- (54) Title of the Invention: **Digital printing system** Abstract Title: Inkjet printing system including intermediate transfer belt and duplex mechanism
- (57) A printing system for printing on front and reverse sides of a substrate comprises a movable intermediate transfer member in the form of a flexible, substantially inextensible, belt 102 guided to follow a closed path, an image forming station (104, Fig.1), a drying station 108 and first and second impression stations (110, 110', Fig.1) spaced from one another in the direction of movement of the belt 102. Each impression station (110, 110', Fig.1) comprises an impression cylinder 110a, 110a' and a pressure cylinder 110b, 110b'carrying a compressible blanket for urging the belt against the substrate supported on the impression cylinder. There is also a transport system (118, Fig.1) for transporting the substrate between the two impression stations (110, 110', Fig.1). The pressure cylinder 110b of at least the first impression station (110, Fig.1) has a first mode of operation in which the belt 102 is urged towards the impression cylinder 110a to cause the residue film on the outer surface of the belt 102 to be transferred onto the front side of the substrate supported on the impression cylinder 110a, and a second mode of operation in which the belt 102 is spaced from the impression cylinder 110a to allow the ink image on the belt 102 to pass through the first impression station (110, Fig.1) and arrive intact at the second impression station (110', Fig.1) for transfer onto the reverse side of the substrate supported on the second impression cylinder 110a'.

