl-4-hydroxylase (fibroblasts). For real-time PCR, isolated synovial fibroblasts were used. Expression of all dopamine receptors (D1 to D5) was evaluated. For cell culture, mixed synovial cells were treated with SCH23390, a D1-like antagonist. After 24hrs treatment, supernatants were collected and IL-6, IL-8, TNF and IL-10 were measured.

Results: In RA patients a large amount of synovial cells are positive for D1, D3, D4, D5 and DAT compared to OA patients. No positive cells are found in control synovial tissue. Doublestaining immunofluorescence reveals that mostly fibroblasts are positive for D5 receptor. Quantitative PCR analysis shows a very strong expression of all DA receptors in RA fibroblasts compared to OA. Treatment with SCH23390 inhibits IL-8 both in OA and RA, and IL-6 in RA patients.

Conclusions: These results show strong upregulation of dopamine pathway in RA synovial cells, especially in fibroblasts. The initiation of dopamine pathway is related to chronic inflammation, as neither dopamine receptor-positive cells nor dopamine-producing cells are present in normal synovial tissue. Functional experiments demonstrate that the blockade of D1-like receptors influence cytokines production during arthritis. Taken together, these results suggest that peripheral upregulation of DA pathway in rheumatoid arthritis patients influence the immune response.

T-Cell Subsets Dys-Regulation and Cytokines Are Predictive of RA Pathogenesis in an ACPA-Positive Background. Richard Cuthbert[2], Rekha Parmar[2], Jackie Nam[2], Edith Villeneuve[2], Diane Corscadden[2], Karen Henshaw[2], Paul Emery[1] and Frederique Ponchel[2]. [1]Chapel Allerton Hospital, Leeds, United Kingdom, [2]University of Leeds

Background: We reported that T-cell subset dys-regulation can predict response to treatment in early RA independently of the treatment received as well as relapse in patients who achieved clinical remission. Naïve cells frequency were the most significant circulating T-cells in early disease although, a subset of regulatory T-cell expressing CD62L showed significance. Cytokine activated T-cells (IRC) were less informative as systemic inflammation was low. The aim of the current study is to determine whether T-cell subset analysis done within 4 hours of blood collection can predict future diagnostic in early inflammatory arthritis.

Methods: 60 patients with < 12 months inflammatory arthritis (IA) were enrolled; age, DAS, CRP, symptom duration, RF, ACPA and shared epitope status were included in the analysis. 6 colour flowcytometry was performed using standard protocols. 36 healthy controls were used to build the age relationship with naïve cell frequency. ELISA were used to measure cytokines and chemokines.

Results: Of the 60 IA patients, 25 satisfied the ACR criteria for RA at baseline, the 35 remained classified as undifferentiated (UA). There was no difference at baseline between groups for age and CRP however DAS was higher in the RA group (P=0.04). There were also no difference between RA and UA for T-cell subsets with the exception of a trend for lower naïve T-cell frequency in RA (P=0.075). In relation with higher CRP, IRC frequency was also higher in RA and the relationship between CRP and IRC was confirmed using both groups (R=0.460, P=0.040). $CD25^{high}FoxP3+$ Treg were reduced in both groups with no difference in CD62L+Treg. Using ACPA positivity as criteria, ACPA+ disease was associated with a trend for higher CRP (n=42, P=0.099) and lower naïve T-cell (P=0.150). In contrast naïve cell in ACPA-negative disease were close to healthy controls. IRC were only increased in ACPA+ disease with normal frequency in ACPA- patients. Similarly, both Treg and CD62L+Treg were lower and higher respectively in ACPA-positive and closer to normal in ACPA-negative disease. Serum levels of all tested cytokines differed in patients compared to healthy controls using both ACR and ACPA as criteria. IL-12 and IL-7 were reduced in both RA (P<0.001) and UA (P<0.001) and MIP-1alpha increased (P=0.02 and P=0.0001). There was no difference between ACPA-positive and negative disease for levels of MIP-1alpha and IL-7 however, IL-12 reduction was more marked in ACPA-negative disease (both P<0.001). The added value of IL7 and MIP for the diagnostic of ACPA-negative RA needs to be further anlysed.

Conclusion: The development of RA appears clearly associated with profoundly abnormal immunological parameters at baseline however more closely associated with ACPA-positive disease. Associated with differences in genetic background between ACPA-positive and negative diseases, these data support two divergent pathogenesis, one involving T-cell in ACPA-positive disease. Providing novel diagnostic criteria by transferring flow cytometry protocols and ELISA from research lab to routine hospital services appears promising.

1091

The Development of the ACPA Repertoire Prior to the Onset of Clinical RA. Lotte A. van de Stadt[4], Margret de Koning[2], Rob J. van de Stadt[1], Gertjan Wolbink[2], B. A. C. Dijkmans[5], Dörte Hamann[3] and Dirkjan van Schaardenburg[2]. [1]Jan van Breemen Instituite, [2]Jan van Breemen Institute, [3]Sanquin Diagnostics, [4]Sanquin Research, [5]VU Medical Centre, Amsterdam, The Netherlands