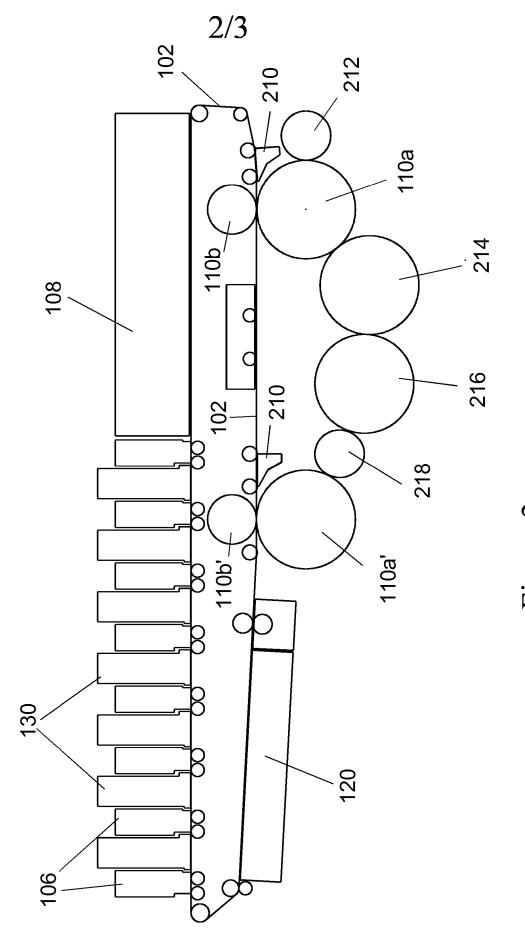

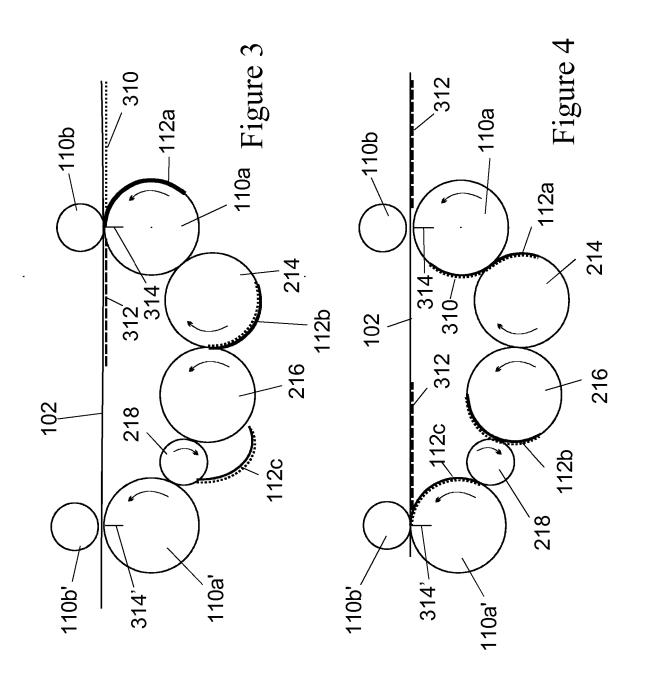

Figure 2

DIGITAL PRINTING SYSTEM

FIELD OF THE INVENTION

The present invention relates to a digital printing system, and in particular to indirect printing systems having a belt serving as intermediate transfer member.

5 BACKGROUND

10

15

20

25

30

Digital printing techniques have been developed that allow a printer to receive instructions directly from a computer without the need to prepare printing plates. Amongst these are color laser printers that use the xerographic process. Color laser printers using dry toners are suitable for certain applications, but they do not produce images of a photographic quality acceptable for publications, such as magazines.

A process that is better suited for short run high quality digital printing is used in the HP-Indigo printer. In this process, an electrostatic image is produced on an electrically charged image bearing cylinder by exposure to laser light. The electrostatic charge attracts oil-based inks to form a color ink image on the image bearing cylinder. The ink image is then transferred by way of a blanket cylinder onto paper or any other substrate.

Inkjet and bubble jet processes are commonly used in home and office printers. In these processes droplets of ink are sprayed onto a final substrate in an image pattern. In general, the resolution of such processes is limited due to wicking by the inks into paper substrates. The substrate is therefore generally selected or tailored to suit the specific characteristics of the particular inkjet printing arrangement being used. Fibrous substrates, such as paper, generally require specific coatings engineered to absorb the liquid ink in a controlled fashion or to prevent its penetration below the surface of the substrate. Using specially coated substrates is, however, a costly option that is unsuitable for certain printing applications, especially for commercial printing. Furthermore, the use of coated substrates creates its own problems in that the surface of the substrate remains wet and additional costly and time consuming steps are needed to dry the ink, so that it is not later smeared as the substrate is being handled, for example stacked or wound into a roll. Furthermore, excessive wetting of the substrate causes cockling and makes printing on both sides of the substrate (also termed perfecting or duplex printing) difficult, if not impossible.

Furthermore, inkjet printing directly onto porous paper, or other fibrous material, results in poor image quality because of variation of the distance between the print head and the surface of the substrate.

Using an indirect or offset printing technique overcomes many problems associated with inkjet printing directly onto the substrate. It allows the distance between the surface of the intermediate image transfer member and the inkjet print head to be maintained constant and reduces wetting of the substrate, as the ink can be dried on the intermediate image member before being applied to the substrate. Consequently, the final image quality on the substrate is less affected by the physical properties of the substrate.

5

10

15

20

25

30

The use of transfer members which receive ink droplets from an ink or bubble jet apparatus to form an ink image and transfer the image to a final substrate have been reported in the patent literature. Various ones of these systems utilize inks having aqueous carriers, non-aqueous carrier liquids or inks that have no carrier liquid at all (solid inks).

The use of aqueous based inks has a number of distinct advantages. Compared to non-aqueous based liquid inks, the carrier liquid is not toxic and there is no problem in dealing with the liquid that is evaporated as the image dries. As compared with solid inks, the amount of material that remains on the printed image can be controlled, allowing for thinner printed images and more vivid colors.

Generally, a substantial proportion or even all of the liquid is evaporated from the image on the intermediate transfer member, before the image is transferred to the final substrate in order to avoid bleeding of the image into the structure of the final substrate. Various methods are described in the literature for removing the liquid, including heating the image and a combination of coagulation of the image particles on the transfer member, followed by removal of the liquid by heating, air knife or other means.

Generally, silicone coated transfer members are preferred, since this facilitates transfer of the dried image to the final substrate. However, silicone is hydrophobic which causes the ink droplets to bead on the transfer member. This makes it more difficult to remove the water in the ink and also results in a small contact area between the droplet and the blanket that renders the ink image unstable during rapid movement.

Surfactants and salts have been used to reduce the surface tension of the droplets of ink so that they do not bead as much. While these do help to alleviate the problem partially, they do not solve it.

In the present Applicants' earlier patent application No. PCT/IB2013/051716, filed March 5, 2013, which is incorporated herein by reference in its entirety, there is disclosed a printing process which comprises directing droplets of an ink onto an intermediate transfer member (e.g., a blanket or a drum) to form an ink image, the ink including an organic polymeric resin and a coloring agent in an aqueous carrier, and the transfer member having a hydrophobic outer surface, each ink droplet in the ink image spreading on impinging upon the intermediate transfer member to form an ink film; drying the ink while the ink image is being transported by the intermediate transfer member by evaporating the aqueous carrier from the ink image to leave a residue film of resin and coloring agent; and transferring the residue film to a substrate, wherein the chemical compositions of the ink and of the surface of the intermediate transfer member are selected such that attractive intermolecular forces between molecules in the outer skin of each droplet and on the surface of the intermediate transfer member counteract the tendency of the ink film produced by each droplet to bead under the action of the surface tension of the aqueous carrier, without causing each droplet to spread by wetting the surface of the intermediate transfer member.

5

10

15

20

25

30

The present invention is concerned with a printing system of the type having an intermediate transfer member in the form a continuous flexible blanket forming an endless belt. Such a blanket can have multiple layers to impart all the required properties to the transfer member. Thus in addition to an outer layer having the desired release properties, hence also called the release layer, the blanket may include in its underlying body a reinforcement layer (e.g., a fabric) to provide the desired mechanical characteristics (e.g., resistance to stretching), a compressible layer so that the blanket can conform to the substrate during transfer, a conformational layer to provide the desired conformability toward the topography of a substrate surface, and various other layers to achieve any desired friction, thermal and electrical properties or adhesion between any such layers.

In an embodiment described in PCT/IB2013/051716, the printing system is designed to be capable of double sided printing. The blanket passes through two impression stations each comprising an impression cylinder supporting the substrate onto which the image is to be printed and a nip roller which may be moved between engaged and disengaged positions. In the engaged position, the nip roller presses the blanket and the substrate against one another to transfer the ink image from the blanket to the substrate and in the disengaged position the nip roller allows the blanket to pass without any image transfer

taking place so that the image may be impressed by the other impression station onto the reverse side of the substrate, following the passage of the substrate through a perfecting system located between the impression stations.

Of the various layers constituting the blanket, the release layer is the most prone to wear and whenever the release layer is in need of replacement, the entire blanket has to be replaced even though the remaining layers remain functional.

5

10

15

20

25

30

To reduce the cost of blanket replacement, the present Applicants have also proposed in PCT/IB2013/051718, filed March 5, 2013, which is incorporated herein by reference, a printing system comprising an image forming station at which droplets of a liquid ink are deposited on to an outer surface of an intermediate transfer member to form an ink image, a drying station for drying the ink image to leave an ink residue film; and an impression station at which the residue film is transferred to a substrate sheet, wherein the intermediate transfer member comprises a thin flexible substantially inextensible belt and wherein the impression station comprises an impression cylinder and a pressure cylinder carrying a compressible blanket of at least the same length as the substrate sheet for urging the belt against the impression cylinder to cause the residue film resting on the outer surface of the belt to be transferred onto the substrate sheet that passes between the belt and the impression cylinder, the belt having a length greater than the circumference of the pressure cylinder and being guided to contact the pressure cylinder over only a portion of the length of the belt. In this proposal, the release layer and the inextensible reinforcement layer together form a thin belt that may be replaced without replacing the remaining layers that are formed as a separate compressible blanket wrapped around the pressure cylinder.

The printing system described in PCT/IB2013/051718 however has only one impression station and for printing twice onto a sheet substrate, be it to print on the reverse side of the substrate or to apply a second overlying ink image or a varnish coating to the same side of the substrate, it is necessary to design a system that returns each sheet back to the same impression station, with or without inversion. Furthermore, the printing system is not capable of duplex printing or applying an overlying image or varnish on a substrate having the form of a continuous web.