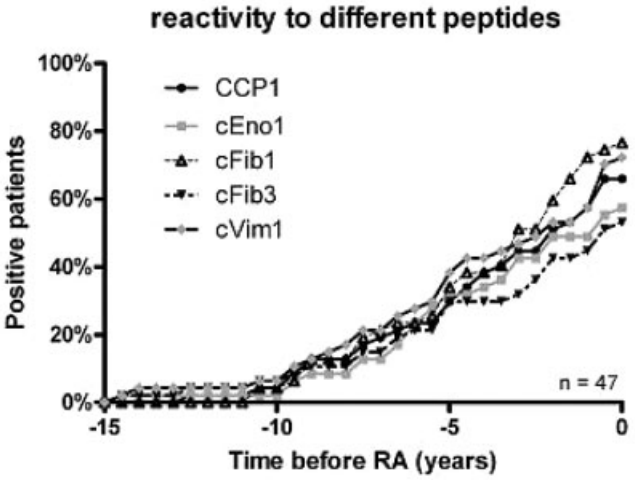
Background: Rheumatoid Arthritis is an auto-immune disease in which anti-citrullinated protein antibodies (ACPA) probably play a pathogenic role. The ACPA response is already expanded before the first symptoms of RA and remains stable thereafter [1].

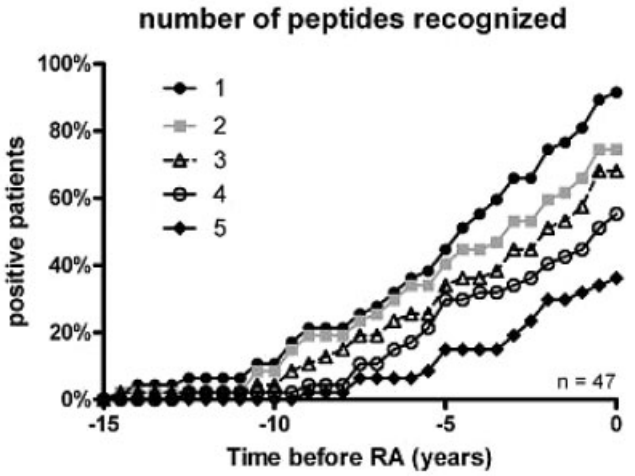
Objectives: To explore the degree of epitope spreading prior to onset of clinical RA and the pattern of auto-antigen reactivity at the start of the immune response.

Methods: Multiple serial serum samples of 79 RA patients who donated blood before disease onset were available for analysis. 47 patients tested aCCP2 positive prior to onset of clinical RA. Of these patients a median of 5 (IQR 3–7) sequential pre-RA sera spaced one to two years apart were tested for reactivity to 5 distinct citrullinated peptides in an ELISA. Two fibrinogen, 1 vimentin, 1 alpha-enolase and 1 cyclic citrullinated peptide (CCP1) were tested. Reactivity to the 5 corresponding arginine peptides was also tested.

Results: Four anti-CCP2 positive patients (9%) did not show reactivity to any peptide. In the selected patient samples seroconversion to ACPA was detected in 24 patients (51%). In 14 of these patients (58%) the immune response started with reactivity to one peptide. In four patients (17%) it started with two peptides, in four (17%) it started with three peptides and in two (8%) it started with four peptides. The number of recognised peptides increased

over time (figure 1). Median antibody titers directed to all peptides also increased over time. The ACPA response did not start with reactivity to one particular peptide (figure 2).





Conclusion: ACPA epitope spreading occurs over several years prior to onset of clinical RA. None of the tested auto-antigens is solely responsible for the initial auto-immune response.

The Differential Effect of HLA-DRB1 *0901 Allele from Shared Epitope on the Development of Rheumatoid Arthritis. So-Young Bang[1], Hye-Soon Lee[1], Ji-Seon Lee[1], Eun-Mi Kim[1], Kyung Wha Lee[2] and Sang-Cheol Bae[1]. [1]Department of Rheumatology, Hanyang University Hospital for Rheumatic Diseases, Korea, Republic of, [2]Hallym Institute for Genome Application, Hallym University Sacred Heart Hospital, Anyang, Korea, Republic of

Objectives: Smoking is associated with rheumatoid arthritis (RA) in individuals with the HLA-DRB1 shared epitope (SE) alleles encoding conserved amino acid sequence (*0101,*0404, *0405, *0410 [^{70}QRRAA^{74}], *0401 [^{70}QKRAA^{74}], *1001 [^{70}RRRAA^{74}]). The HLA–DRB1*0901 [^{70}RRRAE^{74}], non-SE allele, is significantly associated with RA in Asian, but it is rare in Caucasian. We aimed to investigate interactions between HLA–DRB1 susceptible alleles and smoking, to examine the quantitative effects of these alleles on anti-CCP titers, and to study which distinct HLA–DRB1 alleles involve for developing anti-CCP-positive/negative RA in Korean populations with RA.

Methods. All RA patients (n =1482) and controls (n = 1119) were Korean. Four-digit HLA-DRB1 typing was performed by a conventional PCR-SBT method. Information about smoking history was obtained through a questionnaire by interviewers.

Results: Smoking interacted with SE alleles, but no significant interaction was found between *0901 allele and smoking. The SE alleles and smoking were associated with markedly increased titers of anti-CCP. But *0901 allele was significantly associated with reduced median titer of anti-CCP. In addition, DRB1*0405/*0901 heterozygote dramatically increased the risk in anti-CCP-positive RA smokers (OR 120.29 [12.83–1127.63]) and anti-CCP-negative RA smokers (OR 37.96 [2.06–693.47]) compared with nonsmokers without HLA-DRB1 risk alleles.

Table 1. Risk for developing RA according to HLA-DRB1 susceptible alleles and smoking†

HLA-DRB1/Smoking	No. of cases/controls	OR (95% CI)
Shared Epitope alleles