The present invention seeks therefore to provide a printing system that reduces the cost of blanket replacement while retaining the benefits offered by having two separate impression stations.

SUMMARY OF THE INVENTION

5

10

15

20

25

30

According to the present invention, there is provided a printing system for printing on front and reverse sides of a substrate, the system comprising a movable intermediate transfer member in the form of a flexible, substantially inextensible, belt guided to follow a closed path, an image forming station for depositing droplets of a liquid ink onto an outer surface of the belt to form an ink image, a drying station for drying the ink image on the belt to leave an ink residue film on the outer surface of the belt, first and second impression stations spaced from one another in the direction of movement of the belt, each impression station comprising an impression cylinder for supporting and transporting the substrate and a pressure cylinder carrying a compressible blanket for urging the belt against the substrate supported on the impression cylinder, and a transport system for transporting the substrate between the two impression stations; wherein the pressure cylinder of at least the first impression station has a first mode of operation in which the belt is urged towards the impression cylinder to cause the residue film on the outer surface of the belt to be transferred onto the front side of the substrate supported on the impression cylinder, and a second mode of operation in which the belt is spaced from the impression cylinder to allow the ink image on the belt to pass though the first impression station and arrive intact at the second impression station for transfer onto the reverse side of the substrate supported on the second impression cylinder.

The printing system of the invention thus allows double sided printing with a separate impression station for each side of the substrate, yet permits the use of a thin belt because the required conformability of the outer surface of the belt to the substrate is predominantly achieved by the thick blanket carried by the pressure cylinders. The thin belt may display some ability to conform to the topography of the surface of the substrate to allow for the roughness of the surface of the substrate and may include layers having some very slight inherent compressibility. For example, the thickness of the compressible layer in the thin belt may be in the range of 100 to 400 μ m, being typically around 125 μ m, as compared to the thickness of the compressible layer in the blanket which may be in the range of 1 to 6 mm, being typically 2.5 mm.

By "substantially inextensible" it is meant that the belt has sufficient tensile strength in its lengthwise dimension (in the printing direction) to remain dimensionally stable in that direction. Though the printing system herein disclosed may comprise control systems to monitor any such change in the length of the belt, desirably its circumference varies by

no more than 2% or no more than 1% or no more than 0.5% during operation of the system.

In each impression station, the compressible blanket on the pressure cylinder may be continuous, but if it does not extend around the entire circumference of the pressure cylinder then it needs to have a circumferential length at least equal to the maximum length of each image to be printed onto a substrate.

5

10

15

20

25

30

In an embodiment of the invention, the compressible blanket surrounds most but not all of the pressure cylinder to leave a gap between its ends, so that when said gap faces the impression cylinder, the pressure cylinder can disengage therefrom.

If the pressure cylinder of the first impression station is constructed in this manner, or is continuous, then a lifting mechanism may be provided to lower the pressure cylinder for operation in the first mode and to raise the pressure cylinder for operation in the second mode.

The mechanism may take the form of an eccentric supporting an axle of the pressure cylinder and a motor for rotating the eccentric to raise and lower the pressure cylinder.

The mechanism may alternatively take the form of a linear actuator.

As an alternative, the compressible blanket may extend over less than half of the pressure cylinder. In this case, displacement of the axle of the pressure cylinder is not necessary as operation of the pressure cylinder will automatically switch between the first and the second mode as the pressure cylinder rotates about its axis.

It is stated in PCT/IB2013/051716 that the separation between the impression cylinders should be a whole number multiple of the circumference of the impression cylinder divided by the number of sheets of substrate that can be transported by the impression cylinder at one time. In some embodiments of the present invention, such a relationship need not apply.

In a printing system designed to print on a sheet substrate, the impression cylinder may have one or more sets of grippers for retaining the leading edge of each substrate sheet. As the substrate transport system has significant inertia, it normally runs at constant speed and cannot be braked or accelerated between sheets. For this reason, the ink images to be printed on the substrate sheets need to positioned along the belt at regular intervals with the spacing between them corresponding to a whole number multiple of the length of

the arc between consecutive grippers or the circumference of the impression cylinder if it can only support one substrate sheet at a time. Furthermore, the ink images to be printed on the reverse side of the substrate sheets need to be interleaved with the ink images to be printed on the front side of the substrate sheets and, to maximize the use of the surface of the belt, these images should be located at least approximately midway between the ink images intended for the front side of the substrate.

For correct alignment of the front and rear ink images, it is important to ensure that when a substrate sheet arrives at the second impression station after traveling through the perfecting system, it should be in the correct position to receive an ink image that has followed a substantially straight line between the two impression stations. For this relationship to hold true, the total distance traveled by the trailing edge of the substrate at the first impression station (which becomes the leading edge at the second impression station) should be equal a whole number multiple of the distance on the belt between ink images intended to be printed on the front side of the substrate plus the offset between the images to be printed on the reverse side of the substrate and those to be printed on the front side. This distance is determined by the diameters and relative phasing of the grippers of the various cylinders of the perfecting system.

BRIEF DESCRIPTION OF THE DRAWINGS

5

10

15

25

30

The invention will now be described further, by way of example, with reference to the accompanying drawings, in which:

Figure 1 is a schematic representation of a printing system;

Figure 2 is a view to an enlarged scale of part of the printing system of Figure 1; and

Figures 3 and 4 are schematic representations of the two impression stations in Figure 2 at different times during the operating cycle.

DETAILED DESCRIPTION OF ILLUSTRATED EMBODIMENTS

Though the invention can be used in any indirect printing system having similar configuration, it will be described below with reference to a process where liquid inks are deposited as droplets on the outer surface of an endless belt having repelling properties

toward the inks being used. The following examples may refer in particular to the transfer of ink films obtained from the drying of liquid inks having an aqueous carrier typically comprising a coloring agent (e.g., pigments or dyes) and a polymeric resin, these inks having been jetted on a repelling hydrophobic surface of the belt, but the invention need not be limited to such particular embodiments.

5

10

15

20

25

30

In Figure 1, there is shown schematically a printing system 100 having an intermediate transfer member 102 in the form of a belt having a hydrophobic outer surface guided over various rollers of a belt conveyor system 122 to travel in an endless loop. While circulating through the loop, the belt 102 passes through various stations.

At an image forming station 104, print bars 106 deposit droplets of inks onto the hydrophobic outer surface of the belt 102 to form an ink image. The inks of the different bars 106 are usually of different colors and all the inks have particles of resin and coloring agent in an aqueous carrier, apart from some transparent inks or varnishes which may not contain a pigment.

Though the image forming station illustrated in Figure 1 comprises eight print bars 106, an image forming station may comprise fewer or more print bars. For instance, an image forming system may have three print bars each jetting Cyan (C), Magenta (M) or Yellow (Y) inks, or four print bars with the addition of a Black ink (K).

Within the image forming station 104, a gas (e.g., air) is blown onto the surface of the belt 102 in between print bars 106 by means of head units 130. This is to stabilize the ink droplets to help in fixing them to the belt 102 and to prevent bleeding.

The belt 102 then passes through a drying station 108 where the ink droplets are dried and rendered tacky before they reach impression stations 110, 110' where the ink droplets are transferred onto sheets 112 of substrate. Each impression station 110 includes an impression cylinder 110a, 110a' and a pressure cylinder 110b, 110b' which have between them a nip within which the belt 102 is pressed against a substrate. In the illustrated embodiment, the substrate is formed as sheets 112 that are transferred from an input stack 114 to an output stack 116 by a substrate transport system 118. The substrate transport system 118 comprises a perfecting system to allow double-sided, or duplex, printing, which will be described below in more detail. Two impression stations 110, 110' are provided to enable printing on both sides of the substrate, or twice onto the same side,

one impression station being positioned upstream and the other downstream of the transport system 118.

It should be mentioned, that by way of example there are only two impression stations in the teachings herein however, anyone skilled in the field of digital printing may appreciate that the invention may comprise two or more impression stations. For example, a printing system with four impression stations may be utilized in order to facilitate a higher rate of printing. The use of more than two impression stations may facilitate printing of specialized inks in addition to the traditional pigment-based inks.

5

10

15

20

25

30

It should be mentioned that the invention is equally applicable to printing systems designed to print on a substrate in the form of a continuous web instead of individual sheets. In such cases, the substrate transport system is accordingly adapted to convey the substrate from an input roller to a delivery roller.

After passing through the impression stations 110, 110' the belt 102 in Figure 1 passes through an optional cleaning and/or conditioning station 120 before returning to the image forming station 104. The purpose of the station 120 is to remove any ink that may still be adhering to the belt 102 and/or to apply a conditioning agent, to assist in fixing the ink droplets to the outer surface of the belt 102. For belts having certain silicone based outer surfaces, the conditioning agent may be polyethylenimine (PEI). The outer surface of the belt 102 is made hydrophobic to assist in a clean transfer of the tacky ink image to the substrate at the impression station(s) 110. The conditioning station 120 may also act to cool the belt 102 before it returns to the image forming station 104.

The belt 102 in some embodiments of the invention is a thin belt having an inextensible base layer with a hydrophobic release layer on its outer surface. The base layer may suitably comprise a woven fabric that is stretched and laterally tensioned and guided by means of formations on its lateral edges which engage in guide channels. The lateral tension applied by the guide channels in which the side formations of the belt may engage need only be sufficient to maintain the belt 102 flat as it passes beneath the print bars 106 of the image forming station 104. The thin belt 102 may further comprise a conformational layer with a thickness of 100 to 400 microns, but the ability to conform to the topography of the surface of a substrate may alternatively or additionally be provided by the composition of the release layer itself.

The pressure cylinder 110b, 110b' in each of the impression stations 110, 110' carries a thick compressible blanket (not shown) that may typically have a thickness between 1 and 6 mm, typically 2.5 mm, that may be mounted on the cylinder in the same manner as the blanket of an offset litho press or may be a continuous blanket wrapped around or bonded to the entire circumference of the cylinder. The purpose of the blanket on the pressure cylinder is to provide the required overall conformability of the belt to the substrate, serving as a backing cushion to the belt at the impression station. Each of the thin belt and of the compressible blanket may be formed of several layers to modify any other desired capability, such as the mechanical, frictional, thermal and electrical properties of such multi-layered structures.

In essence, the blanket on the pressure cylinder and the thin belt **102** between them provide all the properties described in PCT/IB2013/051716. However, the blanket on the pressure cylinder **110b** is much less prone to wear than the belt **102** allowing the latter to be replaced less expensively when necessary.

Another important advantage offered by separating the intermediate transfer member of PCT/IB2013/051716 into a thin belt **102** and a compressible blanket on the pressure cylinders **110b**, **110b'** is that the mass of the circulating belt is decreased. The reduction in mass reduces the amount of power needed to drive the belt **102** thereby improving the energy efficiency of the printing system. The thin belt being devoid of a compressible layer and substantially lacking compressibility is therefore also referred to as a light belt.

The use of a light belt 102 also results in the intermediate transfer member having a lower thermal inertia, which term represents the product of its mass and its specific heat. As it travels through the various stations, the belt 102 is heated and cooled. In particular, the belt 102 is heated as its travels through the heaters of the drying station 108 and through two further optional heaters 210 positioned immediately preceding the impression stations 110 to render the ink film tacky. The temperature of the belt cannot however be high on entering the image forming station 104 because it could cause the ink droplets to boil on impact. Thus, a function of the treatment station 120 can be to cool the belt 102 before it reaches the image forming station 104. The reduction in its thermal inertia considerably reduces the energy consumption of the printing system as less heat energy is stored in the belt 102 when the ink images are being heated and therefore less energy needs to be removed, and wasted, by the treatment station 120.

The substrate transport system in Figure 2 comprises a feed cylinder 212 that feeds substrate sheets 112 from the stack 114 (not shown, but previously illustrated in Figure 1) to the impression cylinder 110a of the first impression station, at which an image is printed on the front side of each sheet 112. Two transport cylinders 214 and 216 have grippers that hold each sheet by its leading edge and advance each sheet in the manner shown in Figures 3 and 4 past a perfecting cylinder 218. When the leading edge of a sheet 112 on the transport cylinder 216 reaches the position shown in Figure 3, its trailing edge separates from the transport cylinder 216 and is caught by grippers on the perfecting cylinder 218. What was until this point the leading edge of the sheet 112 is then released by the grippers on the transport cylinder 216 and the sheet is offered, reverse side up, to the grippers of the impression cylinder 110a' of the second impression station. As well as turning each substrate sheet over, the perfecting cylinder 218 also inverts the page orientation and this must be taken into account in the manner in which the ink images are formed on the belt 102. Though the afore mentioned cylinders may each have more than one sets of grippers that could hold more than one sheet of substrate on their respective circumference, for clarity a single set of grippers is schematically illustrated as 314 and 314' in impression cylinders 110a and 110a'.

5

10

15

20

25

30

In order for the grippers at the downstream impression station to coincide with the trailing edge of the perfected substrate, the relative phase of the two impression cylinders can be adjusted as a function of the length of the substrate.

In order for an ink image to arrive at the second impression station 110, it must be capable of passing intact through the first impression station 110. For this reason, at least the first impression station 110 must switch between two modes of operation. In the first, the belt 102 is pressed against the substrate and image transfer takes place and in the second mode a gap remains between belt and the first impression cylinder so that the ink image intended for the second impression station may pass unscathed.

In some embodiments, switching between operating modes is effected by raising the axle of the pressure cylinder 110b. This may be carried out by using two eccentrics (one at each end) to supporting the axle of the pressure cylinder and a motor for rotating the eccentrics to raise and the lower the pressure cylinder. Alternatively, the axle may be journalled in slide blocks that are moved by a linear actuator. Such an approach may be used when the compressible blanket on the pressure cylinder encompasses the whole, or the majority, of the circumference of the pressure cylinder 110b.

In an alternative embodiment, the pressure cylinder 110b is made with a larger diameter and the blanket overlies less than half of the circumference. In this case, the axis of the pressure cylinder may remain stationary as engagement between the pressure cylinder 110b and the impression cylinder 110a will only occur at times when the blanket on the pressure cylinder faces the impression cylinder and in any cycle of the pressure cylinder, the impression stage will alternate between the first and second modes of operation.

5

10

15

20

25

30

In Figures 3 and 4, ink images to be printed on the front side of the substrate are represented by dots and those to be printed on the reverse side a represented by dashes. Figure 3 shows the instant at which the nip between the pressure cylinder 110b and the impression cylinder 110a of the first impression station has just been closed. A substrate sheet 112a on the impression cylinder is ready to receive the image 310, represented by dots, and an image 312, represented by dashes, has passed intact through the impression station while the nip was still open. At the same time, a sheet 112b is supported front face down on the transport cylinder 214 and a further sheet 112c is in the process of being transferred from the transport cylinder 216 to the perfecting cylinder 218, the sheet 112c being shown at the point where its trailing edge has been captured by the perfecting cylinder 216.

Continued rotation of the various cylinders in the direction of the illustrated arrows results in the condition shown in Figure 4. Here, the nip of the first impression station has been opened to allow a new image 312 to pass through. The sheet 112a has been transported, front side up, to the transport cylinder 214 and transferred onto the latter cylinder. The sheet 112b has in the meantime been transferred to the transport cylinder 216 and the sheet 112c that was inverted by the perfecting cylinder 218 is now supported by the second impression cylinder 110a' ready to pass through the closed nip of the second impression station to receive the image 312 onto its reverse side.

Figure 3 shows the second impression station with its nip open and this avoids the surface of the belt being pressed against the impression cylinder 110a' when no substrate sheet is present. While this is preferable to avoid wear of the belt and possible dirtying of the impression cylinder if any ink remains on the belt, it is not essential.

The spacing between the two impression stations is not critical to correct alignment of the images on the front and reserve sides of the substrate. The length of the path of the substrate sheets through the transport system needs only to match the spacing between the front and reverse ink images on the belt 102 and this can be achieved by correct dimensioning of the diameters of the various cylinders 214, 216 and 218 and the relative phasing of their grippers.

While the invention has been described above by reference to printing on substrate sheets, it will be clear to the person skilled in the art that the invention is equally applicable to a printing system that prints on a continuous web. In this case, a web reversing mechanism may be used in place of the perfecting cylinder and once again the length of the web between the two impression stations needs to adjust, for example by the use of idler rollers, to correspond to the spacing of the front and reverse ink images on the belt.

In the description and claims of the present disclosure, each of the verbs "comprise", "include" and "have", and conjugates thereof, are used to indicate that the object or objects of the verb are not necessarily a complete listing of members, components, elements or parts of the subject or subjects of the verb. As used herein, the singular form "a", "an" and "the" include plural references unless the context clearly dictates otherwise. For example, the term "an impression station" may include more than one such station.

CLAIMS

1. A printing system for printing on front and reverse sides of a substrate, comprising:

a movable intermediate transfer member in the form of a flexible, substantially inextensible, belt guided to follow a closed path,

an image forming station for depositing droplets of a liquid ink onto an outer surface of the belt to form an ink image,

a drying station for drying the ink image on the belt to leave an ink residue film on the outer surface of the belt,

first and second impression stations spaced from one another in the direction of movement of the belt, each impression station comprising an impression cylinder for supporting and transporting the substrate and a pressure cylinder carrying a compressible blanket for urging the belt against the substrate supported on the impression cylinder, and

a transport system for transporting the substrate between the two impression stations;

wherein the pressure cylinder of at least the first impression station has a first mode of operation in which the belt is urged towards the impression cylinder to cause the residue film on the outer surface of the belt to be transferred onto the front side of the substrate supported on the impression cylinder, and a second mode of operation in which the belt is spaced from the impression cylinder to allow the ink image on the belt to pass though the first impression station and arrive intact at the second impression station for transfer onto the reverse side of the substrate supported on the second impression cylinder.

- 2. A printing system as claimed in claim 1, wherein, in each impression station, the blanket on the pressure cylinder is continuous.
- 3. A printing system as claimed in claim 1, wherein in each impression station, the blanket extends only partially around the circumference of the pressure cylinder.

- 4. A printing system as claimed in claim 3, wherein, in each impression station, the blanket surrounds most, but not all, of the pressure cylinder to leave a gap between the ends of the blanket, the pressure cylinder and the impression cylinder being disengaged from one another when the gap faces the impression cylinder.
- 5. A printing system as claimed in claim 2 or 4, wherein a lifting mechanism is provided to lower the pressure cylinder for operation in the first mode and to raise the pressure cylinder for operation in the second mode.
- 6. A printing system as claimed in claim 5, wherein the lifting mechanism comprises eccentrics supporting opposite ends of an axle of the pressure cylinder and a motor for rotating the eccentrics to raise and the lower the pressure cylinder.
- 7. A printing system as claimed in claim 3, wherein the blanket of each impression station extends over less than half of the circumference of the pressure cylinder.
- 8. A printing system as claimed in any preceding claim, wherein the transport system includes a perfecting system for inverting the substrate during transportation between the two impression stations.
- 9. A printing system as claimed in claim 8, wherein the perfecting system is formed of transport cylinders and a perfecting cylinder each having grippers to grip edges of individual substrate sheets, and wherein the dimensions of the cylinders and the phasing of the grippers are such that the length of the path followed by the trailing edges of the substrate sheets through the perfecting system is a multiple of the circumference of the impression cylinder plus the offset between the front and reverse ink images on the belt.
- 10. A printing system as claimed in claim 8, wherein the perfecting system is designed to transport and invert a web substrate.

- 11. A printing system as claimed in any preceding claim, wherein the belt is provided with formations along its lateral edges engageable in channels to guide the belt and maintain the belt in lateral tension.
- 12. A printing system as claimed in any of claims 1 to 8, wherein the relative phase of the impression cylinders is adjustable.
